Spectral irradiance is the power per unit area attributable to radiation within a specified wavelength interval. The Sun emits radiation that ranges in wavelength across the entire electromagnetic spectrum, from very short-wavelength x-rays, to ultraviolet (UV), visible, infrared (IR) and very long-wavelength radio waves. Figure 1 illustrates the dependence of solar spectral irradiance on wavelength, a dependence that covers more than six orders of magnitude and peaks in the visible spectrum.

Solar irradiance is not constant. Although the total irradiance has in the past been termed the solar 'constant', levels of total and spectral irradiance fluctuate continuously in concert with solar activity (see SOLAR ACTIVITY). During recent epochs of high solar activity, near maxima of the 11 year solar cycle (see SOLAR CYCLE), mean levels of total irradiance increased by about 0.1% (1.3 W m^{-2}) relative to solar cycle minima levels. Spectral irradiance also increases with solar activity, by different amounts depending on wavelength, as shown in figure 1 for a recent 11 year cycle. Small increases of less than a few tenths of a per cent occur at visible and near-infrared wavelengths, whereas radiation at the shortest x-ray and longest radio wavelengths can change by factors of two and more. Note that the actual radiant energy falling on the Earth varies by $\pm 3\%$ annually because of regular changes in the distance of the Earth from the Sun. This wavelength-independent fluctuation is not intrinsically solar but, rather, a geometrical effect. Solar irradiance variability refers to changes arising in the Sun itself, specified at a fixed Sun–Earth distance of 1 AU.

Acquiring reliable observations of solar irradiance has proven a challenging technological task. The longest continuous irradiance database—that of total (i.e. spectrally integrated) irradiance—has yet to cover two 11 year solar activity cycles. Since the late 1970s, more than five total irradiance instruments on various space platforms have utilized electrical substitution cavity pyrheliometers to achieve total irradiance measurements with uncertainties approaching $\pm 0.2\%$ and long-term repeatabilities of the order of $\pm 0.01\%$. Spectral irradiance observations are less reliable and less frequent than are total irradiance observations. Even in the UV spectrum, where most spectral irradiance measurements have been made, uninterrupted monitoring has yet to be accomplished for a complete solar cycle. Using combinations of redundant gratings and filters (to achieve spectral dispersion), photoelectric detectors and on-board calibration tracking, solar UV spectroradiometers that have operated continuously in space since late 1991 are at present achieving uncertainties in the range ± 6–10%, and long-term repeatabilites approaching $\pm 1\%$. Regular monitoring of the Sun's visible and infrared spectrum remains to be undertaken.

Close physical relationships between the Sun's radiative output and magnetic fields in the solar atmosphere (see SOLAR MAGNETIC FIELD) facilitate the primary mechanisms of solar irradiance variability. Magnetic fields, when present in the Sun's atmosphere, perturb its radiative processes by altering temperature and density (see, for example, SOLAR SPECTROSCOPY AND DIAGNOSTICS). Thus, magnetic active regions (see ACTIVE REGIONS) are sites of local enhancement or depletion of solar radiation. Particularly important for their effects on solar irradiance are dark sunspots—in which radiation is depleted (see SUNSPOTS)—and bright faculae—which are sources of enhanced radiation (see SOLAR PHOTOSPHERE). The variable occurrence and inhomogeneous distribution of both sunspots and faculae on the solar disk throughout the solar cycle produce net fluctuations in irradiance (i.e. the emission from all radiative sources integrated over the entire disk), with strong wavelength dependences. Particularly significant perturbations ($>100\%$) occur in emissions at the shortest (x-ray) and longest (radio) wavelengths that are formed in the highest and hottest layers of the solar atmosphere.

Past and future solar irradiance variability potentially exceed the range detected by space-based solar irradiance observations. Compared with historical proxy records of solar activity, including sunspot and geomagnetic records, and cosmogenic archives in ice cores and tree rings, current solar monitoring has been accomplished during an epoch of overall high levels of solar activity and larger than average 11 year cycle amplitudes. Associations of modern magnetic sources with historical solar activity proxies suggest that total irradiance may have increased a few tenths of a per cent since an epoch of anomalously low solar activity during the seventeenth century. Called the Maunder minimum, this episode of solar quiescence appears to be but the most recent of similar episodes that have occurred semiregularly in the Sun's multicentennial past, and are expected in its future.

Solar irradiance is the primary energy source for the Earth. Thus it is a crucial geophysical quantity for modeling and understanding a myriad of terrestrial processes including global climate change and space weather (see SOLAR–TERRESTRIAL CONNECTION). Radiation at wavelengths longer than 300 nm penetrates though most of the Earth's atmosphere to within 15 km of the surface. This radiation comprises 99% of total irradiance and its fluctuations have long been speculated to alter surface temperatures and other climatological phenomena on decadal and centennial time scales, vying with greenhouse gases and sulphate aerosols in the industrial epoch. The Earth's atmosphere absorbs the remaining 1% of the Sun's irradiance, including the high-energy UV, extreme

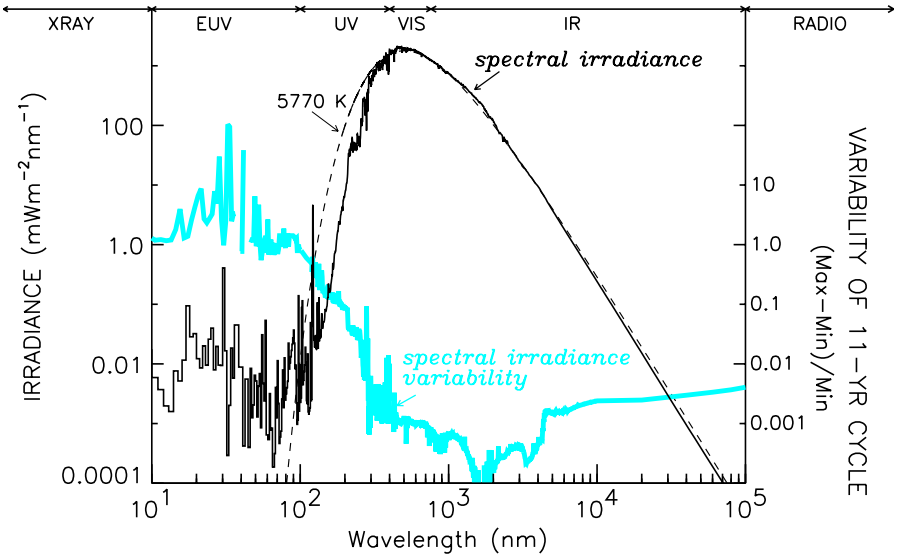

Figure 1. The spectrum of the Sun's radiation incident on top of the Earth's atmosphere (thin dark curve), and of a blackbody at 5770 K (thin dashed curve). The Sun's total irradiance is the integral over all wavelengths of this spectral irradiance. The broad spectral bands identified along the top of this figure are designated the extreme ultraviolet (EUV), ultraviolet (UV), visible (VIS) and infrared (IR). The x-ray spectrum lies shortward of the EUV spectrum and at wavelengths longward of the IR is the microwave or radio portion of the solar spectrum. Also shown (thick gray cuvre) are estimates of the variations in solar spectral irradiance for a recent 11 year activity cycle. At wavelengths longer than 400 nm these estimates are speculative because very limited observational data exist.

ultraviolet (EUV) and x-rays. These radiations would have detrimental biological effects were they able to penetrate to the Earth's surface. Rather, short-wavelength solar radiation provides the primary energy input to the atmosphere, where it initiates and controls the ozone layer in the stratosphere and, at higher altitudes, the ionosphere and thermosphere. More variable by orders of magnitude than the total irradiance, solar ultraviolet emissions may impact global change indirectly through middle atmosphere coupling with the biosphere. Solar heating and ionization perturbations of the upper atmosphere by highly variable extreme ultraviolet radiation impact communications and satellite drag.

Spectrum of the Sun's radiation

The spectrum of the Sun's radiation—its distribution of irradiance with wavelength, shown in figure 1—is a combination of continuum, emission and absorption features. Solar continuum radiation has a smoothly varying spectral shape similar to that of a black body near 5770 K (also shown in figure 1), which is the approximate temperature of the Sun's visible surface. The Sun's surface is defined as the layer of its atmosphere from which radiation at 500 nm (near peak irradiance levels of the blackbody spectrum) emerges with unit optical depth. Most (>99%) of the Sun's irradiance—that at wavelengths from 160 nm to 5 μm—also emerges from the vicinity of the solar surface, in a layer of the Sun's atmosphere a few hundred kilometers thick called the photosphere.

Numerous emission and absorption lines are superimposed on the dominant solar continuum. Gases in the Sun's atmosphere cause these spectral features by either absorbing the underlying continuum radiation (producing, for example, Fraunhofer lines) or by augmenting the continuum radiation with local emission processes. Least absorption by the solar atmosphere of the underlying photospheric continuum emission occurs in the vicinity of 1.6 μm (1600 nm). This radiation thus emerges from the deepest observable layers of the Sun and is the least variable region of the solar spectrum (see figure 1).

Many species in the solar atmosphere, for example Al, Mg, Ca, O, Fe, He and H, absorb radiation at UV, visible and IR wavelengths. In the visible and infrared spectrum their absorption lines are superimposed on the dominant 5770 K blackbody continuum. In the UV spectrum, however, this line absorption is so strong that it depletes significantly the underlying continuum radiation. At about 500 km above the Sun's visible surface the solar atmosphere temperature has a minimum value of 4500 K that delineates the upper boundary of the solar photosphere from the overlying chromosphere and corona. The solar spectra near 160 nm and from 75 μm to 300 μm originate near this temperature minimum region.

Radiation at wavelengths increasing shortward of 160 nm and longward of 300 μm emerges from increasingly higher, and generally hotter, layers of the solar atmosphere. In the solar chromosphere and corona temperatures in the range of 10^4 to 10^6 K produce excited and ionized states of atoms. Emission processes of these species emit radiation with characteristic spectral signatures whose strengths depend on the local temperature and composition of the solar atmosphere. Of

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

these features, the emission by Hydrogen I produces the strongest line, at 121.57 nm, clearly evident in figure 1. Although the net irradiance of line emission at EUV and x-ray wavelengths is many orders of magnitude less than the visible continuum irradiance, it nevertheless exceeds by orders of magnitude the blackbody radiation in this short-wavelength spectral regime.

Observations of total irradiance

Attaining reliable observations of the Sun's total irradiance—the energy radiated at all wavelengths—has been a goal for more than a century, motivated by the need to specify fluctuations in the radiative energy input to the Earth. On the basis of observations made with ground-based instrumentation from 1874 to 1976, the total irradiance of the Sun was considered to be invariant with time, and hence designated the solar 'constant'. But the measurements lacked the accuracy and repeatability to establish either the correct absolute value of the irradiance, or its variability, to better than about half a per cent.

During the past two decades, solar radiometers flown on orbiting spacecraft (to eliminate interference by the Earth's atmosphere) have detected real total irradiance variability at levels of tenths of a per cent. These observations have achieved uncertainties in absolute calibration of $\pm 0.2\%$ and long-term repeatabilities better than 0.01% by utilizing the technique of electrical substitution radiometry, combined with detailed characterization and monitoring of in-flight sensitivity changes in the radiometers. A cavity in the instrument collects solar photons independently of their wavelength. The inside surface of the cavity is blackened and shaped so that every absorbed photon contributes thermal energy when a shutter permits solar radiation to reach the cavity. With the shutter closed, electrical power substitutes for the radiant power to maintain the cavity at a constant temperature. Knowing the aperture of the cavity then provides a direct measure of the incident total irradiance in absolute units of power per unit area (W m^{-2}), at the known distance of the cavity from the Sun.

The five or more radiometric instruments that have observed the Sun's total irradiance at various times during the past two decades have each realized a slightly different absolute scale, uncertainty and long-term stability. The various instruments have different cavity, baffle and aperture geometries, thermal losses, drift compensations and electronic readouts, and have flown on space platforms with different thermal stabilization and pointing capabilities. Figure 2 shows a composite record of daily mean total irradiance obtained from the cross-calibration of overlapping datasets to adjust for scale differences, taking into account drifts in the sensitivities of the individual radiometers during different phases of their missions. Whereas the time series in figure 2 presents the most probable observational record of the Sun's total irradiance, individual radiometric data at times deviate notably from this composite record, and from each other, because of instrumental sensitivity drifts. A primary cause of these drifts is solar exposure itself, which alters the blackness of the cavity surface and affects the thermal energy conversion. Drifts in temperature-sensitive electrical components and in the orientation of the cavity to the Sun also contribute. The most successful observations of total irradiance are achieved from instruments that utilize a number of redundant cavities with widely different duty cycles to effect in-flight calibration tracking, and that are mounted on thermal- and view-stabilized platforms.

Time scales of variability present in the observational record of total irradiance range from decades to minutes. Prominent in the composite record in figure 2 is an 11 year cycle that tracks closely the solar activity cycle, represented in this figure by the smoothed sunspot number. Monthly to yearly irradiance changes reflect the impact of the evolution of magnetic complexes that comprise sunspots and faculae. Significant irradiance dips of a few tenths of a per cent on a monthly and semimonthly cadence are associated with the impact on solar irradiance of the Sun's rotation on its axis. This rotation modulates irradiance by presenting different populations of magnetic active regions to the Earth's view. Peaks in the power spectrum shown in figure 2 identify these effects near 13 and 30 days and in additional longer period peaks. Total irradiance responds as well to the 5 min pressure mode oscillation of the solar interior (see HELIOSEISMOLOGY: THEORY, HELIOSEISMIC OBSERVATIONS), and possibly to the hourly time scales of gravity modes as well, but these fluctuations are not resolved in the daily mean data in figure 2.

At present two instruments are monitoring the Sun's total irradiance from space: the Active Cavity Radiometer Irradiance Monitor (ACRIM II) on the Upper Atmosphere Research Satellite (UARS, launched in 1991) and the Variability of Irradiance and Gravity Oscillations (VIRGO) instrument on the Solar Heliospheric Observatory (SOHO, launched in 1995). NASA's Earth Observing System (EOS), the European Space Agency (ESA) attached pallet to the International Space Station (ISS), France's CNES and the US National Polar-orbiting Operational Environmental Satellite System (NPOESS) each have programs for subsequent measurements. Acquiring reliable knowledge of the Sun's total irradiance variability on decadal time scales, independent of instrumental drifts, will require the indefinite continuation of solar irradiance monitoring using radiometers with greater stability than those that have flown in the past two decades, mounted on space platforms with highly stabilized thermal and pointing environments.

Observations of spectral irradiance

Reliable observations of the Sun's spectral irradiance must, like those of total irradiance, be made from space to avoid contamination by the Earth's overlying atmosphere. In particular, the solar spectrum at wavelengths shorter than 310 nm can only be observed from space as the Earth's atmosphere absorbs this radiation entirely. Because of their importance for understanding processes

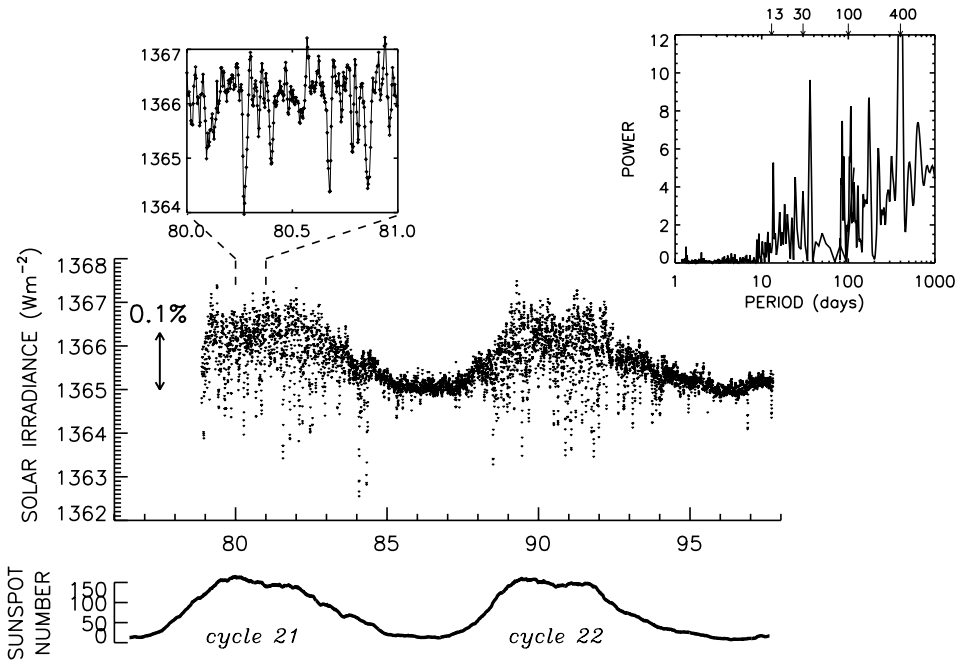

Figure 2. Daily mean values of the Sun's total irradiance are shown from 1979 to 1997. This composite irradiance record was constructed from observations made by four different solar radiometers at various times throughout the epoch. Evident is a pronounced 11 year cycle with an approximate peak-to-peak magnitude of 0.1%, on which are superimposed larger weekly to monthly fluctuations of a few tenths of a per cent. The 11 year total irradiance cycle tracks the general level of solar activity, indicated by the sunspot numbers in the lowest plot. The subset of data shown in the upper left hand plot provides details of rotational modulation, and the power spectrum in the upper right hand plot summarizes various apparent cycles in the composite total irradiance record.

in the Earth's atmosphere, the UV, EUV and x-ray regions of the solar spectrum have been monitored far more frequently than has any other part of the solar spectrum. But even these shorter-wavelength measurements have, over the past two decades, been made only intermittently. Except for two narrow x-ray bands, which Geostationary Operational Environmental Satellites (GOES) have monitored operationally since the 1970s, continuous reliable time series of solar spectral irradiance have not been procured for even one 11 year solar cycle. Figure 3 provides a sample of UV spectral irradiance monitoring—that made of the upper photospheric emission at 200 nm by instruments on the UARS and Solar Mesosphere Explorer—and of the coronal soft x-ray 0.1–0.8 nm fluxes.

Solar spectral irradiance instruments typically operate only over a limited wavelength range. They achieve wavelength discrimination by employing optical elements, usually gratings or spectral band filters, to disperse or select specified bands of the solar spectrum. Since narrow wavelength bands comprise significantly less solar power than the 1365 W m^{-2} total irradiance, spectral irradiance instruments utilize detectors, typically photomultipliers or diodes, which have sensitivities higher by many orders of magnitude than that of an electrical substitution cavity. These detectors amplify the small signal incident on them from the dispersing element when it is positioned at a known wavelength setting. Unlike total irradiance radiometers, spectral irradiance instruments are not electrically self-calibrating. Rather, pre-flight laboratory calibrations and characterizations establish the absolute irradiance scale at each wavelength by using standard irradiance sources and detectors. For all but the most recent UV spectral irradiance measurements, whose uncertainties approach ±6%, pre-flight calibrations of instruments typically achieve uncertainties in the range ±10–50%. On-orbit sensitivity degradation can introduce additional large uncertainties to long-term monitoring of spectral irradiance variability. Only the most recent UV spectral irradiance instruments, those flying on the UARS, have the capability for on-orbit calibration tracking of these changes, and achieve long-term repeatabilities approaching ±1% at some UV wavelengths.

Significant instrumental uncertainties are present in the historical database of solar spectral irradiance observations, arising from different realizations of absolute spectral irradiance scales combined with in-flight sensitivity drifts of the instruments. Exposure to solar radiation degrades the reflectivities and transmittances of optical elements in solar spectroradiometers; slippage in grating drive mechanisms contributes uncertainties in the wavelength of the radiation. At most wavelengths in the solar spectrum, the uncertainties in the historical irradiance database are comparable to, or exceed, the

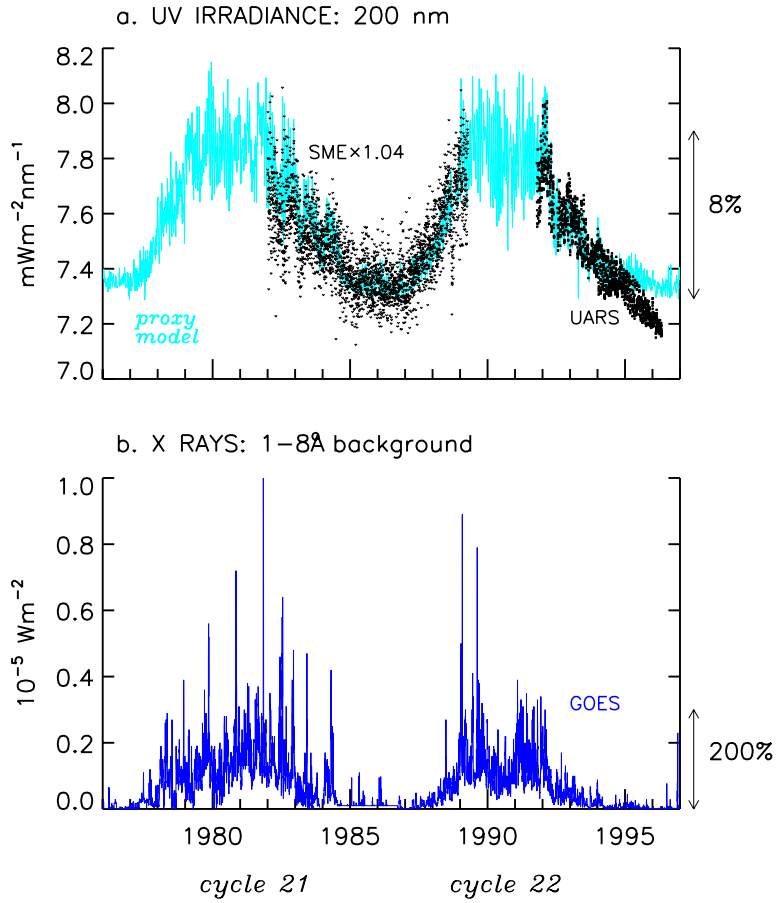

Figure 3. Variations occur in the Sun's radiation at wavelengths throughout the spectrum, and are shown in (*a*) the UV 200 nm irradiance measured by instruments on the SME and UARS spacecraft and (*b*) the GOES 1–8 Å background flux measured by a series of operational spacecraft. These spectral irradiance variations occur in concert with solar activity, whose long-term changes produced the variable sunspot record in figure 2. An empirical solar variability model that utilizes a facular proxy to estimate the 200 nm irradiance is also shown (gray line) for comparison with the SME and UARS 200 nm irradiance observations, which do not overlap in time and which cannot therefore be cross-calibrated to remove instrumental calibration scale differences.

amplitude of the solar cycle variability itself. In the visible and infrared solar spectrum, monitored by only a very few filter radiometers, instrument sensitivity changes in the range 5–50% far exceed the real solar variations which are thought to be in the range of a few tenths of a per cent; reliable observational determination of solar visible and infrared spectrum variability has thus far not been achieved. Knowledge of the irradiance and variability of even the strongest line in the entire solar spectrum—the emission of hydrogen Lyman α (121.6 nm)—remains uncertain by 30% to 50%, as does that of most EUV emission lines. Only in the spectral region from 250 to 120 nm have instrument sensitivity drifts been tracked with a repeatability of a few per cent, sufficient to estimates solar cycle changes of order of 3–30%, but these data exist thus far for less than one 11 year cycle.

In spite of their limitations, the available spectral irradiance measurements have established beyond doubt that the solar spectrum varies in concert with solar activity over multiple time scales. As shown in figure 1 for a typical 11 year activity cycle, the amplitude of the variability is strongly wavelength dependent. Spectrum variability occurs on time scales shorter than the solar cycle because active region evolution, solar rotation and interior oscillation also modulate spectral irradiance, in different degrees depending on the source of the irradiance within the solar atmosphere. In general, the emissions formed in higher, hotter solar atmospheric layers vary the most. Coronal x-rays are seen in figure 3(*b*) to vary by two orders of magnitude; these emissions are highly sensitive to magnetic activity, especially eruptive instabilities that produce flares, but they are insensitive to interior oscillations. EUV radiation from the solar chromosphere and transition region can vary by factors of two or more and UV radiation by a few to 50%; the 200 nm fluxes shown in figure 3(*a*) decreased by 8% from the maximum to minimum of the most recent 11 year cycle. Radiation formed in the vicinity of the Sun's surface is the

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

least variable with solar cycle amplitudes of no more than a few tenths of a per cent. This radiation is insensitive to flares and sensitive to interior oscillations, which are detectable in irradiance time series made with sufficiently high time resolution.

At present, two instruments also on board the UARS are measuring solar spectral irradiance at wavelengths from 120 to 420 nm in 1 nm bands. These are the Solar Stellar Irradiance Comparison Experiment (SOLSTICE) and the Solar Ultraviolet Spectral Irradiance Monitor (SUSIM). GOES spacecraft continue operational solar x-ray monitoring, augmented since mid 1991 by soft x-ray observations made using an imaging (rather than full disk flux) instrument on board the Yohkoh spacecraft. Apart from VIRGO's filter radiometers on SOHO, which cover three selected near-UV, visible and IR narrow (5 nm) bands, the solar visible and IR spectrum is not monitored at present. Future programs include observations of the total and spectral irradiances by EOS, ESA and NPOESS, and of the EUV spectral irradiance by the Thermosphere Ionosphere Mesosphere Energetics and Dynamics spacecraft. Apart from NPOESS, these programs are of insufficient duration to determine long-term spectral irradiance trends, but they will advance significantly knowledge of shorter-term spectral irradiance variability.

Mechanisms of present irradiance variability

Mechanisms of solar irradiance variability arise from the fundamental connections between radiation and magnetism in the Sun's atmosphere. The prominent 11 year cycles in the total and spectral irradiance in figures 2 and 3 are simply global manifestations of these connections. So too are irradiance fluctuations that track multimonthly evolution of active regions, the 27-day rotation of the Sun on its axis, and a range of shorter time scale variability related to meso- and super granulation (see SOLAR PHOTOSPHERE: MESOGRANULATION; SUPERGRANULATION). In each case, the eruption, rearrangement and disappearance of magnetic fields in the solar atmosphere modify the Sun's radiative output. Magnetic fields perpetrate distinctive features in different solar atmosphere regimes, as displayed in the images in figure 4. These features, which include dark sunspots and bright faculae, affect solar irradiance at different wavelengths in different ways. Thus, the three time series in figure 4, of total, UV and x-ray irradiances emitted from respectively the photosphere, upper photosphere and corona, exhibit markedly distinct temporal variability even though solar magnetism is ultimately their common origin.

In the photosphere near the Sun's surface, from whence emerges near-UV, visible and IR radiation, sunspots are the pre-eminent signature of solar magnetism. Formed by compact clumps of magnetic fields, sunspots are darker and cooler than the surrounding photosphere because the magnetic fields inhibit the upward flow of energy from the Sun's convection zone to its visible surface. Less compact aggregates of magnetic field lines also abound in the photosphere. Being only slightly brighter than the surrounding photosphere, and much less compact than sunspots, these features, the faculae, are barely detectable in images of the solar disk recorded with visible continuum radiation, except near the limb. However, because of their greater dispersion over the entire solar surface they are equally important in modifying the net radiative output of the Sun (see FACULAE, SOLAR PHOTOSPHERIC MAGNETIC FLUX TUBES).

Hundreds of kilometers above the Sun's surface the primary evidence of magnetic fields are bright, rather than dark, activity features. In the largest of these regions, called plage, magnetic fields clump together to form complexes of activity that extend over much more of the solar disk than do the compact sunspots. Bright emission is also present in a network that covers most of the solar surface, and in a range of interspersed magnetic features that have smaller spatial scales than active regions. Plage and network are evident as regions of enhanced emission in the image of the Sun's chromosphere in figure 4 made in the core of the Ca K Fraunhofer line. These bright magnetic features are the chromospheric counterparts of photospheric faculae, and are sources of significantly enhanced UV and EUV emission from the upper photosphere, chromosphere and transition region. Thus the fluctuations in solar UV and EUV spectral irradiance track closely the evolution of bright faculae, with little discernible sunspot influence. Higher still, in the Sun's corona, magnetic fields form bright loops and extended magnetic complexes that obliterate distinct connections to sunspots, plage and network below. As seen in the Yohkoh soft x-ray images in figure 4, coronal magnetic structures at times extend over much of the solar disk; they emit prodigious levels of x-ray, EUV and radio flux and control irradiance variability at these wavelengths.

Specific knowledge of the areas and brightnesses of the various magnetic features present in different solar atmospheric regimes permits the empirical modelling of solar irradiance variability for comparison with directly observed irradiance data at different wavelengths. Ground based, visible light solar images record areas and locations of sunspots that are used to calculate sunspot darkening contributions. Other spectroheliograms, such as the Ca K images in figure 4, record the locations and areas of enhanced emission in plage, faculae and the surrounding bright network. Solar variability models that combine, in different amounts, global parametrizations of these two components can explain much of the observed irradiance variability from the photosphere and chromosphere. A model with significant contributions from both sunspot darkening and facular brightening accounts for almost 90% of the variance in the daily mean total irradiance data over nearly two decades, shown in figure 2. In comparison, the model estimates shown in figure 3(*a*), used to cross-calibrate two on-overlapping

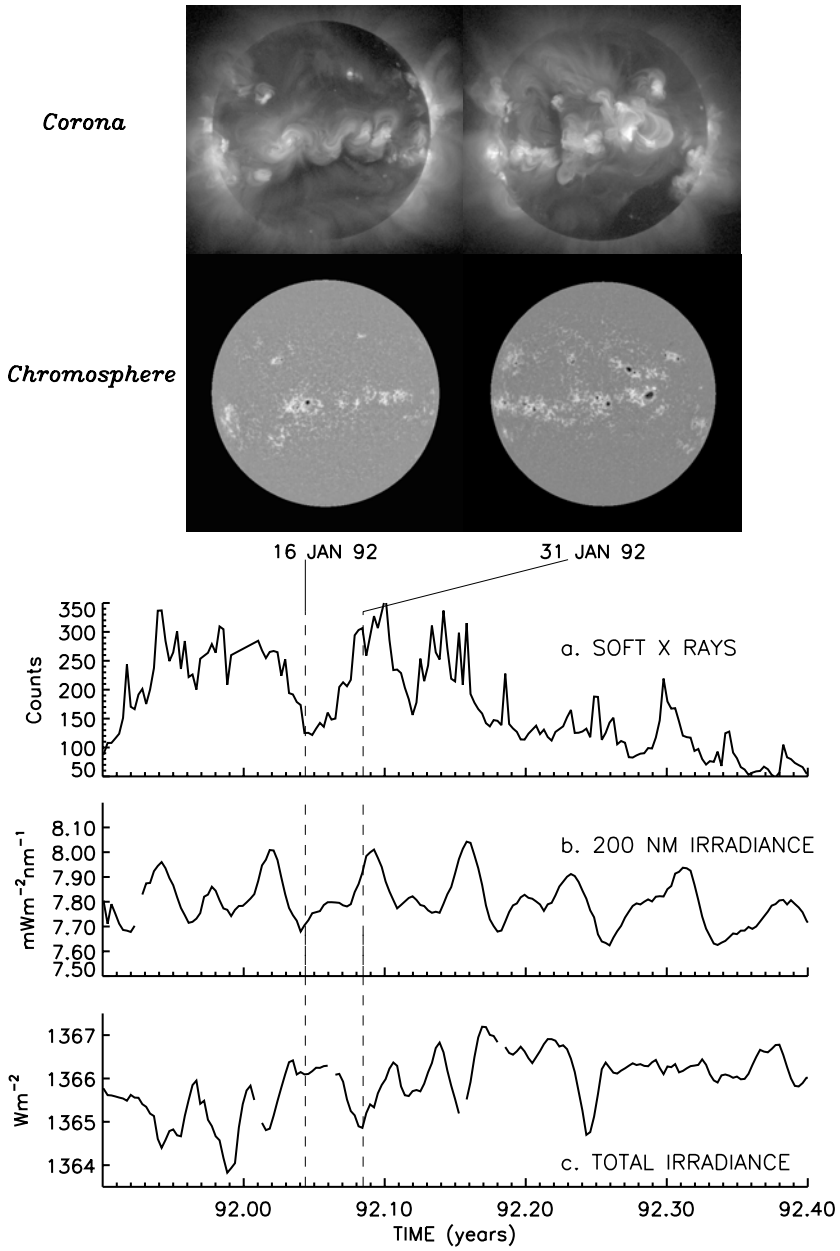

Figure 4. Solar activity and solar rotation alter the distribution of magnetic features in the solar atmosphere, viewed from Earth, as shown in two types of solar images made in 1992 near maximum levels of solar activity. These changes generate irradiance variability. Soft x-ray (upper) images measured by the Yohkoh spacecraft display the changing occurrence of global-scale magnetic features in the corona. Ca II K (lower) images measured at the Big Bear Solar Observatory show related but less extended magnetic features present in the chromosphere on the same days. Soft x-rays fluxes measured by Yohkoh (*a*), the UV 200 nm irradiance measured by UARS (*b*) and total irradiance (*c*) measured by ACRIM on UARS track the changing distributions of active regions projected toward Earth during solar rotation and over the solar cycle.

datasets of UV 200 nm irradiance, utilizes the facular component alone.

Irradiance variability on historical time scales

How might solar irradiance have varied in the past, and what are the prospects for future variability? Astrophysics and geophysics both motivate the need for this understanding. Examining long-term variability of other stars like the Sun can provide clues about broader aspects of stellar evolution (see SOLAR–STELLAR CONNECTION); and long-term solar variability has implications for terrestrial climate and global change on centennial time scales and

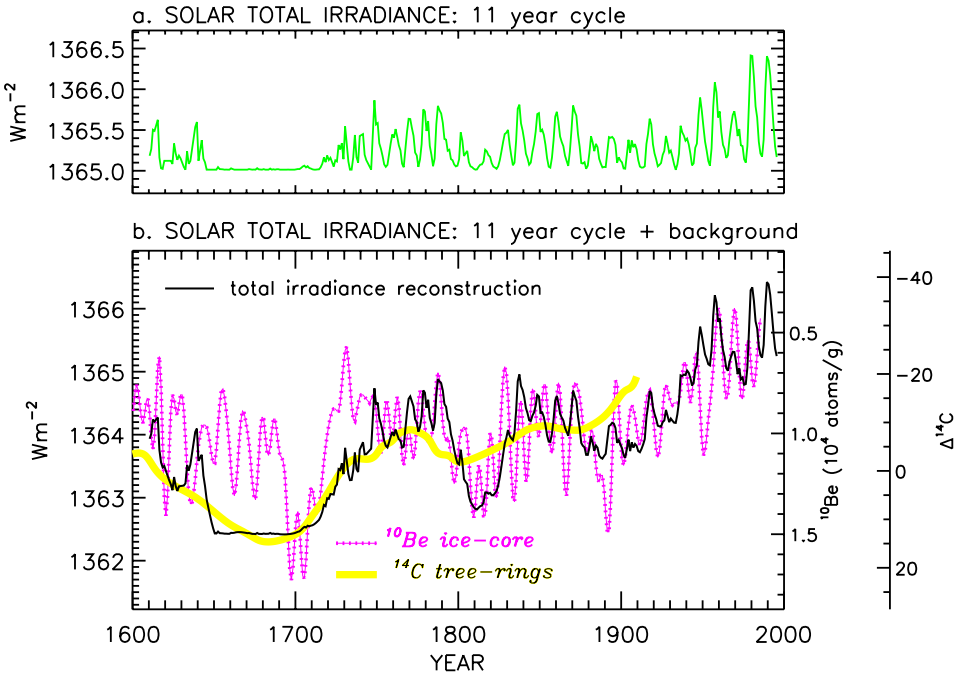

Figure 5. Reconstructions of the Sun's total irradiance, assuming in (*a*) an 11 year cycle alone and in (*b*) the 11 year activity cycle and a longer-term component based on the average amplitude of each sunspot cycle. This latter irradiance reconstruction (dark solid curve) is compared with ^{10}Be (small squares) and ^{14}C (thick gray curve) cosmogenic isotope records.

longer, thereby aiding in the specification of natural climate variability for comparison with anthropogenic influences (see SOLAR–TERRESTRIAL CONNECTION: LONG-TERM AND SHORT-TERM CLIMATE VARIABILITY).

A variety of solar, geomagnetic and geological records contain information about long-term solar activity fluctuations and the irradiance changes that presumably accompanied these fluctuations. Images of the Sun that depict sunspots have been made from ground based observatories since the seventeenth century, including during the Maunder minimum when for many years sunspots occurred only very infrequently. Conceptually, the sunspot record indicates that solar activity increased from anomalously low levels during the Maunder minimum to the present epoch of frequent sunspot occurrence with numbers as high as any witnessed during the past 400 years. Furthermore, indices of geomagnetic activity recorded at the Earth during the past 150 years indicate an overall upward activity trend concurrent with increasing solar cycle amplitudes. Geological records of ^{14}C and ^{10}Be cosmogenic isotopes in, respectively, tree rings and ice cores confirm that overall levels of solar activity have increased during the past three centuries. The isotope levels reflect variations in the terrestrial flux of galactic cosmic rays that arise from solar activity modulation of the magnetic coupling of the Sun and the Earth. Consistent with the evidence from sunspots, geomagnetic data and cosmogenic isotopes, the Sun's present activity is in the high range of levels seen in a collection of solar-like stars.

Two decades of space-based solar irradiance monitoring has thus been conducted during an era of overall high solar activity compared with levels during the past few centuries. This suggests the plausibility of solar irradiance levels lower than any yet observed in recent solar cycle minima, for example during the Maunder minimum. Speculated longer-term changes are not yet detectable in the limited-duration observational irradiance record. However, estimates of historical solar irradiances are possible by using solar activity proxies to parametrize irradiance variability mechanisms—such as the influences of sunspots, faculae and network as quantified for the present-day irradiance record. Figure 5(*a*) shows a reconstruction of the 11-year total irradiance cycle, alone, since 1610, whereas in figure 5(*b*) the 11 year irradiance cycle is combined with an assumed longer-term irradiance variability component. Adopting this longer-term component permits better agreement between the irradiance reconstruction and both the geomagnetic and cosmogenic isotope records, the latter of which are also shown in figure 5(*b*).

Total irradiance increased by about 0.25% from 1650 to the present, according to the historical reconstruction shown in figure 5. A variety of similar techniques yield estimates of long term total irradiance variability in the range of 0.2 to 0.5%. At UV wavelengths, long term spectral irradiance changes are estimated to be factors of two larger than the solar cycle changes. But these estimates of the Sun's irradiance variability on historical time scales

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

are by necessity highly speculative; and they will remain so until the observational record is of sufficient length to establish that long-term irradiance variability is in fact present, in addition to the confirmed variability during the 11 year cycle and on shorter time scales.

Solar Magnetic Field

Electrical currents flowing in the solar plasma generate a magnetic field, which is detected in the SOLAR ATMOSPHERE by spectroscopic and polarization measurements (SOLAR MAGNETIC FIELD: INFERENCE BY POLARIMETRY). The SOLAR WIND carries the magnetic field into interplanetary space where it can be measured directly by instruments on space probes.

The structure of the solar magnetic field comprises a wide spectrum of spatial and temporal scales. A global order is apparent in the periodic reversals of the magnetic polarity in connection with the 11 yr cycle of SOLAR ACTIVITY. In the SOLAR PHOTOSPHERE the magnetic field is highly inhomogeneous with small-scale filaments formed through its interaction with the convective flows. In the upper layers of the solar atmosphere, the magnetic force dominates over all other forces, so that the magnetic field acquires a less intermittent structure and fills all available volume. Magnetically 'open' regions with diverging field lines reaching into interplanetary space and 'closed' regions pervaded by loop-like structures characterize the magnetic field in the CORONA. Further out, the solar wind dominates the dynamics and, in concert with solar rotation, imprints a spiral structure onto the magnetic field.

It is generally assumed that the magnetic flux observed in the solar atmosphere is generated by a hydromagnetic DYNAMO mechanism working near the bottom of the convection zone (see SOLAR INTERIOR: CONVECTION ZONE). Due to MAGNETIC BUOYANCY, the field rises through the convection zone in the form of magnetic flux tubes. In the solar atmosphere, the emerging magnetic flux forms magnetically bipolar SOLAR ACTIVE REGIONS and sunspot groups. The various manifestations of solar activity are all intimately related to the magnetic field. Apart from its variability on timescales determined by the dominant convective patterns and the modulation of flux emergence in the course of the activity cycle, a long-term variability of the solar magnetic field is indicated by a marked variation of the intensity of the 11 yr cycles and by extended periods of very low solar activity, like the second half of the 17th century when sunspots were almost absent (see SOLAR ACTIVITY: LONG-TERM RECORDS).

Large-scale structure and active regions

A magnetogram (i.e. a map of the magnetic field on the solar surface, figure 1) exhibits bipolar magnetic regions (active regions) as well as large areas of apparently unipolar field in a network pattern, which outlines the boundaries of large convection cells (SOLAR PHOTOSPHERE: SUPERGRANULATION). In particular, such unipolar regions can nearly always be found around the solar poles. They suggest the existence of a global dipole component of the solar magnetic field, which is nearly aligned with the rotation axis. The orientation of this dipole field reverses in phase with the 11 yr cycle of solar activity (SOLAR CYCLE).

The network structure of the magnetic field outside active regions continuously rearranges itself in response to the birth and decay of supergranules with a timescale of several days. Together with an analogous process on the much smaller scale of granulation (see SOLAR PHOTOSPHERE: GRANULATION), this effectively represents a diffusion process, spreading magnetic flux over large areas and thereby allowing flux elements of opposite polarity to cancel. Besides such turbulent diffusion, two other processes contribute to the distribution and transport of magnetic flux at the solar surface. Firstly, a meridional flow of about 10 m s^{-1} directed from the equator to the poles and, secondly, latitude-dependent DIFFERENTIAL ROTATION. Computer simulations incorporating local flux emergence and the various transport processes reproduce the evolution of the magnetic field on large spatial scales remarkably well, including the reversals of the global dipole field.

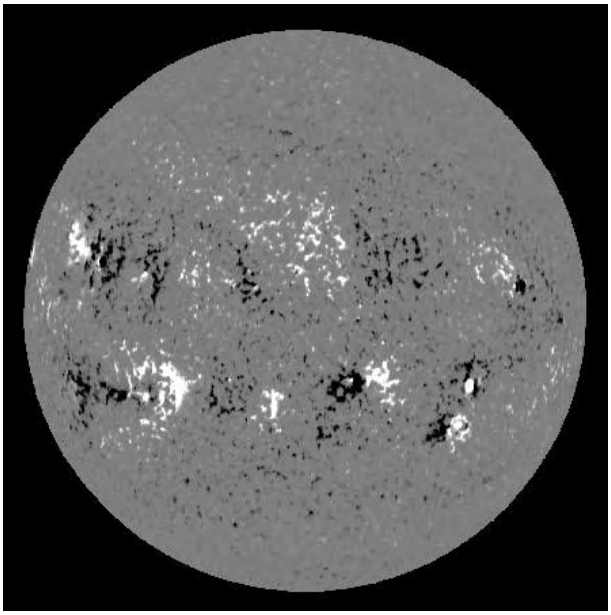

Figure 1. Map of the magnetic field in the solar photosphere on 25 July 1993. Black and white indicate positive and negative magnetic polarity, respectively. The dominant features are bipolar active regions and extended unipolar domains with a network structure outlining the convective flow pattern of supergranulation. (Courtesy National Solar Observatory, USA.)

The most conspicuous magnetic phenomena in the visible layers of the solar atmosphere are SUNSPOTS. Their magnetism was discovered in 1908 when G E Hale derived magnetic field strengths of a few 100 mT from the Zeeman splitting of spectral lines. Sunspots are found in active regions and typically appear in groups comprising spots of both magnetic polarities. The magnetic polarities in sunspot groups and active regions are roughly oriented in the east–west direction of solar rotation. They obey systematic polarity rules: during one 11 yr cycle, all active regions have the same east–west polarity orientation in the northern hemisphere of the Sun, while the opposite orientation is found in the southern hemisphere. All

polarities are reversed in the subsequent activity cycle. These properties reveal the magnetic nature of the 11 yr cycle and show that a full magnetic cycle has a duration of 22 yr. The polarity rules can be understood in terms of a large-scale, east–west oriented (toroidal) magnetic field below the visible surface. This field is antisymmetric about the equator and gives rise to active regions and sunspots at the surface through the emergence of magnetic loops (SOLAR INTERIOR: EMERGING MAGNETIC FLUX TUBES).

Active regions and sunspots appear on the Sun within broad activity belts on both sides of the equator. In the course of the 11 yr cycle, these zones migrate from about 35 degrees latitude toward the equator. Upon dissolution of an active region, its magnetic flux spreads over an increasing area until it merges with the general network pattern of the background field.

The magnetic flux emerging at the solar surface shows a broad spectrum in both area and amount of magnetic flux of bipolar active regions: from large sunspot groups with a total flux (sum of both polarities) of more than 10^{14} Wb and with dimensions exceeding 100 Mm down to the small ephemeral active regions with diameters of some tens of Mm, containing a few times 10^{10} Wb. The number of active regions emerging per unit time on the solar surface increases strongly with decreasing total flux of the region: ephemeral active regions are capable of replenishing the magnetic flux of the background field within about 2 d. Since the total magnetic flux is not observed to accumulate in time, similarly effective processes of flux removal or flux cancellation must be at work. Apparently due to their small intrinsic length scales, however, these processes are difficult to observe and not well understood. While the ephemeral active regions obey the magnetic polarity rules (at least in a statistical sense) and so are part of the global solar cycle, at smaller length scales (below 1 Mm) magnetic flux is continuously reprocessed by fragmentation, clustering, collision and advection of small flux elements by convective flows, mainly granulation.

The polarity rules of active regions, the latitude migration of the activity belts, and the reversals of the dipole field demonstrate the global nature of the solar magnetic field. On the other hand, this large-scale organization is accompanied by strong fluctuations on a wide range of spatial scales.

Photospheric flux tubes

The inhomogeneous distribution of magnetic flux on large spatial scales (active regions and network structure) illustrated in figure 1 continues down to the smallest scales that are accessible to observation (see figure 2 as an example of a medium-resolution magnetogram): the major part of the magnetic flux permeating the solar photosphere is filamented into a spectrum of flux tubes (SOLAR PHOTOSPHERIC MAGNETIC FLUX TUBES) with field strength above 100 mT and mainly vertical orientation. These flux tubes contain almost all of the magnetic energy. The largest photospheric flux tubes are sunspots with diameters between a few Mm and 50 Mm and central

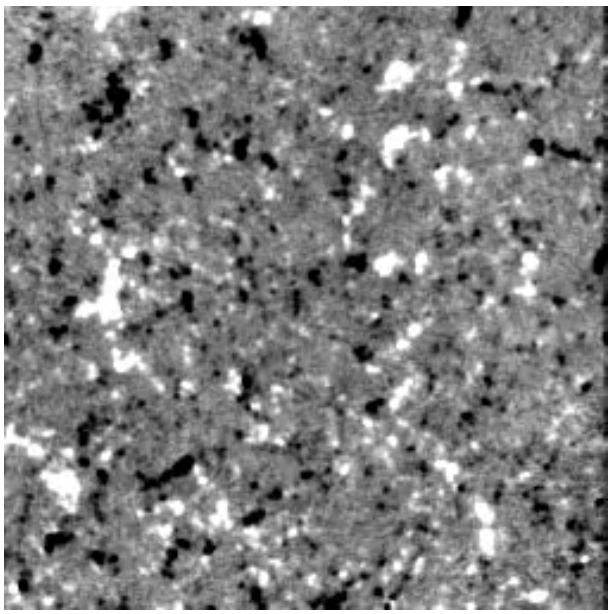

Figure 2. Magnetogram showing the intermittent magnetic field distribution in a 'quiet' region of the solar photosphere (size $\simeq 160 \times 160$ Mm^2). Black and white indicate negative and positive magnetic polarity, respectively. Most of the magnetic flux is contained in patches of strong field appearing in a broad range of sizes down to the resolution limit of the observation; there is no dominant polarity. (Courtesy C Denker, Big Bear Solar Observatory, New Jersey Institute of Technology.)

magnetic field strengths between $\simeq$200 mT and 350 mT. Sunspots represent the biggest accumulations of magnetic flux in the photosphere. Large sunspots are composed of a dark core (see SUNSPOT UMBRA) surrounded by a striated annular region called penumbra (see SUNSPOT PENUMBRA). Small sunspots without a penumbra are called pores (see SUNSPOT PORES); they comprise the size range between about 0.5 Mm and 5 Mm. Flux tubes smaller than pores appear bright in white light and in selected spectral bands containing many spectral lines; they are called magnetic elements (figure 3).

The (relative) darkness of sunspots is caused by the suppression of convective energy transport due to their strong magnetic field (MAGNETOHYDRODYNAMICS: MAGNETOCONVECTION). On the other hand, a small flux tube appears brighter than the average solar surface because its partially evacuated interior is efficiently heated by radiation from its surroundings in the deeper layers and, presumably, also by dissipation of mechanical energy in its higher atmospheric layers. Note that, for a cylindrical flux tube, the ratio of the heating surface area of its 'wall' and the internal volume to be heated is inversely proportional to the tube radius. The hot walls of small flux tubes become best visible near the limb of the Sun, where the combined effect of many flux tubes gives rise to bright FACULAE. Averaged over the whole Sun, the enhanced brightness of the magnetic elements dominates over the reduced energy

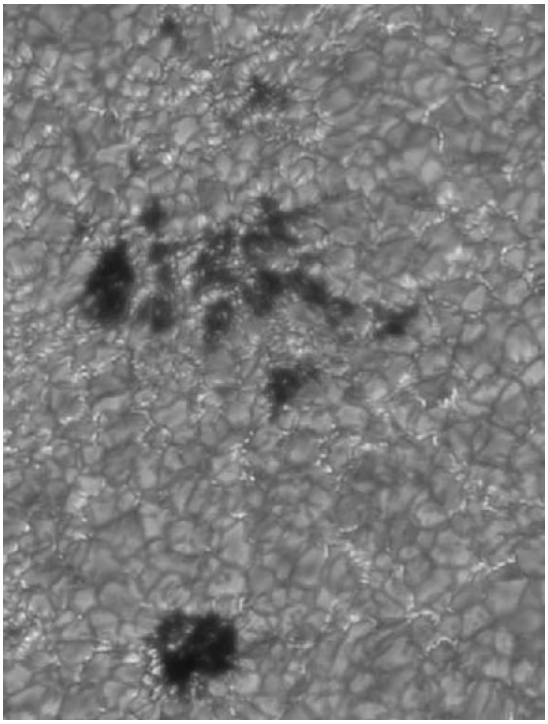

Figure 3. Size-dependent brightness signature of magnetic flux tubes in the solar photosphere: large tubes (sunspots and pores) are darker than the average solar surface, while small flux tubes (magnetic elements) appear as bright dots, often strung together like chains. The roughly polygonal pattern is due to convective motions (granulation). The darker intergranular lanes are cool downflow regions while the brighter granules are formed by hot upflows. The magnetic elements are predominantly located in the intergranular lanes. The image has been taken with a 10 nm wide filter around 468 nm wavelength. (Courtesy G Scharmer, Stockholm Observatory.)

flux in the sunspots, so that the total solar radiation output increases with growing magnetic flux in the photosphere. As a consequence, the brightness of the Sun increases by about 0.1% from minimum to maximum of the activity cycle (SOLAR IRRADIANCE).

In contrast to the rather strong variation in brightness, the field strength inside flux tubes depends only weakly on their size. In fact, the average over their full cross section remains nearly constant at values between 150 mT and 200 mT. Only the very smallest flux tubes show indications of a significantly reduced field strength. Note that the magnetic pressure (MAGNETOHYDRODYNAMICS) of a field of 150 mT is comparable to the gas pressure at the base of the photosphere, so that the magnetic flux tubes must be nearly evacuated at that height in order to attain force balance.

Observations with low spatial resolution average over the intermittent structure of the magnetic field and thus yield a mean magnetic flux density. The range of measured values between roughly 0.1 mT in magnetically 'quiet' areas and up to 30 mT in active regions (outside sunspots) can be understood in terms of a varying area fraction occupied by strong flux tubes: values between less than 0.1% in quiet areas and 20% in active regions are indicated.

Spectroscopic observations in circularly polarized light, which originates exclusively from the magnetic regions in the photosphere, reveal details of the internal structure of magnetic flux tubes. This has led to semi-empirical models for the thermodynamic and magnetic structure of flux tubes in the network and in plage regions. These results indicate that the photospheric layers of small flux tubes are hotter than their environment and that the plasma within a tube is in rapid motion caused by flows, waves, oscillations and shocks. The tubes are embedded in downflowing gas and often show rapid horizontal displacements. This dynamical nature of the tubes is probably relevant for transporting mechanical and magnetic energy into the upper atmosphere, where it contributes to the heating of these layers (CHROMOSPHERE: HEATING MECHANISMS; CORONAL HEATING MECHANISMS).

If the area fraction occupied by flux tubes is not too large, the distribution of the magnetic flux tubes over the photospheric 'surface' of the Sun reflects the convective flow patterns: magnetic flux tends to accumulate in the downflow lanes. On the scale of supergranulation, this leads to the large-scale network pattern with a typical mesh size of 30 Mm. A similar structure is repeated on the scale of granulation. Such a distribution indicates the operation of flux expulsion, i.e. the sweeping of vertically oriented magnetic field lines into the downflow regions by the horizontal convective flows. This process is capable of enhancing the field to about equipartition of the magnetic energy density with the kinetic energy density of the flow, leading to a field strength of about 50 mT. In fact, freshly emerging magnetic flux appears in the photosphere with about this equipartition field strength. Theoretical studies and numerical simulations suggest that further intensification of the field strength up to 150 mT is caused by the combined effects of the strongly superadiabatic stratification of the convective region just below the photosphere, the suppression of convective motions by a magnetic field of sufficient strength, and the efficient cooling of the photospheric region due to radiative losses. These processes conspire in exciting an instability of convective type. This results in a strong downflow and cooling within the magnetic region, leading to a partial evacuation of its photospheric layers. The pressure force exerted by the external plasma causes a contraction of the tube and thereby amplifies the field. This process continues until the magnetic field becomes sufficiently strong to suppress the instability and maintain lateral force balance. The principle of this convective collapse mechanism is schematically sketched in figure 4.

The collapse process loses its efficiency for flux tubes with a diameter smaller than the photon mean free path of about 100 km at the base of the photosphere. At that limit, the tube interior is kept at the temperature of its environment and the evacuating downflow is throttled, so that the equipartition limit cannot be exceeded. In

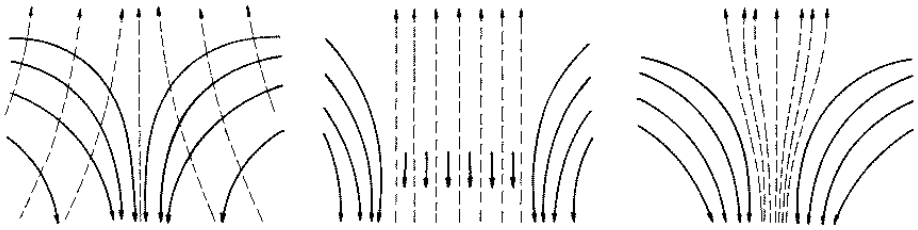

Figure 4. Schematic sketch of the processes that lead to intensification of magnetic field in the solar (sub)photosphere. Left: the horizontal flows of granular convection sweep magnetic flux towards the downflow regions (full: streamlines, dashed: field lines). Middle: magnetic forces suppress the convective motions when the magnetic energy density becomes comparable to the kinetic energy density. This throttles the energy supply into the magnetic region, the gas cools off due to radiative losses and the internal downflow is enhanced. The superadiabatic stratification further amplifies the flow. Right: the downflow has evacuated the upper layers and the magnetic field in the quenched tube has increased accordingly to maintain lateral force balance.

fact, observations in the infrared spectral range reveal the existence of small magnetic features with about equipartition field strength in the photosphere. This relatively weak field is dominated by the convective motions; the corresponding field direction is found to be predominantly horizontal (PHOTOSPHERE: INTRANETWORK AND TURBULENT MAGNETIC FIELDS).

An illustration of the coexistence of strong vertical flux tubes and weaker horizontal field in the solar photosphere is given in figure 5, which shows a snapshot from a numerical simulation of the interaction between magnetic field and convective flow in the photosphere. A vertical flux tube with a strong field has formed by the convective collapse process in a downflow region. Magnetic flux that has not been swept to the flux tube is wrapped up by the convective pattern and brought to the surface by upflows, where it forms patches of mainly horizontal field with about equipartition field strength. Such simulations are also consistent with the observed dynamic nature of the flux tubes: they show strong internal flows, wave and shock propagation, as well as a horizontal swaying of the flux tube.

Besides the flux tubes and the equipartition-field features, a third component of the photospheric magnetic field is indicated by measurements of the Hanle depolarization in spectral lines. In contrast to the measurements based on the circular polarization, this method is most sensitive to weak fields and the signal does not vanish for mixed magnetic polarity within the observational resolution element. Measurements based upon this technique suggest the existence of a small-scale turbulent magnetic field with no preferred direction and a field strength in the range of 0.4–4 mT.

Upper atmosphere

In the atmospheric layers above the photosphere, magnetic field measurements are difficult. Since the temperature rises to values of about 2×10^4 K in the chromosphere and up to a few times 10^6 K in the corona, the atoms become highly ionized and most of their spectral lines shift into the (extreme) ultraviolet range, where the Zeeman splitting is very small while the lines are thermally

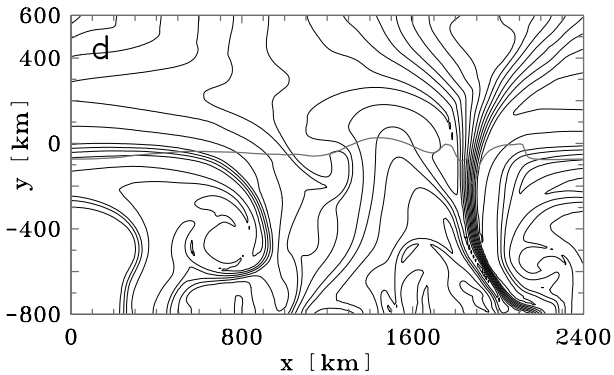

Figure 5. Magnetic field distribution arising during numerical simulation of the interaction between magnetic field and convective flows under conditions prevailing in the solar photosphere. Shown are magnetic field lines in a 'box' spanning a horizontal distance of 2400 km on the Sun, while the vertical coordinate ranges from 800 km below the surface (optical depth unity at 500 nm wavelength for a mean solar atmosphere model) to 600 km above it. The mainly horizontally running line located around $y = 0$ indicates optical depth unity (from Grossmann-Doerth *et al* 1998).

broadened due to the large temperature of the gas. Moreover, the magnetic field strength in the flux tubes decreases with height due to the diminishing external gas pressure. Alternatives to the Zeeman effect are the Hanle effect (SOLAR MAGNETIC FIELD: ZEEMAN AND HANLE EFFECTS) and gyro-synchrotron emission (SOLAR SPECTROSCOPY: CONTINUUM RADIO EMISSION AND DIAGNOSTICS), but the precision of the measurements and their spatial resolution are much lower than for the magnetic field in the photosphere. Field strengths obtained by these methods range from 1–10 mT in PROMINENCES and reach 10 mT at the base of the corona in active regions; above sunspots, values up to 100 mT are found. Further out, a typical field strength at two solar radii is 0.1 mT.

For increasing height in the solar atmosphere, the magnetic field becomes dynamically as well as energetically dominant: while the gas pressure decreases

exponentially with height, the magnetic field strength follows a radial power law above the height of the magnetic canopy (CHROMOSPHERE: MAGNETIC CANOPY), where the photospheric flux tubes merge; above this level, the magnetic field occupies all available space. As a consequence, in quiet regions the magnetic pressure becomes comparable to the gas pressure in the chromosphere and lower corona, while it exceeds the gas pressure in active regions. Apart from very dynamic phenomena like SOLAR FLARES or SOLAR CORONAL MASS EJECTIONS, the magnetic energy density also exceeds the kinetic energy density contained in the bulk motion of the plasma.

Since there is no component of the magnetic Lorentz force along the magnetic field lines, material motion in the upper atmosphere is strongly guided by the magnetic field. Moreover, the particle collision rate decreases with height and thermal conduction in the corona becomes anisotropic, i.e., heat is conducted much easier parallel to the field lines than in the perpendicular direction. Under these circumstances, the magnetic field channels the mass and energy flows in the upper atmosphere, so that any structure visible in absorbed or emitted radiation naturally tends to outline the pattern of magnetic field lines. The overall arrangement of the field can thus be inferred from the geometry of intensity structures. Examples are the myriads of CORONAL LOOPS, which are best observable in soft x-rays (SOLAR SPECTROSCOPY AND DIAGNOSTICS: X-RAY EMISSION), the chromospheric fibrils and spicules visible in the hydrogen H_α line (CHROMOSPHERE: FIBRILS; SPICULES), and the white-light morphology of the corona as observed during total eclipses or with coronographic telescopes (SOLAR TELESCOPES AND INSTRUMENTS: GROUND). All this structure owes its existence to the magnetic field since the magnetic forces can easily balance the corresponding pressure gradients.

The magnetic topology of the corona is divided into 'closed' regions dominated by coronal loops connecting regions of opposite magnetic polarity in the photosphere (like active regions) and large unipolar 'open' regions with roughly radial field lines. While the closed regions are bright in x-ray and EUV emission, the open regions are more tenuous and, therefore, show much less emission (CORONAL HOLES). The magnetic force hampers the flow of the solar wind in the closed regions, while matter can freely stream outward along the field lines in open regions. This is consistent with the observation that the coronal holes are the source regions of the fast solar wind while only a relatively low-speed and unsteady outflow emanates from the closed regions. Because the field lines are rooted in the rotating solar body, the field develops a spiral pattern in interplanetary space (SOLAR WIND: MAGNETIC FIELD).

A relatively simple configuration develops around the phases of minimal solar activity: the polar regions are open while closed fields dominate near the equator; further out, the kinetic energy density of the solar wind dominates also in the equatorial regions and draws the field open, so that coronal streamers form. During solar activity maximum, many bipolar regions dominate the magnetic field distribution so that the closed regions cover a larger part of the corona and the magnetic configuration becomes more complicated.

Generation of magnetic flux

What is the origin of the solar magnetism? The electrical conductivity of the solar plasma is sufficiently large to prevent the dissipation of a large-scale magnetic field permeating the whole Sun over its lifetime. Consequently, if the Sun inherited a magnetic field from the interstellar cloud that it was formed from, the large-scale part of this field could still remain as a slowly decaying fossil field. However, if such a field exists, it must be buried in the solar interior since no indication for its existence is found in the solar atmosphere. On the other hand, the nearly rigid rotation of the solar radiative core below the convection zone found by HELIOSEISMOLOGY can be most easily understood in terms of magnetic stresses exerted by a weak fossil field of the order of 0.1 mT (SOLAR INTERIOR: ROTATION).

The magnetic field observed at the surface varies on a broad range of timescales and even the large-scale dipole component reverses during each 11 yr cycle. This indicates that induction processes due to plasma motion play a crucial role in the generation and evolution of the solar magnetic field (DYNAMO THEORY). Two kinds of such motion are of particular relevance: convection and differential rotation. The latter is capable of generating a toroidal (east–west directed) magnetic field from a field in meridional planes (poloidal field). The existence of a strong toroidal field component is inferred from the east–west orientation and the polarity rules of sunspot groups. The dynamo cycle is completed by the generation of a poloidal field from the toroidal field through the systematic twist of convective motions under the influence of the Coriolis force. If the new poloidal field has reverse polarity with respect to the original field, the toroidal field generated, in turn, from that field is reversed as well. The full dynamo cycle is closed when a poloidal field of the same polarity as the original field has been generated. This sequence is in accordance with the characteristics of the 22 yr magnetic cycle of the Sun.

Theoretical considerations show that indeed differential rotation and convective flows are capable of sustaining a self-excited hydromagnetic dynamo that generates a periodically oscillating magnetic field. Models agree with many observed properties of the solar cycle provided the adjustable parameters of the models (typically related to the turbulent part of the velocity field) are properly chosen. Therefore, it is widely accepted that a hydromagnetic dynamo working in the convection zone generates the solar magnetic field. On the other hand, there is as yet no consensus about its detailed modus operandi. Currently discussed models propose that the dynamo mechanism operates near the lower boundary of the convection zone, some 200 Mm below the solar surface. There are two main reasons for this conjecture: (1) helioseismology has shown

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills, Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

that in a layer at the bottom of the convection zone the rotational velocity varies rapidly with radius thus producing a strong local shear flow; (2) magnetic flux must be prevented from rapidly rising to the surface due to magnetic buoyancy before it could be sufficiently amplified by the dynamo process. Buoyancy can be suppressed in a layer of overshooting convection at the bottom of the convection zone. It is thought that where the field has grown sufficiently strong it becomes unstable and magnetic flux tubes start to rise towards the surface due to the stratification of the convection zone. Emerging at the photosphere, a magnetic flux tube forms an active region. In order to be compatible with observed properties of active regions (emergence latitude, orientation, asymmetry) the field strength at the bottom of the convection zone must be in the range of 3–10 T. This puts a tight constraint on the operation of the dynamo since the associated magnetic energy density is 1–2 orders of magnitude larger than the kinetic energy density of the convective motions.

Solar Magnetic Field: Inference by Polarimetry

Most solar structure and phenomena occurring in the solar atmosphere arise from the presence of magnetic fields. This article describes techniques for remote sensing of the solar magnetic field, primarily via analysis of the polarization it imparts to the radiation emitted by the Sun.

The ZEEMAN EFFECT provides by far the most useful diagnostic of the solar magnetic field. Accordingly, most of this article is devoted to polarimetry of spectral lines sensitive to the Zeeman effect. As a result of recent advances both in technology and in techniques for interpretation of solar polarimetry, it is now possible to infer routinely not only the strength of the field in the solar photosphere but also its orientation. These vector magnetic field measurements provide powerful new diagnostics of solar phenomena; accordingly, much of this article is devoted to these techniques. A few different polarimetric diagnostics are described which provide different information about the magnetic field. This article does not embrace *in situ* measurements of the interplanetary magnetic field.

Importance of the magnetic field

Solar magnetic fields arise within the Sun, and also within its atmosphere, as a result of fluid motions interacting with the magnetized ionized gas (plasma) of which the Sun is composed. Because the gas is ionized, it is an excellent conductor of electricity. Electric currents are quickly established, which in turn induce magnetic fields, which in turn may then react back on the plasma, sustaining a dynamo (see DYNAMOS: SOLAR AND STELLAR). A glance through this volume will quickly convince the reader of the extraordinary, pervasive importance of magnetic fields in solar physics. They give rise to many phenomena such as SUNSPOTS, SOLAR FLARES, PROMINENCES, coronal structure and SOLAR CORONAL MASS EJECTIONS and the intrinsic variability of the Sun itself. Inference of this fundamental property of the solar plasma is central to advancement in our understanding of these phenomena.

Over many decades, qualitative measurements of solar magnetic fields have given us a glimpse of the evolution of the global SOLAR MAGNETIC FIELD as well as insight into solar activity. Recent advances in instrumentation and analysis techniques have placed the measurement of solar magnetic fields on a quantitative footing, so that it is now possible to provide strong observational guidance for the rapidly advancing theoretical understanding of solar processes.

Polarimetry and the Zeeman effect

The presence of a magnetic field in the solar atmosphere breaks the degeneracy of atomic levels, causing wavelength shifts of transitions between levels. The orientation of the magnetic field also establishes a reference frame for preferred interaction of these atomic states with polarization states of electromagnetic radiation. The strengths of the magnetic fields encountered in the solar atmosphere are such that bound–bound transitions may be characterized by the ZEEMAN EFFECT, the article on which in this volume describes its origin and its influence on the polarization of atomic transitions observed in the solar spectrum. Figure 1 illustrates the polarization of spectral lines in and around a sunspot. It is this polarization, along with the observed intensity, that permits one to infer both the strength and the orientation of the magnetic field.

Polarized light may be described by four quantities known as the Stokes 4-vector $\boldsymbol{S} = [I, Q, U, V]^T$ (the superscript ^{T} indicates transpose of the 4-vector). The components of the Stokes vector may be generated by a set of ideal polarization measurements: I is the intensity, Q is the difference of intensity between measurements with an ideal linear polarizer with polarization axis oriented vertically minus the measurement with the polarizer rotated by 90°, U is obtained in a similar fashion to Q except that the orientations of the polarizer are rotated by 45° with respect to those defining Q, and V is the difference measurement of ideal circular polarizers: right- minus left-handed. Figure 1 illustrates that the measures of linear polarization (Stokes Q, U) are fundamentally *symmetric* about the center of these absorption lines and Stokes V is fundamentally *antisymmetric*. Furthermore, the magnitude of the splitting is proportional to the strength of the magnetic field; linear polarization is present only if the field vector $\boldsymbol{B}$ is inclined to the line of sight, and circular polarization is present only if the field has a component along the line of sight. The complete polarization information represented by the Stokes 4-vector, when provided for the spectral variation of solar absorption lines, contains *almost* (except for an ambiguity of π in the azimuth angle of the field: see below) enough information for a complete description of both the strength and the orientation of the magnetic field in the solar atmosphere. Indeed, the magnetic field is a physical quantity that now may be measured remotely with considerably higher accuracy than many of the other thermodynamic properties of the solar atmosphere. A device that provides a map of the magnetic field at the solar surface is known as a magnetograph.

'Longitudinal' magnetometry

At wavelengths of visible radiation, even those atomic transitions with the greatest Zeeman splitting show atomic states fully separated in wavelength (i.e. greater than the thermal broadening of the lines) only for the strongest fields (>2000 G) present in the solar atmosphere. Note this splitting in spectra from the dark sunspot umbra in figure 1, where the field strength typically is in excess of 2000 G. Weaker fields produce splitting that is incomplete, and the degree of circular polarization (Stokes V) then approaches a proportionality with the wavelength splitting and hence with the field strength $|\boldsymbol{B}|$. Additionally, V depends on the angle of the field with respect to the line of sight γ. In the limit of weak magnetic fields, the peak amplitude of Stokes V is given

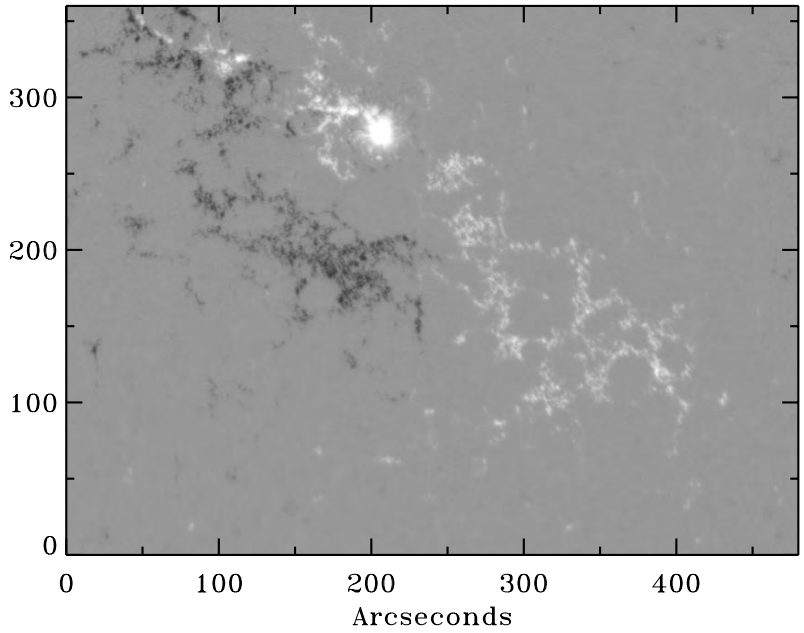

Figure 2. Longitudinal magnetogram from SOHO/MDI measured on 30 August 1997.

by $V_{max} \propto |\boldsymbol{B}| \cos\gamma$: the component of the field along the line of sight. Hence, magnetographs which measure the amplitude of the circular polarization signal are called longitudinal magnetographs. The measured difference between right- and left-handed circular polarization at one (or more) wavelengths in a Zeeman-sensitive spectral line (see figure 1) constitutes a magnetographic measurement. Systematic longitudinal magnetography of solar magnetic fields began with the Babcock magnetograph at the Mt Wilson Observatory in 1951, and it has continued and improved up to the present, as embodied by the superb data from the Michelson Doppler Imager (MDI) aboard the NASA/ESA Solar Heliospheric Observatory mission (SOHO), an example of which is shown in figure 2.

The great advantage of magnetograms like the one shown in figure 2 lies in their ability to reveal the temporal evolution of the fields. Operating continuously outside of the Earth's atmosphere, the MDI instrument is giving the first steady view of this evolution, ranging from large time and spatial scales corresponding to the disk passage of magnetic regions to the rapid evolution of small-scale flux elements.

Longitudinal magnetographic measurements provide approximate, nonetheless extremely useful, measures of the solar magnetic field. The magnetic field in the solar photosphere is highly structured at small scales. Outside of sunspot umbrae, magnetographic measurements are very far from resolving this structure. Longitudinal magnetographs in fact *do not* present us with a measure of the line-of-sight component of the field, but rather they provide some indicator of the magnetic flux $(\boldsymbol{B}\cdot\mathrm{d}\boldsymbol{A})$ within the spatial resolution element $\mathrm{d}\boldsymbol{A}$ of the instrument. Note also that $\mathrm{d}\boldsymbol{A}$ is defined in the plane of the sky, not the local normal to the solar surface. Calibration of magnetographic data to a quantitative scale of magnetic flux is often hindered both by incomplete resolution of the spectral line shapes and by approximate 'calibration constants' that do not account for variation in the structure of the solar atmosphere from point to point on the solar disk.

Vector magnetometry

The magnetic field is a vector quantity. Many solar processes involving the magnetic field will be best understood with knowledge of the full magnetic vector. There are numerous examples of the utility of vector magnetometry, of which the following is only one. Distinct modes of wave and oscillatory motions are possible in a magnetic field, and certain of these modes may transport mechanical energy of convection from below the surface into the upper layers where they heat the atmosphere (MAGNETOHYDRODYNAMIC WAVES). One may distinguish these modes by the direction of the motions with respect to the field vector, so it is important in this example, as in many other problems, to precisely establish the orientation of the field. When one needs to specify individual components of the magnetic vector, the field measurement becomes a highly quantitative endeavor. Vector magnetometry thus demands high precision from both the polarimetric measurements and the analysis.

The circular polarization from the Zeeman effect is commonly much greater than the linear polarization because, in the limit of small $|\boldsymbol{B}|$, the total linear polarization is approximated by $P_L = (Q^2 + U^2)^{1/2} \propto (|\boldsymbol{B}| \sin\gamma)^2$. Offsetting this difficulty is the great

advantage that linear polarization is sensitive to the component of the field *transverse* to the line of sight. Advances in technology for both detectors and data acquisition, coupled with parallel developments in techniques for analysis of polarimetric data, have made possible routine vector magnetometry of the Sun.

Modern spectropolarimeters provide low-noise polarimetry from which it is possible to infer the components of the field vector in the solar atmosphere within a few per cent accuracy. This accuracy is achieved through a combination of the following attributes of the measurement:

- measurement of the complete, spectrally resolved absorption profiles of the solar spectrum lines;
- simultaneous measurements of two or more lines having similar thermodynamic sensitivity but differing sensitivity to the Zeeman effect;
- high signal-to-noise ratio of the measurements—typically $S/N = 10^3$ in the spectral continuum, or better;
- high-cadence polarization measurements to minimize image distortion from the Earth's atmosphere.

The measurements shown in figure 1 satisfy these requirements. The two broad solar absorption lines arise from neutral iron (Fe I) in the solar atmosphere. They are members of the same multiplet (816) of Fe I, and hence they respond similarly to point-by-point variations in temperature, pressure and ionizing radiation in the solar atmosphere. They differ principally in their sensitivity to the Zeeman effect: this difference is evident in the sunspot umbra where the splitting is noticeably smaller in the spectrum line on the left.

A sequence of such measurements, where the spectrograph slit is stepped in small increments in the direction perpendicular to its length, allow one, after involved analysis, to construct the vector field map shown in figure 3.

Analysis of polarization data

The fundamental data for vector magnetic field measurement are the spectral profiles of the Stokes parameters, as shown in figure 1 and also in figure 4 for the single spectrum highlighted in figure 1. Three quantities are needed to completely specify a vector. From the perspective of analysis of polarimetric data, a useful representation of the vector is the magnetic field strength (the length of the field vector) $|\boldsymbol{B}|$, the azimuth angle ϕ of the field vector in the plane of the sky relative to some coordinate frame (usually measured counterclockwise from the solar West direction) and the inclination angle γ of the field relative to the line of sight.

The field strength, or flux density $|\boldsymbol{B}|$, is normally presented in *cgs–emu* units of *gauss*. Even when the Zeeman splitting of the lines shown in figures 1 and 4 is less than the intrinsic (thermal + nonthermal) Doppler broadening of the solar plasma, subtle differences in the line shapes of the spectral profiles of the two lines permit an accurate measurement of the field strength when the S/N ratio of the observations is adequate. Thus, it is not necessary to rely solely on the amplitude of the ratio of Stokes V/I for a field strength measurement, as that quantity often leads to severe underestimate of $|\boldsymbol{B}|$ owing to the magnetized plasma filling only a small fraction of each spatial resolution element. Because the multiple-line analysis is independent of this magnetic fill fraction f, it is then possible to extract a crude measure of f from the data as well.

The linear polarization Stokes parameters Q, U are related to field azimuth ϕ through a simple rotation of the coordinate system for the linear polarization. Neglecting the magneto-optical effect[1], ϕ is determined by a simple rotation of the coordinate system to minimize the Stokes U profile from the solar lines. When precision linear polarization measurements are available, ϕ is well determined.

The ratio $P_L^{1/2}/V$ provides an approximate measure of the inclination angle γ. The differing sensitivity of P_L and Stokes V to $|\boldsymbol{B}|$ demands that γ be determined in concert with $|\boldsymbol{B}|$. Underestimates of $|\boldsymbol{B}|$ that result from ignoring the possibility of $f < 1$ may lead to spurious values of γ which are far more inclined to the line of sight than reality. This potential source of error is circumvented by the full line profile analysis described below.

At present, the most practical way to extract measures of the vector magnetic field from spectropolarimetric measurements is by numerical fits to the Stokes spectral profiles. The result of such a fit is indicated by the solid curves in figure 4. In this particular case, an analytic solution to the transfer of polarized radiation in a somewhat simple model solar atmosphere provides the basis for the fitting procedure. Of order nine parameters are needed to obtain reliable fits to the Stokes profiles: the vector field (three parameters), the fill fraction (one), the Doppler shift (one) and the thermodynamics of the atmosphere (four). This technique gives an accurate indicator of the field vector averaged along the line of sight within the range of heights in the solar atmosphere where the Zeeman-sensitive spectral lines form. Even though this analysis technique uses a simple model of the magnetized solar atmosphere, it usually gives a good fit to the Stokes profiles, and much experience with the technique shows that the results of this fitting are robust and accurate.

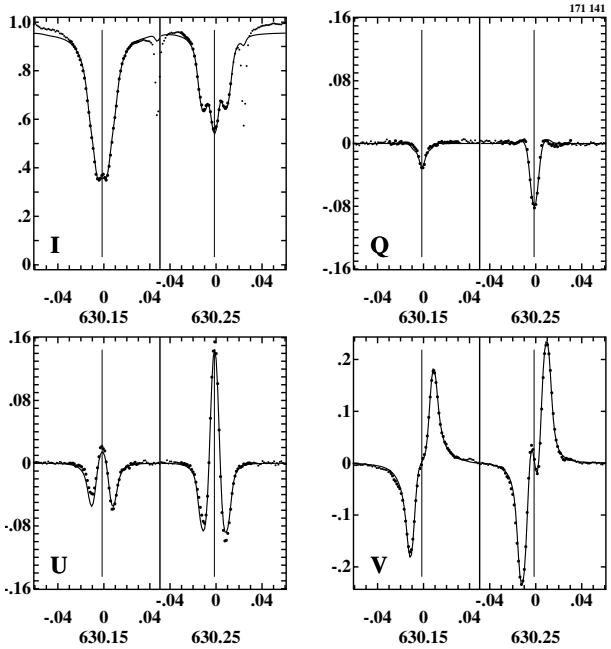

Figure 4. Polarization profiles and least-squares fits. A set of individual Stokes spectra from the location indicated in figure 1 are shown (dots), along with least-squares fits to the two solar spectrum lines (solid curves). The wavelength scale is indicated in nanometers. The extracted magnetic field parameters for this location in the sunspot are $|\boldsymbol{B}| = 2206$ G, $\phi = 140^\circ$, $\gamma = 134^\circ$.

The standard analysis technique allows only the temperature to vary along the line of sight; it does not permit estimates of line-of-sight *gradients* of the field, the line-of-sight velocity component or the other important thermodynamic properties. Such gradients may break the symmetries of the Stokes profile shapes about the central wavelength of the line, and the degree of asymmetry carries important information about the sign and magnitude of gradients. Recently, sophisticated fitting procedures have been developed which are based on more realistic models of the solar atmosphere, including gradients. The knowledge of local gradients of all components of $\boldsymbol{B}$ allows one to extract the electric current

[1] When the optical thickness of the spectrum lines becomes considerably larger than unity, Faraday rotation, also known as the magneto-optical effect, causes the direction of linear polarization to rotate as a function of wavelength near the centers of spectral lines. It also causes an anomalous 'reversal' in the core of the Stokes V profile to the right in figure 4. This effect may be accounted for in the least-squares fitting described below, and it actually helps to establish the optical depth of the lines in that analysis.

density ($\boldsymbol{J} = (c/4\pi)\boldsymbol{\nabla} \times \boldsymbol{B}$) vector: an important diagnostic of the solar plasma. Furthermore, it provides a glimpse of the 3-dimensional structure of the atmosphere, albeit limited in extent to the few scale heights in the atmosphere over which the diagnostic spectral lines form.

The Zeeman effect carries no information on the *parity* of the component of the vector field transverse to the line of sight $\boldsymbol{B}_t$. That is, $\boldsymbol{B}_t$ is said to be *ambiguous* to within a multiple of π rad because the linear polarization introduced by the Zeeman effect responds identically to either $\boldsymbol{B}_t$ or $-\boldsymbol{B}_t$. Resolution of this ambiguity in the field azimuth angle ϕ requires additional information about the field or about its origin. Such information may take the form of an assumption. As examples, the azimuth may be chosen such that it is closest to that of the potential field defined uniquely by the locally vertical component of the field B_z, or one may choose the azimuth such that discontinuities of the field vector from one point in the magnetogram are minimized. A few techniques have been proposed to add different information to the problem, but none has yet seen practical use. In large measure, the resolution of the azimuth ambiguity remains an art, and, in special cases, errors of π may persist in the transverse field component of vector magnetograms.

Infrared field diagnostics

The Zeeman effect causes a splitting in the energy of atomic states proportional to $|\boldsymbol{B}|$. The splitting in wavelength is thus proportional to $|\boldsymbol{B}|\lambda^2$, but the Doppler broadening of an atomic transition is proportional only to λ. As a result, the Zeeman splitting relative to the intrinsic width of spectrum lines varies as $|\boldsymbol{B}|\lambda$. Spectrum lines forming in intrinsically weak solar magnetic fields of less than 1000 G do not show a separation of the Zeeman components at visible wavelengths, but the splitting of a line in the infrared (see INFRARED ASTRONOMY) can be nearly complete (i.e., comparable with or larger than the Doppler broadening; see figure 5).

Infrared measurements then offer a clear advantage for the study of weak-field regions in the solar atmosphere. The large splitting in the infrared relaxes the requirement for precision polarimetry. One drawback of solar magnetometry in the infrared is that the diffraction limit of the telescope is also proportional to λ. This limitation is a practical concern, particularly for measurements in the thermal infrared. Countering the reduced resolution are the improvements in atmospheric seeing and the polarizing properties of optics at infrared wavelengths. More importantly, when the Zeeman components of the line are fully or nearly split, magnetic elements unresolved within the observing element which differ only in $|\boldsymbol{B}|$ are easily identified based on their differing Zeeman splitting. Detailed analysis of the separate components is possible even without resolving them spatially. Furthermore, the size, efficiency and availability of infrared array detectors has increased in recent years. Infrared vector magnetometry has become progressively more useful as it provides unique tools to study weak solar magnetic fields.

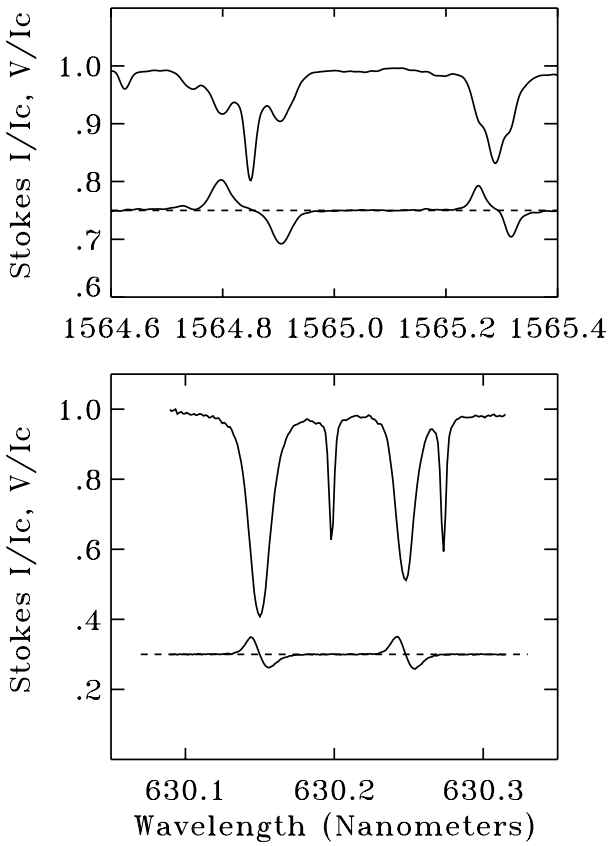

Figure 5. Comparison of Zeeman splitting in visible and infrared. The bottom panel shows Stokes I (top) and V (bottom) spectral profile shapes for a typical plage region as seen in the neutral iron line at 630 nm. The top panel shows analogous spectra, and correspondingly much larger Zeeman splitting, for a plage region observed in the neutral iron lines at 1565 nm (courtesy of I Rüedi). Dashed lines indicate the level of $V = 0$.

Prospects for magnetic field measurements above the photosphere

Most solar magnetograms sample magnetic fields in the photosphere—the thin layer of the solar atmosphere near the visible surface of the Sun—but many of the interesting physical challenges of solar physics arise from phenomena and processes in the higher layers: the chromosphere and corona. Thus, it is of great scientific interest to pursue analagous diagnostics of the chromospheric and coronal magnetic fields.

Several circumstances hinder efforts to measure fields above the photosphere. There are only a handful of spectral lines accessible to ground-based observations that form significantly above the photosphere, and these lines are not as sensitive to the Zeeman effect as those lines commonly used as photospheric field diagnostics. Owing to the larger nonthermal velocities, the chromospheric lines are intrinsically broader than photospheric lines and thus they produce smaller polarization signals. Most importantly, however, the magnetic fields of the

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

chromosphere and corona are commonly very much weaker than photospheric fields.

Although there is as yet no fully satisfactory means of measuring magnetic fields above the photosphere, routine longitudinal measurements are carried out daily for a line forming in the upper photosphere and low chromosphere (figure 6). These measurements graphically illustrate that the field has 'fanned out' considerably from the concentrated fields of the photosphere, mostly because of the combination of highly localized fields at the photospheric level and the rapidly decreasing density with height in the atmosphere.

Several research programs are aimed at improving chromospheric field measurements. For chromospheric lines forming in the visible and near-ultraviolet, it will be necessary to increase substantially the polarization sensitivity of the measurements over that commonly used for the photosphere. Infrared measurements would be ideal for this purpose, but few suitable spectral lines have yet been identified. The chromospheric neutral helium line at 1083 nm shows promise as a diagnostic of chromospheric fields.

Under most circumstances, the magnetic forces acting on the tenuous corona are far greater than the pressure forces of the gas itself. Magnetic fields thus play a dominant role in coronal structure and dynamics, and therefore any measurement of coronal magnetic fields is highly desirable. Because of the intrinsic weakness of coronal fields and the difficulty of observing the weak coronal emission outside of eclipse, there are few prospects for coronal field measurements. This situation may change in the future, as a few emission lines in the infrared could prove to be useful coronal field diagnostics: the Stokes V signature arising from the Zeeman effect should be measurable.

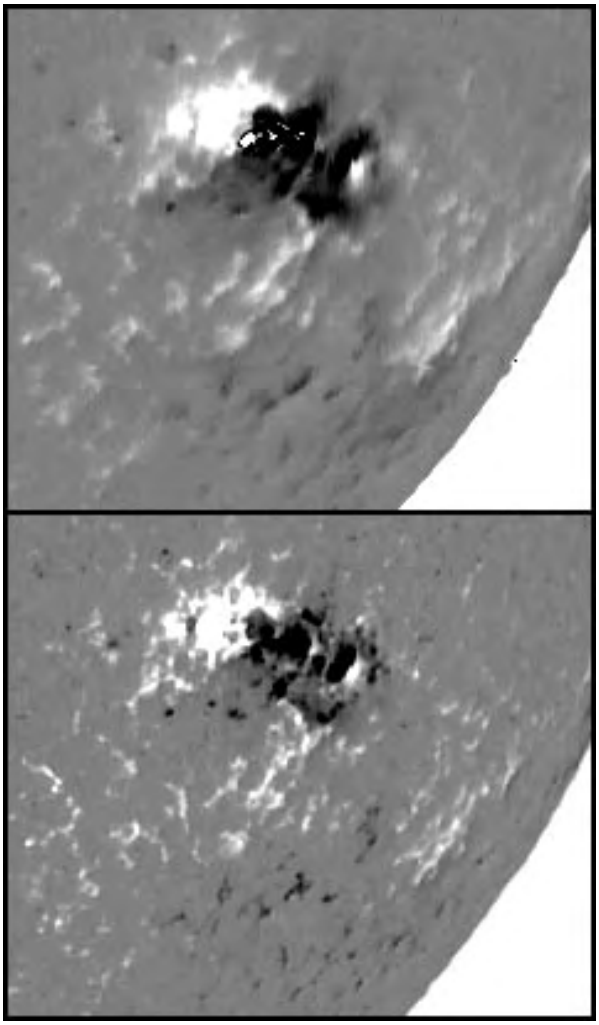

Figure 6. Expanding fields with height. The bottom image shows a photospheric longitudinal magnetogram of a typical active region near the southwest solar limb on 15 May 1998. The top image is a magnetogram of the same active region as observed in the singly ionized chromospheric calcium line at 854.2 nm, showing a considerably more diffuse appearance as a result of the expansion of the magnetic field with height in the solar atmosphere. Images supplied courtesy of J Harvey.

Other diagnostics of the solar magnetic field

The Zeeman effect introduces polarization into the solar spectrum. Another valuable diagnostic is the Hanle effect (see SOLAR MAGNETIC FIELD: ZEEMAN AND HANLE EFFECTS). When a weak magnetic field is present, the Hanle effect causes a reduction of the degree of linear polarization, accompanied by a rotation of the polarization direction, in spectrum lines which scatter an anisotropic radiation field. The degree of depolarization is a sensitive diagnostic of intrinsically weak magnetic fields in the solar atmosphere, and it has been used to reveal the presence of a weak, ubiquitous 'turbulent' field in the photosphere, presumably arising from the turbulent convection. Anisotropy of the radiation is most commonly encountered near the edge of the solar disk, owing to the variation of the brightness of the Sun with angle from the normal to the solar surface (limb darkening). Similar radiative processes acting in SOLAR PROMINENCES make the Hanle effect very useful for sensing the orientation of magnetic fields in these structures, thus helping to constrain theoretical models of the magnetic fields which suspend the cool, dense prominences in the hot, tenuous solar corona.

Anisotropy of the photospheric radiation also induces polarization at certain wavelengths corresponding to forbidden transitions of highly ionized atomic species, just as it does for transitions subject to the Hanle effect. Here, however, the Zeeman effect modifies the atomic level populations and thus alters the linear polarization of light scattered by these atoms. This emission line polarization may be used as a diagnostic of the orientation of the magnetic field, interpretation of the polarization is complicated by the presence of many magnetic structures along the line of sight through the optically thin solar

Dirac House, Temple Back, Bristol, BS1 6BE, UK

corona. If the usual circular polarization from the Zeeman effect can be measured at the same time, it will provide an indication of the strength of the field.

The microwave emission of the solar plasma provides another magnetic field diagnostic, based on rapid changes of the opacity of the chromosphere and low corona near the gyroresonance frequency for electrons precessing in the magnetic field. This technique can yield an indication of those temperatures of the upper atmosphere at which specific field strengths are encountered, but so far it seems to be limited to the very strong fields encountered over sunspots.

Future instrumentation

The magnetic field in the solar photosphere is structured on very small scales, and many processes of importance to heating and dynamics of the upper solar atmosphere occur principally at these small scales. It is therefore of utmost importance to describe the dynamical behavior of magnetic fields at these scales, accompanied by observations of the consequences in the upper layers at equally high angular resolution. The upcoming Japanese–USA mission SOLAR-B will provide continuous, high-resolution imaging polarimetry and spectroscopic polarimetry, along with imaging and spectroscopy of the upper layers. When this mission is launched in early 2004, it will provide the first space-based high-resolution quantitative vector field measurements. Efforts are also underway to develop space instrumentation of even higher resolution which should be able to actually resolve the tiny, intense photospheric flux elements and their accompanying dynamical interaction with the solar convective motions. In the meantime, one continues to improve the resolution of solar magnetometry from the ground using various image reconstruction and real-time image correction techniques.

The recent advances in techniques for vector magnetometry reveal the need for more comprehensive observations of this nature in order to better understand the workings of the solar cycle. To this end, the National Solar Observatory has begun development of instrumentation to provide frequent vector magnetograms of the entire solar disk, based on quantitative spectral measurements of the type shown in figure 1. This instrument is part of the SOLIS package for long-term, synoptic observations of the Sun.

Solar Magnetographs

The Sun's disk is covered with magnetic fields, not only the strong kilogauss concentrations of SUNSPOTS, but also as slightly weaker flux in PLAGES, the network, and probably as truly weaker flux everywhere (see also CHROMOSPHERE: NETWORK). These fields may be mapped using the Zeeman effect: a spectral line formed in the presence of a field splits into components, the separation of which is proportional to the field strength, and the components are polarized depending on the orientation of the field (see also SOLAR MAGNETIC FIELD: ZEEMAN AND HANLE EFFECTS). An instrument that measures magnetic fields using the Zeeman effect is called a magnetograph; it is a tool central to solar research.

History

A Sun without magnetism would be a featureless sphere and would exhibit no activity. That the Sun possesses surface magnetism had been suspected already for two centuries in 1900, since the structure of the corona at a total eclipse mimics the patterns of iron filings on a paper over a bar magnet (figure 1). In 1896 Pieter ZEEMAN discovered in the laboratory the effect that bears his name. Soon after, in 1908, George Ellery HALE demonstrated Zeeman splitting in the spectrum of sunspots. His observations were both visual and by photography (figure 2). This was the first cosmic magnetism ever detected. For the next 3 decades the Sun's 'general field' outside of sunspots was pursued without any being found.

Finally, in 1953, Horace BABCOCK at the MOUNT WILSON OBSERVATORY, taking advantage of WWII technology, invented the solar magnetograph (although credit should also be given to G Thiessen and K O Kiepenheuer for earlier developments). Using a large spectrograph, Babcock arranged for a double exit slit to bisect a Zeeman-sensitive spectral line. The light from the line wings was directed to a pair of photomultiplier tubes (PMTs). An electro-optic modulator (EOM) at the entrance slit, actually an image slicer, alternated the transmission of first right-circular and then left-circular incident light. Output from the two PMTs was connected to a difference amplifier which yielded a signal at the EOM switching frequency of 120 Hz. Even minute Zeeman shifts produced a clear signal. Although the splitting in the quiet Sun was a small fraction of the line width, the signal had a low noise owing to the high efficiency of the PMTs. Some polarization is introduced by oblique reflections at the telescope feed mirrors, but this unwanted component is common to both input channels and cancels at the difference amplifier.

Fields were mapped by slowly scanning in a raster pattern the entire solar disk. Spatial resolution was sacrificed, being only about 20 arcsec × 20 arcsec, in order to have enough light to detect weak fields the order of a gauss. Magnetism was found over the entire disk. What Babcock and other contemporary workers did not appreciate was that in reality the fields are strong, mostly at least 1000 G, but highly fragmented into sub-arcsec elements except in sunspots. A 1000 G element whose size is 0.5 arcsec × 0.5 arcsec will appear as 0.6 G at 20 arcsec × 20 arcsec resolution. Solar magnetographs based on Babcock's design were built at observatories world-wide.

Figure 1. Corona at total eclipse.

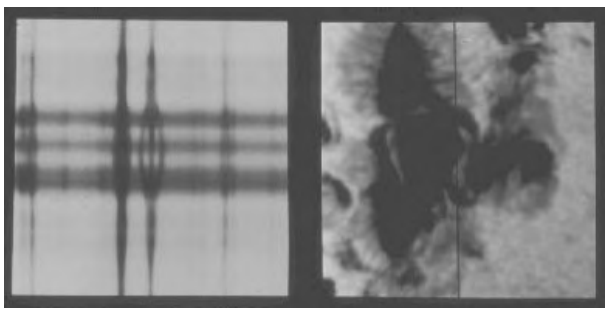

Figure 2. Zeeman splitting in the spectrum of a sunspot.

Today most magnetographs have a spatial resolution more like an arcsec and the fields they measure are accordingly much stronger. High resolution is achieved by using diode arrays or CHARGE-COUPLED DEVICES (CCDs) instead of PMTs. For space applications the spectrograph is replaced with an optical filter whose passband is comparable with line width. A few such instruments are described below.

Spectral lines for magnetographs

Depending on the height of the solar atmosphere to be probed, there are a few especially favorable lines for magnetometery. Zeeman splitting is proportional to $g\lambda^2$, where g is the Landé factor, which depends on the term values of the spectroscopic transition, and λ is the wavelength. Landé g ranges from 0 to 3, but is typically about 1. As spectral line width increases linearly with λ, the effective splitting is actually $g\lambda$. Obviously there is an advantage to the red and infrared wavelengths. Other considerations include the height of line origin

Table 1. Some useful lines for magnetographs.

Species	λ (μm)	Landé g	$g\lambda$	Origin	Problems
Fe	0.5250	3.00	1.57	Photosphere	Temperature
Fe	0.6302	2.5	1.57	Photosphere	
Hα	0.6562	1	0.65	Chromosphere	Broad
Ni	0.6768	1.5	1.02	Photosphere	
Fe	0.8688	1.66	1.44	Photosphere	
Fe XIII	1.0747	1	1.07	Corona	
Fe	1.5648	3.00	4.69	Photosphere	
Ti	2.2310	2.5	5.6	Photosphere	Umbral only
Fe	4.1364	1.7	7.0	Photosphere	Blends
Mg	12.32	1	12.32	High photosphere	No quiet Sun

(photosphere, chromosphere or corona), line strengths and telluric or other blends.

Babcock chose Fe 0.5250 μm which has $g = 3$ and is unblended. Also, its wavelength is well matched to the maximum of PMT response. Because this line arises from an excitation state near ground level, it is somewhat temperature sensitive and weakens in plages which are hotter than the average quiet Sun. Less affected by temperature is Fe 0.6302 μm, $g = 2.5$. The availability of InSb near-IR arrays makes Fe 1.5648 μm, $g = 3$, a winner. By a wide margin Mg 12.32 μm, $g = 1$, is the best, but this line is found only in active regions and near the Sun's limb; it is absent on the quiet disk. Table 1 lists a few useful lines.

Modern magnetographs

The Kitt Peak vacuum system

This is basically a Babcock-type magnetograph except that the detector is a 512 × 242 CCD chip. Anamorphic optics demagnify the 10.7 m Littrow spectrograph focal plane by 1/6 in the dispersion (wavelength) direction and 1/18 in the spatial. The 242 pixel width of the CCD means that information on line shape and intensity can be recorded for some observations. Circular polarization modulation is done with a liquid crystal device. A full disk observation using Fe 0.8688 μm with a 1 arc-sec pixel size requires about 45 min. This is done daily and the results are distributed around the world by the US Government Space Environment Laboratory in Boulder, Colorado. Figure 3 is an example of an active Sun magnetogram; figure 4 shows a quiet Sun magnetogram (see also KITT PEAK NATIONAL OBSERVATORY).

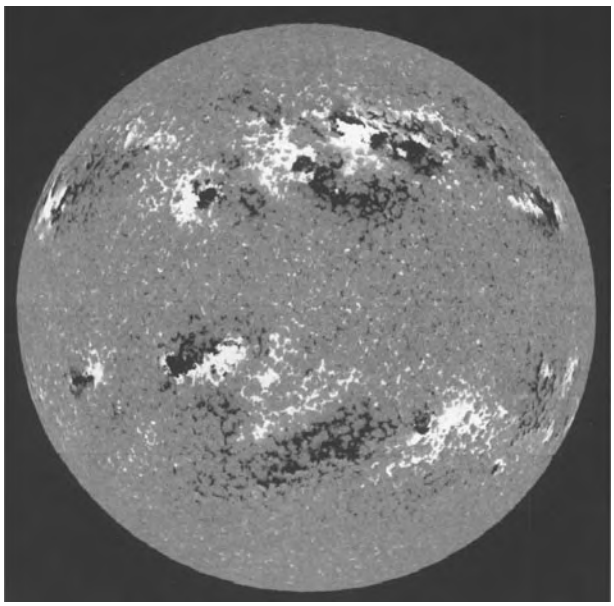

Figure 3. Active Sun magnetogram.

The Marshall Space Flight Center vector magnetograph

Fields directed toward or away from the observer are called longitudinal and give rise to oppositely circularly polarized light in the line wings. This is easy to detect by the means described above. Transverse fields result in an undisplaced linearly polarized line and split components, which are both linearly polarized in the same direction and at right-angles to the central part. Unless the splitting is comparable with line width, as in a sunspot umbra, there will be no 'difference' signal as in the longitudinal case and the field is difficult to measure and separate from any telescope polarization. Nevertheless, many instruments have been constructed that propose to measure vector fields (see Bray and Loughhead (1965) for examples).

One vector magnetograph that has seen much use is that at MSFC. This uses a beautifully built Zeiss birefringent filter of 0.125 Å bandwidth centered at 0.5250 μm. Modulation is by a combination of rotating quartz waveplates and a potassium dideuterium phosphate (KD*P) EOM. To avoid telescope polarization the instrument points directly at the Sun without any oblique reflections from feed mirrors. Sensitivity is about 4 G for longitudinal fields and 60 G for transverse. The main use of this system has been to try to understand the role of transverse fields in the production of solar flares (see also MARSHALL SPACE FLIGHT CENTER).

The Michelson Doppler Imager magnetograph on the satellite SOHO

The MDI instrument has a tunable Michelson interferometer with a 0.094 Å bandpass that can be tuned across the

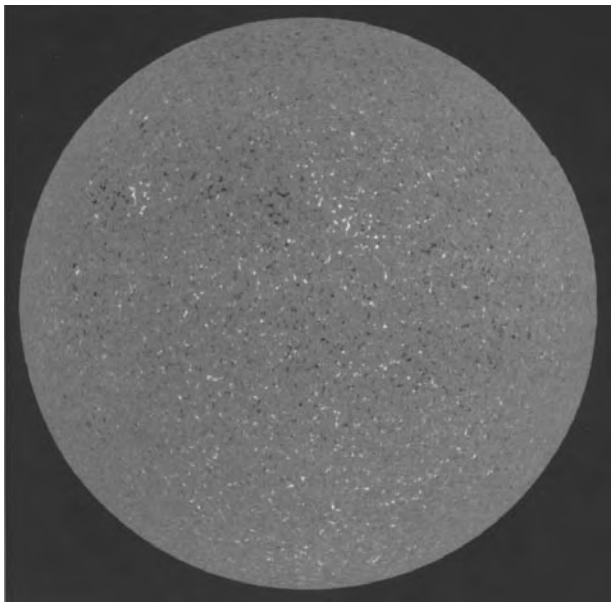

Figure 4. Quiet Sun magnetogram.

Ni 0.6768 μm, $g = 1.5$ line. Rotating wave plates are satisfactory in the absence of (atmospheric) seeing. Also many magnetograms can be averaged to reduce noise without a loss of resolution for the same reason (see also SOHO).

The vector spectromagnetograph for SOLIS

Synoptic Optical Long-term Investigations of the Sun (SOLIS) represents a next generation program to monitor the Sun. At the heart of this telescope cluster of instruments is a vector magnetograph. Using a ferroelectric liquid crystal as the polarization modulator, a 2048 $\times$ 1 pixel (1 arcsec) CCD detector, and using the favorable Fe 0.6302 μm line, full-disk vectorgrams are the end product. The aim is not one but several full disk observations per day. Much of the system is automated and may be remotely controlled.

Solar Maximum Mission (SMM)

NASA satellite designed to study solar flares during the peak of the solar cycle. Launched in February 1980. Carried seven instruments to record flares in visible, x-ray, ultraviolet and gamma ray wavelengths. Also measured the solar constant. Discovered x-rays originating from the bases of loop structures in flares. Failed after nine months, but was repaired by Shuttle astronauts in 1984. Re-entered the atmosphere in 1989.

Solar Photosphere

The photosphere (Gr $\phi\omega\varsigma$, *light*) of the Sun are those layers in its atmosphere that one observes in white light (broad band visible light). An image in such light (figure 1) shows a sharp edge, as if the light were emitted from a single layer, the 'visible surface' of the Sun. Since stars are gaseous, they do not have sharp surfaces, however. Moreover, the radiation at different wavelengths is generally emitted from different heights in the atmosphere of a star. A more precise and generally applicable definition of the term 'photosphere' is often needed. The observed photons are produced in the atmosphere, which also absorbs these same photons. The probability that a photon, newly produced at some depth in the atmosphere, escapes from the star depends on the optical depth. If a_λ is the extinction coefficient (cm^{-1}) (see SOLAR SPECTROSCOPY AND DIAGNOSTICS) at a wavelength λ, and if z is a depth coordinate in the star such that $z \to -\infty$ outside the star, then the optical depth at this geometrical depth z is defined as

$$\tau_\lambda = \int_{-\infty}^{z_P} a_\lambda \, \mathrm{d}z. \tag{1}$$

The probability that a photon created at depth τ escapes from the star without being absorbed or scattered is $\mathrm{e}^{-\tau}$. In the deeper layers where τ is large, this probability is small: the photons are trapped, diffusing outward by repeated scattering or absorption and re-emission processes. These regions are not directly observable. From higher layers where the optical depth is small, photons can escape freely, but the atmosphere is also tenuous there, and produces only few photons. A common definition of the photosphere at wavelength λ is now the layer in the atmosphere from which the bulk of the observed photons are emitted, roughly from $\tau_\lambda = 0.1$ to $\tau_\lambda = 3$. Since the optical depth is a function of the wavelength of the photons, photons of different energy each escape from their own photosphere. For this reason, one often speaks of a visible photosphere, an infrared photosphere, a radio photosphere, etc. If the term photosphere is used without reference to a particular wavelength, the wavelength range is implied in which the bulk of the energy is radiated. The Sun emits its energy mostly in the visible range of the electromagnetic spectrum; a nominal photospheric surface is sometimes defined for the Sun as the surface $\tau_{500} = 2/3$, i.e. at a wavelength of 500 nm (green light).

For stars, the photospheric surface so defined is roughly spherical, but the definition allows it to be corrugated (for example by GRANULATION, below) or deformed (for example flattened by rotation of the star).

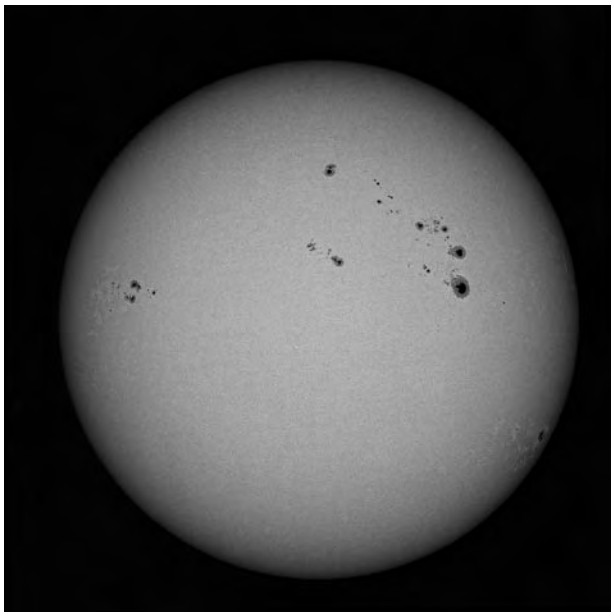

Figure 1. Image of the Sun in visible light, showing the photosphere with sunspots (dark) and plages (irregular brighter regions visible near the limb). Note general darkening towards the limb. Equilibrium structure

The type of radiation emitted reflects the temperature and density of the plasma at the photosphere as well as the physical processes producing the radiation. The bulk of the energy emitted by normal stars is in the UV to near-infrared range. The processes producing this radiation are known with high accuracy (see SOLAR SPECTROSCOPY), so a detailed comparison between theory and observed radiation is possible. The situation is complicated, however, by the presence of flows and magnetic fields in the atmospheres of stars. In particular the magnetic processes cannot as yet be computed from first principles, and their manifestations are noticeable in the entire electromagnetic spectrum. They even dominate the radiation in the radio and x-ray ranges. Nevertheless, important aspects of the physics of the photosphere can be understood by pretending that the atmosphere is static and without magnetic fields (see STELLAR ATMOSPHERES). It is then in *hydrostatic* and *radiative* equilibrium, and the structure of the atmosphere is determined by the basic parameters of the star: its luminosity L, radius R and mass M.

In hydrostatic equilibrium, the pressure drops with height in the atmosphere according to the barometric height formula, as in the Earth's atmosphere. The pressure P increases with depth z as $\mathrm{d}\ln P/\mathrm{d}\ln z = 1/H_P$, where the pressure scale height H_P is

$$H_P = \frac{\mathcal{R}T}{\mu g}. \tag{2}$$

Here $\mathcal{R}$ is the gas constant (8.134×10^7 erg K^{-1} mol^{-1}), μ the mean atomic weight per particle (1.28 for un-ionized gas of solar composition), g the acceleration of gravity at the surface,

$$g = GM/R^2 \tag{3}$$

and G is the constant of gravity.

If the energy radiated by the star is transported from the interior entirely by photons, the star is in radiative equilibrium. This is not the case in the Sun, since the energy is actually carried to the photosphere by convection, but for the observable layers it is still a fair approximation which is also of significant historical interest. The energy flux per unit surface area through the atmosphere is $F = L/4\pi R^2$. This flux has to be carried by photons diffusing outward; hence the density of photons has to decrease outward. Where photons are created and destroyed rapidly, the temperature of the gas is in equilibrum with the radiation (local thermodynamic equilibrium or LTE). Under this assumption, a decrease of the photon density requires a decrease of the temperature. The photosphere is cooled by radiation into the 3 K vacuum of space, and heat flows towards it from the hotter interior in the form of photons. A simple but useful estimate of the temperature variation through the atmosphere is obtained by assuming the extinction coefficient to be independent of photon energy (setting it equal to the value at the mean energy of the emitted photons, for example; this is called a grey atmosphere). Then the temperature T varies with the optical depth τ as:

$$\sigma T^4(\tau) \approx \tfrac{3}{4} F(\tau + \tfrac{2}{3}). \tag{4}$$

Here $\sigma = 5.669 \times 10^{-5}$ erg s^{-1} cm^{-2} K^{-4} is the radiation constant appearing in Stefan–Boltzmann's law, which says that a black body of temperature T radiates an energy flux $F = \sigma T^4$ per unit area of its surface. At $\tau = 2/3$, the temperature in this simple model is equal to the so-called effective temperature of the star, about 5780 K for the Sun.

In reality the extinction is not independent of photon energy. At wavelengths where it is low, one looks deeper into the atmosphere, where the temperature is higher, than at wavelengths where the extinction is high. If the dominant radiation processes are absorption and emission of photons (rather than scattering), the radiation generated in the atmosphere is close to that of a black body (i.e. the Planck function at the temperature of the plasma). Since the temperature in the atmosphere depends on depth, the temperature seen at each wavelength is different. This reflects itself in the spectral energy distribution of the star (the wavelength dependence of the emitted radiation), which can differ strongly from a black-body spectrum. This effect is responsible, in part, for the appearance of dark lines in the spectrum of a star at the wavelengths of atomic transitions. Through these deviations from a black-body spectrum, the spectrum can be used to make inferences about the composition and the thermal structure of the atmosphere.

Although the photosphere extends over a depth range in the atmosphere of a few hundred km, this is only a tiny fraction of the solar radius ($R_\odot \approx 700\,000$ km, see SUN: BASIC PROPERTIES). Even when seen with the best existing telescopes, which reach angular resolutions of about 0.25 arcsec (corresponding to 180 km), the Sun (figure 1) has a sharp edge. This sharpness is related to the temperature T and the acceleration of gravity g at the surface. Neglecting for the present purpose the deviations from hydrostatic equilibrium caused by oscillations (see HELIOSEISMIC OBSERVATIONS) and convection, we can apply the barometric height formula (2). This gives $H_\mathrm{p} \sim 150$ km for the scale height of the photosphere, only 1/5000 of the solar radius, and too small (0″2) to be resolved with existing telescopes. That this is indeed the scale height of the photosphere can be verified, however, during a solar eclipse. The moon moves about 0.5 arsec s^{-1} across the sky. Projected at the distance of the Sun, the lunar limb therefore occults the atmosphere at a rate of 300 km s^{-1}, or about 2 scale heights s^{-1}. By measuring the brightness variation in the last second before totality of the eclipse, one can accurately measure the extent of the solar atmosphere.

With the isothermal sound speed $c_\mathrm{i} = (\mathcal{R}T/\mu)^{1/2}$ (about 6 km s^{-1} for the solar photosphere), the ratio of pressure scale height to stellar radius can also be written as

$$H_\mathrm{p}/R = c_\mathrm{i}^2/v_\mathrm{e}^2 \tag{5}$$

where v_e is the escape speed from the surface, $v_\mathrm{e} = (GM/R)^{1/2}$, about 440 km s^{-1} for the Sun. For red supergiants such as Betelgeuse or Mira, which are about 200 times larger than the Sun but have similar masses and surface temperatures, this ratio is about 0.1. Such stars will therefore look much fuzzier when seen close up (techniques for such close-ups are becoming available through OPTICAL INTERFEROMETERS).

Determination of the temperature structure

Moving up into the atmosphere, the temperature declines from a value around 6400 K at $\tau_{500} = 1$ to around 4100 K at a height of 500 km ($\tau_{500} \sim 10^{-3}$). Above this height, the so-called temperature minimum, the average temperature starts inceasing again owing to the mechanical heating processes that produce the CHROMOSPHERE and CORONA. This variation of temperature with height in the photosphere can be deduced directly from the center-to-limb variation and from the strengths of *spectral lines* (see SOLAR PHOTOSPHERE: CENTER-TO-LIMB VARIATION; THE LIMB EFFECT AND GRAVITATIONAL REDSHIFT). An image of the Sun in the visible (figure 1) is noticeably darker towards the limb; the degree of this darkening depends on wavelength. For parts of the surface observed near the limb, the optical depth between the observer and a given level in the atmosphere is larger than for parts seen near the center of the disk, since the line of sight passes through a larger amount of mass. Near the limb, one therefore receives radiation from somewhat higher layers in the atmosphere. A limb darkening results if the temperature decreases with height at the observing wavelength, a limb brightening if the temperature increases. This effect is one of the classical ways for deriving empirical models for the solar atmosphere.

The second, equally classical, method can also be used for stars, where the disk cannot be resolved. It

uses the shape and strength of spectral lines. Quiet stellar atmospheres show spectral lines in *absorption*, i.e. dark, because the opacity in a spectral line is higher than in the nearby continuum. The known variation of the opacity with wavelength through the profile of the line can be used to invert the observed profile into a variation of (brightness) temperature with height, assuming that the line is formed under conditions of LTE. Such direct inversion of limb darkening and line profiles is not used in practice any more, since forward modeling by *spectral synthesis* (see SOLAR ATMOSPHERE: EMPIRICAL MODELS and SOLAR SPECTROSCOPY: VISIBLE EMISSION) is necessary to properly account for the radiative transfer process, in particular deviations from LTE.

Since the solar surface is inhomogeneous and not quite static, there are limits to what can be deduced from average limb darkening and line profiles. For example, line profiles are strongly affected by the Doppler shifts due to the convective flows. These distortions are an important test and diagnostic of the radiation–hydrodynamic simulations of granulation (see SOLAR INTERIOR: CONVECTION THEORY).

Physical conditions

With a temperature around 6400 K, the photospheric plasma is only partially ionized. At $\tau_{500} = 1$ there are less than 0.001 electrons per hydrogen atom. These few electrons come mostly from less abundant elements with low ionization potentials such as magnesium, while hydrogen and helium are almost completely atomic. In spite of this low degree of ionization, the plasma is almost infinitely conducting, for most purposes. The electron–hydrogen collision rate (the dominant rate at photospheric conditions) is about 10^{11} s^{-1}, and the mean free path of the electrons carrying the electric currents about 10^{-3} cm. With these values, the behavior of magnetic fields embedded in the plasma is described accurately by the ideal MHD approximation, at the length scales of interest (see MAGNETOHYDRODYNAMICS). In particular, the magnetic field and the gas are intimately tied to each other: the gas can move along the field lines without changing it, but in the direction perpendicular to the field either the gas is carried with the field, or the gas flow carries the field with it. One says that the field is *frozen in* to the gas.

The degree of ionization increases very steeply with depth. At a depth of only 50 km below the surface $\tau_{500} = 1$ of a granule, the temperature is 11 000 K. At this temperature some 10% of the hydrogen is ionized, 100 times more than at the surface. (In the cooler intergranular lanes, the increase is less strong.) With this increasing ionization, the opacity of the plasma increases by similar factors. This is mostly because the abundance of the H^- ion, the main source of continuum opacity in the solar photosphere, is proportional to the electron density. At the same time, the population of excited levels in all atomic species increases when partial ionization sets in, so that a great variety of atomic bound–free and bound–bound transitions starts adding to the opacity. Under these conditions, the horizontal mean free path of photons (in the visible continuum) is only 1 km, down by a factor of 50 from its value at $\tau = 1$.

Convection

The high opacity of a partially ionized plasma impedes the flow of heat through the outer envelope of a star like the Sun. To transport the heat emitted at the surface by radiation alone, through this opaque layer, a very steep temperature gradient would be needed. However, a stratification with a temperature gradient steeper than an adiabatic gradient (the 'adiabatic lapse rate') is unstable to convection (as in the earth's troposphere). The partially ionized envelopes of low-mass stars ($M < 2M_\odot$) are therefore *convective*. By overturning fluid motions, heat is carried bodily to the surface of the star, bypassing the inefficient transport by radiation, and is radiated away at the photosphere. The convective flows in the solar envelope are the cause of all its activity, including its magnetic fields (see SOLAR MAGNETIC FIELD), the corona, SOLAR FLARES, SUNSPOTS and its p-mode oscillations (see HELIOSEISMOLOGY).

The convection process can be observed in detail in the photosphere in the form of its granulation. A granule forms where the hot opaque gas from the envelope approaches the photosphere. As it is exposed to the interstellar vacuum it cools suddenly and becomes transparent. By cooling, the gas also becomes denser than its surroundings, and starts dropping down, a process observed in the form of intergranular lanes. In response to this disappearing cool gas, hot gas flows up from below to replace it. In this way the entire flow field making up the granulation is driven by the cooling at the photosphere. In fact, the flow field in the entire convection zone is probably a consequence mostly of this surface process. This is unlike the case of, for example, daytime convection in the troposphere, where thermals form by gas rising from the heated surface of the Earth. It is also different from laboratory convection where top and bottom surfaces of the container contribute equally to the production of convective flows. Heating from below plays such a minor role in the case of a stellar envelope because of the extreme stratification of density. At the base of the solar convection zone (at 200 000 km, or 30% of a solar radius below the surface), the density ρ is a million times higher than at the surface. The relative temperature excess $\Delta T/T$ in upward plumes generated at the base is also roughly a million times lower than at the surface. The acceleration of a convective flow, which is proportional to $g\Delta\rho/\rho \sim g\Delta T/T$, is therefore roughly a million times weaker at the base of the convection zone than at the surface.

In the granulation one thus observes the primary process of stellar envelope convection. The solar granulation can presently be reproduced with high fidelity with *ab initio* numerical simulations, which use only the equations of hydrodynamics, radiative transfer and the (large amount of) atomic physics of ionization and radiative processes. Other manifestations of convection

visible at the surface are flows on larger scales than granules: the mesogranulation, supergranulation and large scale flows (see SOLAR PHOTOSPHERE: MESOGRANULATION; SUPERGRANULATION).

Magnetic fields

Apart from the granulation, the main sources of structure seen in the photosphere are magnetic fields. In addition to the conspicuous sunspots, there are structures on smaller scales (see SOLAR PHOTOSPHERE: FILIGREE; FACULAE, and SOLAR PHOTOSPHERIC MAGNETIC FLUX TUBES), down to and probably well below to the resolution limit of current telescopes. The field strength in these structures can be measured through the Zeeman effect on spectral lines (see SOLAR MAGNETIC FIELD: INFERENCE BY POLARIMETRY). This is done most accurately in the infrared, where the Zeeman splitting is larger relative to the line width than in the visible. The field strengths found range from about 1000 G in the smallest structures to 3000 G in sunspots. At 1000 G, the magnetic pressure $P_{\rm m} = B^2/8\pi$ is 4×10^4 erg cm^{-3}, a significant fraction of the gas pressure P at $\tau = 1$, $P \approx 10^5$. Magnetic structures with such field strengths are therefore called 'strong fields'. (In addition to these strong fields, there is evidence for a less conspicuous weaker field component in the photosphere with strength of 300 G or less; see SOLAR PHOTOSPHERE INTRANETWORK AND TURBULENT MAGNETIC FIELDS.) The structures in this strong field component are sharply bounded: the normal photosphere in which they are embedded is only weakly magnetic, and the transition between the structure and its surroundings usually is sharper than can be resolved with current instruments.

Although all magnetic structures evolve in size and shape, the time scales for these changes are long compared with the time it takes a sound wave to cross their width. These structures are therefore approximately in pressure balance with their environment. This is possible only if the gas pressure inside the structures is less than in the surrounding photosphere, since the magnetic field exerts an additional pressure that has to be balanced. At the photospheric level, magnetic structures are thus confined by the gas pressure in their surroundings. The reduced internal pressure also makes the plasma more transparent, so that the photosphere is locally depressed inside the magnetic structures: they are dimples in the surface. This depression ranges from about 150 km in the smallest structures to 600 km in sunspots. In spots, the effect is large enough to cause an easily observable distortion (called *Wilson depression*, see figure 1 in SUNSPOTS: WILSON EFFECT) when they are seen near the solar limb. This effect also applies to small magnetic structures; they appear as little dimples in the surface. In the smallest elements of the magnetic field, the side walls of these dimples radiate extra heat from the hot subsurface layers, making them bright when seen near the limb of the Sun. Clusters of these elements make up the faculae.

Magnetic fields are most easily observed, through the Zeeman effect, in the photosphere. Field lines have no ends, however, and extend both above into the chromosphere and corona, and below into the convection zone. The magnetic patches seen as spots at the surface are only the intersections of this surface with three-dimensional magnetic structures. The rapid decrease of the gas pressure with height in the atmosphere means that, at a height of a only few hundred km above $\tau = 1$, the gas pressure is insufficient to confine a magnetic field of 1000 G. The magnetic structures adapt to this by expanding or 'fanning out' with height (figure 2). At a height of 500–1000 km, they have expanded so much that the fields of neighboring structures meet. Above this level (which depends on the average field strength, or 'degree of magnetic activity' of the photosphere), the entire atmosphere is magnetic. This situation applies to the higher atmospheric levels which one observes in the cores of strong spectral lines in the visible, such as H_α, as well as in all wavelengths longer than a few cm. These wavelengths probe the chromosphere and corona.

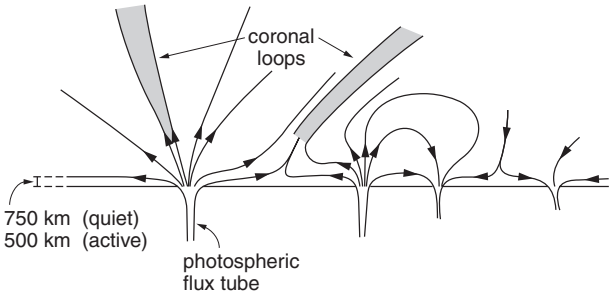

Figure 2. Vertical cross section through the solar atmosphere showing its magnetic structure (sketch). Below the surface, field lines are bundled into magnetic ropes with field-free convecting gas between; above the surface, the field lines fan out to occupy all available space. Sunspots are the locations where large magnetic ropes cross the surface.

The atmosphere as seen, for example, in H_α (figure 1 in CHROMOSPHERE: FIBRILS) looks very different from an image in the visible continuum: instead of granules the surface is covered with filamentary structures. These so-called fibrils trace field lines, much like iron filings around a bar magnet. In this magnetically dominated atmosphere the gas pressure is generally less than the magnetic pressure. Rather than being confined by the gas, the field here is in equilibrium with itself, with the magnetic pressure and tension forces balancing each other. The presence of the gas causes only small changes in the magnetic field: it is approximately force free. A familiar example of such a force-free field is the vacuum field (current-free field) around a bar magnet. A force-free field cannot exist entirely on its own: its internal stresses must be taken up at some boundary. In the case of the bar magnet, these stresses are taken up by the solid-state forces in the bar. In the case of the solar atmospheric magnetic field, the stress is taken up by the dense plasma in the convection zone into which the field lines are anchored (figure 2). In the atmospheric magnetic field, on the other hand, the motion of the gas is restricted. Flows along

the field lines are unimpeded, but strong Lorentz forces limit displacements perpendicular to the field lines. The transition from the gas pressure dominated interior to the magnetically dominated atmosphere of the Sun happens to lie roughly at the photosphere. This is a coincidence that applies to most stars with convective envelopes but not to some other stars, such as strongly magnetic A stars and white dwarfs.

Although the convection zone is of course far from solid, it is able to take up the magnetic stresses acting in the atmosphere by its large inertia. This inertia is conveniently expressed in terms of the Alfvén speed $v_A = B/(4\pi\rho)^{1/2}$, where ρ is the gas density. This is the speed at which bends in the field, for example imparted by convective flows, propagate along the field lines. At 1000 G (a typical field strength in small-scale magnetic structures), the Alfvén speed at photospheric densities is of the order 5 km s^{-1}, while the typical convective velocity is around 2 km s^{-1}. At a depth of only 10 000 km, the density is 2500 times higher, and the Alfvén speed at the same field strength is only 100 m s^{-1}. This is of the order of the convective velocities, or smaller. At these high densities, the convective flows can displace field lines faster than an Alfvén wave can react to restore the shape of the field lines. The flow then effectively carries the field around as an inclusion. At the low gas densities in the photosphere, on the other hand, the field lines at the same field strength of 1000 G behave much more 'stiffly' and to a large extent resist bending by flows.

Since the gas density is also lower inside the photospheric magnetic structures (because of the lower pressure), they are *buoyant*. The lower density makes them behave like 'tethered balloons': they follow the motion of their feet in the deeper layers but tend to stay vertical in the atmosphere. Small structures, and those with weaker fields, are more easily bent and displaced by flows than large structures such as spots. The strongest flows in the photosphere are those due to the granulation. Accordingly, the small-scale field is found almost exclusively in the intergranular lanes and the vertices between granules, where the horizontal flows converge. Large structures such as spots behave much more independently. For example, they are observed to form by coagulation of many small fragments, each of which finds its way to the spot under construction independently of, and often opposite to, the photospheric flow field (see SUNSPOT EVOLUTION).

In this way, the magnetic fields seen at the photosphere and their evolution are only very partially governed by local processes at the photospheric level. In order to interpret their observed evolution, one has to envisage the entire three-dimensional structure. This immediately raises the question at what depth inside the Sun one should locate the 'roots' of a spot or a small scale structure. Current understanding of the solar magnetic cycle puts the source of the magnetic field near the base of the convection zone. In this picture, the photospheric magnetic structures are connected to the base of the convection zone by approximately vertical fields. At the base of the convection zone, there is believed to be a layer of horizontal field which is the source of the magnetic fields seen at the surface. The appearance of a new ACTIVE REGION at the surface is an event that has lifted a bundle of fields lines from this layer and has made them loop up through the photosphere, like a stitch of yarn pulled from a woollen sweater. After the eruption of the active region, in this view, the connection between the surface manifestations, such as spots, and source layer is by approximately vertical field lines, as sketched in SOLAR INTERIOR: EMERGING MAGNETIC FLUX TUBES. Apart from disturbances due to the kicking and shoving around by flows in the convection zone, the evolution of the surface field might actually be an image of the evolution of its roots in the source layer.

The magnetic fields at the photosphere have a small effect on the brightness of the Sun (see SOLAR IRRADIANCE). Sunspots, being dark, cause a decrease in brightness, plage areas an increase. The areas outside plages and spots remain unaffected: the darkness of spots is not, for example, compensated by increased brightness of the nonmagnetic parts of the surface. This is understood theoretically as a consequence of the heat transport and heat storage properties of the concvection zone.

Solar Photosphere: Center-to-limb Variation

Many phenomena which are observable on the Sun's 'surface' change in characteristic ways between the center and LIMB of the apparent disk (e.g. the shapes of sunspots, the profiles of Fraunhofer lines, etc). The most obvious and easily noticeable (e.g. at sunrise or sunset, or on a good photograph) center-to-limb variation is the decrease of brightness from the disk center towards the limb. This so-called limb darkening is treated in the present article, in particular for wavelengths representing the continuous spectrum between the FRAUNHOFER LINES.

Limb darkening and angular distribution of radiation

Actually, limb darkening is a direct consequence of the fact that the intensity (I in W cm^{-2} ster^{-1}) of the radiation emerging from the photosphere depends on the angular distance (θ) from the direction of the solar radius (see figure 1). Ignoring any small- or large-scale structures of the photosphere (e.g. granulation, spots, faculae, etc), and a possible (but not yet clearly proved) dependence on heliographic latitude, we suppose here that the intensity I depends on r/R (or θ) only and exhibits at any time an exact rotational symmetry. In other words, in this article the intensity distribution across the solar disk is treated as an ideal smooth function $I = I(r/R)$ (see figure 2), which can be approximated by one or other mathematical formulae and which represents then the average for the whole disk and for an appropriate interval of time (e.g. near the minimum of solar activity).

The wavelength dependence of solar limb darkening

The decrease of intensity towards the Sun's limb depends on wavelength λ (unit nm). If special exceptions are ignored, the dependence follows the rule that the shorter the wavelength the stronger the decrease. This rule is illustrated in figure 2, which displays the center-to-limb variation of the intensity I_λ (unit W cm^{-2} ster^{-1} nm^{-1}) for two wavelengths, one in the UV (λ = 350 nm) and one in the infrared (λ = 950 nm). For both wavelengths, I_λ is shown as a function of r/R (limb-darkening 'curves') and of θ as well. As a consequence of the λ rule, also the color of the Sun's disk exhibits a center-to-limb variation: it reddens from the center towards the limb (see also SOLAR PHOTOSPHERE: THE LIMB EFFECT AND GRAVITATIONAL REDSHIFT).

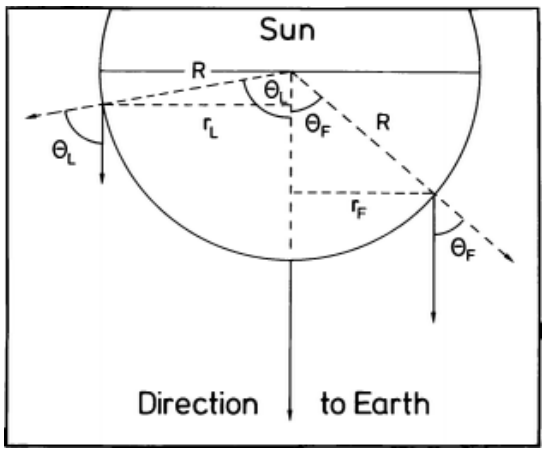

Figure 1. Geometric relations. R = angular radius of apparent solar disk as viewed from Earth (16'16" in early January, 15'44" in early July), r = angular distance of observed surface element from center of disk, θ = angle at solar 'surface' between the normal at position r and the direction towards the Earth. Two special cases are shown: suffix F refers to the position where the intensity equals the average disk intensity ($\theta_F \simeq 50°, r_F/R \simeq 0.76$), suffix L to a position about 14" from the limb ($\theta_L = 80°, r_L/R \simeq 0.985$). One notes easily that $r/R = \sin\theta$.

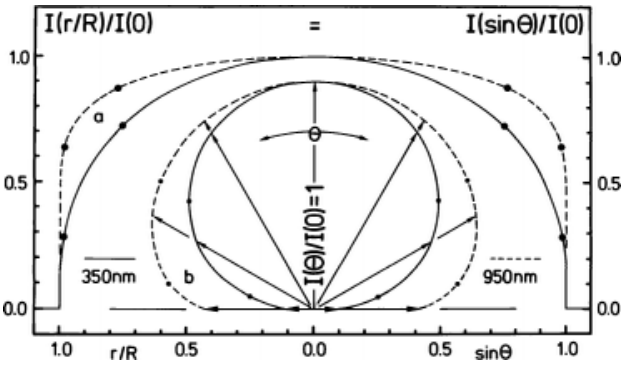

Figure 2. Solar limb darkening for λ = 350 and 950 nm from observations made with the McMath–Pierce Solar Telescope of Kitt Peak National Solar Observatory in 1975/76 and in 1986/87. (*a*) $I_\lambda = I_\lambda(r/R) = I_\lambda(\sin\theta)$; (*b*) $I_\lambda = I_\lambda(\theta)$ (for θ = 0°, 30°, 60°, 90°). In both cases the intensities are normalized to the disk-center intensity: $I_{350}(0) = 3.35$, $I_{950}(0) = 1.41$ W m^{-2} ster^{-1} nm^{-1}. The full circles refer to the positions specified in figure 1 ($\theta_F \simeq 50°$, $\theta_L = 80°$).

The reason for solar limb darkening and limb reddening

Usually, the intensity (I_λ) of the radiation from any homogeneous, hot, solid or fluid surface of uniform temperature T (unit K) does not depend on the angular distance (θ) from the direction perpendicular to the surface: the brightness of such a surface does not depend on the angle from which it is viewed. In this case, the intensity (I_λ) for any direction (θ) is simply given by the

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

product $e_\lambda B_\lambda(T)$, where e_λ denotes the (dimensionless) emissivity of the surface material ($e_\lambda \leq 1$) and $B_\lambda(T)$ the intensity given by the Planck law of radiation; $B_\lambda(T)$ is a universal function with λ and T as the only essential parameters (unit W cm^{-2} ster^{-1} nm^{-1}); actually, $B_\lambda(T)$ also depends on the refractive index of (or on the velocity of light in) the medium (vacuum, air) where the radiation is observed or analysed.

But the radiation from the Sun is not emitted by a well-defined surface; instead, it emerges from a gaseous layer about 300 km deep, the so-called SOLAR PHOTOSPHERE. Inside this photosphere, almost all physical parameters depend on the depth t (unit m; counted from an arbitrary level 'zero'). For limb darkening two of these parameters are essential: the temperature T and the (continuous) absorption coefficient κ_λ (unit m^{-1}) (= fraction of radiation lost along a unit of length; roughly, the complement to the transparency). Note that κ_λ refers to the radiation between the Fraunhofer lines. Both parameters increase with increasing depth. κ_λ defines, together with the angle θ, the photospheric layers contributing the essential part of the emerging radiation, and the temperatures T define the amount of radiation emitted by these layers. The role of the angle θ may be inferred from figure 1: the larger θ, the smaller are the depths of the layers being relevant for the observed radiation. Noting that these depths vary (approximately) with cos θ, one realizes easily that limb darkening just reflects the decrease of temperature from the 'bottom' to 'top' of the photosphere. At the limb (r/R = 1, cos θ = 0), we receive of course only radiation from its highest layer (at level 'zero').

Recording the solar limb darkening

Measurements of solar limb darkening need a telescope yielding a solar image that is as large as possible (e.g. the McMath–Pierce Telescope of Kitt Peak National Solar Observatory; focal length $\simeq$87 m, diameter of solar image $\simeq$81 cm), a spectrometer to select the desired wavelength λ and a suitable detector (e.g. photomultiplier) plus electronic equipment. The observations are usually made by sampling the spectrometer output as the solar image drifts across the spectrometer entrance slit (telescope drive off, center of disk must pass the slit center!). The resulting 'drift curves', which then yield the intensity distribution along the solar diameter defined by diurnal motion, resemble of course the curves shown in figure 2(*a*); they yield the intensities of the Sun and of the (preceding and subsequent) skies in arbitrary units ('counts per second'), as a function of time (daily motion: 1 solar diameter in about 2.2 min).

However: the actual, individual drift curves differ from any 'true' mean distribution in two important aspects:

(a) The Sun's GRANULATION (and rare phenomena of solar activity) causes an appreciable 'noise' (standard deviation at 350 nm about 1.5%, at 950 nm 0.6%).
(b) Phenomena of the EARTH'S ATMOSPHERE (seeing, blurring, scattered light) and imperfections of the telescope (stray light) lead to systematic errors in the intensity signals, in particular near the Sun's limb. Also, imperfect electronics may cause small errors, but these can be avoided with special care (e.g. multiplier hysteresis).

For the reduction of the actual drift curves also the determination of the 'limb' positions is problematic. Even the true intensity cut-off at the limb is not perfectly sharp: the intensity drops exponentially within about 1". Thereby, the position of the steepest gradient (by definition the limb) depends on wavelength: at the local maximum of the continuous absorption coefficient near λ950 nm, the true solar radius is about 0.1" larger than at the minimum near 350 nm. Seeing and blurring not only cause considerably larger 'smearing' of the limb, but also lead to noticeable displacements of the 'limb inflection points'. Even for the averages of many drift curves these displacements don't cancel out completely: depending on both the size of the seeing (blurring) parameter and the shape of the drift curve, the solar radii are shortened systematically by amounts between about 0.05" (seeing parameter 1", $\lambda \simeq$ 950 nm) and more than 0.5" (3", $\lambda \simeq$ 350 nm).

Mathematical treatment of limb darkening observations

We don't discuss here the rather complex treatment of the intensity signals to account for the errors caused by the phenomena of the Earth's atmosphere and the instrumental imperfections. Supposing that the necessary corrections are made in one way or the other, the next and final step is then to fit a mathematical expression representing the limb darkening 'law' to the observed signals. Thereby one must realise that a theoretically reasoned, mathematical 'law' (comparable to, for example Planck's law of radiation, or the shape of a planetary orbit), does not exist *a priori*. Therefore, one has to find empirically a solution which fits the observations as well as possible, and, if possible, also fulfils special physical requirements.

In figure 3(*a*) the same two intensity distributions are plotted as in figure 2, but here versus μ = cos θ instead of r/R = sin θ. Both curves can be considered as being composed of two terms: a linear term $M(\mu) = m + (1 - m)\mu$ (note $m_{350} < m_{950}$), and a term $D(\mu)$ which represents the deviations from the linear relation. The characteristic behavior ($D(\mu) > 0$ except for $D(0) = D(1) = 0$; maxima between μ = 0.3 and 0.5) is found for all wavelengths

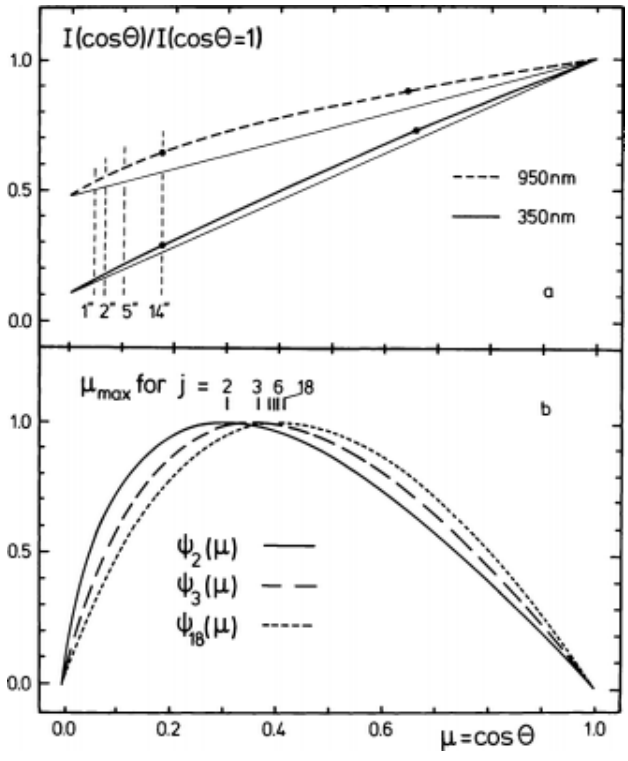

Figure 3. (*a*) Observed $I_\lambda(r/R)/I_\lambda(0)$ plotted versus $\mu = \cos\theta$ (heavy curves), from same data as in figure 2. Again, the full circles refer to the positions specified in figure 1. Vertical dashed lines indicate distances from the 'limb' of 1", 2", 5" and 14". Weak, straight lines indicate the linear relations $M(\mu) = m + (1-m)\mu$ defined by the intensities at the center ($\mu = 1$: $M = 1$) and 'limb' ($\mu = 0$: $M = m$) of the solar disk; thereby, the deviations $D(\mu)$ of the observed limb darkening from linearity are clearly noticeable. (*b*) Functions $\psi_j(\mu)$ which are the physically most reasonable functions to represent the deviations $D(\mu)$, shown for $j = 2$, 3 and 18; maximum positions are marked for $j = 2$ to 6 and 18. Note that maximum(ψ_j) = 1.00 for all j, and that μ(max) increases with increasing j from $\mu = 0.302$ for $j = 2$ to a limit near $\mu = 0.42$.

$\lambda > 330$ nm, while one finds for $\lambda < 320$ nm $D(\mu) \leq 0$, with shallow minima instead of lowly maxima. So, searching for the appropriate, mathematical relation which fits the observed limb-darkening curves, one must 'just' find a general relation which represents the terms $D(\mu)$.

The most reasonable relation approximates $D(\mu)$ by a series of very special (and more or less complex) mathematical functions, $\psi_j(\mu)$ ($j \geq 2$), which all have the same characteristics: $\psi_j(0) = \psi_j(1) = 0$, maximum ($\psi_j$) = 1.00. Three of these functions are shown in figure 3(*b*).

Accordingly, the most appropriate, empirical limb darkening 'law' is:

$$\frac{I_\lambda(\mu)}{I_\lambda(\mu=1)} = L_n(\mu) = c_0 + (1-c_0)\mu + \sum_{j=2}^{n} c_j \psi_j(\mu). \tag{1}$$

The meaning of the coefficients is clear: c_0 is a measure for the 'limb'-intensity and defines the linear term of the limb darkening function, and the coefficients c_j ($j \geq 2$) measure the maximum contributions of the functions $\psi_j(\mu)$ to the deviations $D(\mu)$. In practice it is sufficient to choose $n = 4$.

The functions $L_n(\mu)$ yield of course also the ratios between average disk intensity F_λ and disk center intensity $I_\lambda(\theta = 0)$, which are defined by equation (2):

$$F_\lambda / I_\lambda(\theta=0) = \frac{\int 2\pi r I_\lambda(r)\,\mathrm{d}r}{I_\lambda(0)\int 2\pi r\,\mathrm{d}r} = 2\int_0^{\pi/2} \frac{I_\lambda(\theta)}{I_\lambda(0)} \cos\theta \sin\theta\,\mathrm{d}\theta. \tag{2}$$

Specifying $n = 4$ and presenting just numerical values instead of the explicit, rather complex mathematical formula, the result following from relations (1) and (2) is:

$$\{F_\lambda/I_\lambda(0)\}_{L_4} = \tfrac{2}{3} + \tfrac{1}{3}(c_0 + 1.665c_2 + 1.764c_3 + 1.798c_4). \tag{3}$$

Now we recall that the intensity distribution across the Sun's disk depends on the vertical distribution of temperature (T) and (continuous) absorption coefficient (κ_λ) inside the Sun's photosphere. This dependency can be treated even exactly by using equation (4):

$$I_\lambda(\theta) = \{I_\lambda(\theta)/I_\lambda(0)\} I_\lambda(0) = \int_0^\infty B_\lambda(T(\tau_\lambda)) \exp(-\tau_\lambda/\mu)\,\mathrm{d}(\tau_\lambda/\mu). \tag{4}$$

Here, τ_λ is the optical depth of the layer with the geometrical depth t (m) below the level zero:

$$\tau_\lambda = \int_0^t \kappa_\lambda\,\mathrm{d}t. \tag{5}$$

Note that relation (4) describes the intensity $I_\lambda(\theta)$ of the observed radiation as the sum of all contributions from the 'visible' photospheric layers below the 'surface': implying local thermodynamic equilibrium, the contribution from the layer with temperature T is given by the intensity following from Planck's law of radiation, multiplied by a factor (<1) which accounts for the absorption along the light-path from that layer to the 'surface'; the length of this path is proportional to $1/\mu$ (further details are found in almost any relevant text-book; see, e.g. Minnaert (1954)).

Dirac House, Temple Back, Bristol, BS1 6BE, UK

In case of the limb darkening law presented by equation (1) it can be stated that it corresponds precisely to a well defined 'source function', $B_\lambda(\tau_\lambda)$:

$$B_\lambda(\tau_\lambda) = I_\lambda(0)\left\{k_0 + k_1\tau_\lambda + \sum_{j=2}^{n} k_j E_j(\tau_\lambda)\right\}. \tag{6}$$

where the E_js are the so-called exponential integral functions defined by

$$E_j(\tau) = \int_1^\infty [\exp(-t\tau)/t^j]\,dt \tag{7}$$

while the coefficients k_j are well defined functions of the coefficients c_j. Although the basic functions entering the solution ($\psi_j(\mu)$,$E_j(\tau)$) are rather complex (but present no problems in the PC era!), compared to other solutions they provide the important advantage that they don't lead to physically unrealistic structures in the limb darkening curves and—in particular—in the source function, which could be introduced by the natural scatter in the observations.

For example, if observed limb darkening curves are fitted by polynomials P_n in μ

$$I_\lambda(\mu)/I_\lambda(\mu = 1) = P_n(\mu) = \sum_{i=0}^{n} a_i \mu^i \tag{8}$$

as was usually done in the pre-computer era, then even slight errors in the coefficients a_i may cause large, unrealistic fluctuations in the corresponding polynomials representing then the source function:

$$B_\lambda(\tau_\lambda) = I_\lambda(0)\sum_{i=0}^{n} A_i \tau_\lambda^i \qquad \text{with } A_i = a_i/(i!). \tag{9}$$

In particular, in this case the source function also does not have the correct asymptotic behavior for both $\tau\to\infty$ and $\tau\to 0$. But observational scatter does not harm the resulting ratios of average to disk center intensity:

$$\{F_\lambda/I_\lambda(0)\}_{P_n} = 2\sum_{i=0}^{n} a_i/(i+2). \tag{10}$$

Wavelength dependence of the limb darkening coefficients (c_j)

Once any functions like those defined by equations (1) or (8) have been fitted to limb darkening observations made at many different wavelengths, the λ dependence of the coefficients (c_j,a_i) can be analysed. However, it seems that reliable results are obtained only if (a) the observations were made in a relatively short time interval (about 1 month; possibly near the minimum of solar activity), and (b) the data were fitted by curves defined by equation (1). Only very recently (1997) could it be shown (by means of data obtained in 1986/87 in two four-week observing seasons), that in this case the coefficients (c_j) of the limb darkening functions (L_4) and the corresponding function $\{F_\lambda/I_\lambda(0)\}_{L4}$ depend on λ in a very obvious, simple way:

$$c_0 = c_{00} + c_{01}\lambda^{-1} \tag{11a}$$

$$c_j = c_{j0} + c_{j1}\lambda^{-5} \qquad \text{for } j = 2,\ 3,\ \text{and } 4 \tag{11b}$$

$$F_\lambda/I_\lambda(0) = f_0 + f_1\lambda^{-1} + f_2\lambda^{-5} \tag{12}$$

with—according to relations (3) and (11*a*,*b*) —

$$f_0 = \tfrac{2}{3} + \tfrac{1}{3}(c_{00} + 1.665c_{20} + 1.764c_{30} + 1.798c_{40}) \tag{13}$$

$$f_1 = \tfrac{1}{3}c_{01} \tag{14}$$

$$f_2 = \tfrac{1}{3}(1.665c_{21} + 1.764c_{31} + 1.798c_{41}). \tag{15}$$

The good definition of these functions is demonstrated in figure 4, which exhibits the λ dependence of c_0 and of $F/I(0)$. Different sets of coefficients must of course be used for the spectral regions 'left' or 'right' from the Balmer 'jump' (at $\log\lambda \simeq 2.6$). Another obvious peculiarity is the 'bump' at $\log\lambda \simeq 3.2$ ($\lambda \simeq 1650$ nm); it is due to the minimum of H^- absorption between the spectral regions with bound–free and free–free transitions.

Possible variations of solar limb darkening

Usually, the coefficients of published limb darkening functions show—when plotted against λ—a considerable scatter, which prevented realistic fits by handy functions in the past. In this respect one should realize that there are no sets of limb darkening data which come from just one short-term 'snapshot'.

The usual observing procedure (wavelength after wavelength, day after day, some observing campaigns extending even over months or years) necessarily yields results which are influenced by all sorts of variable phenomena. In particular, in the case of the polynomials

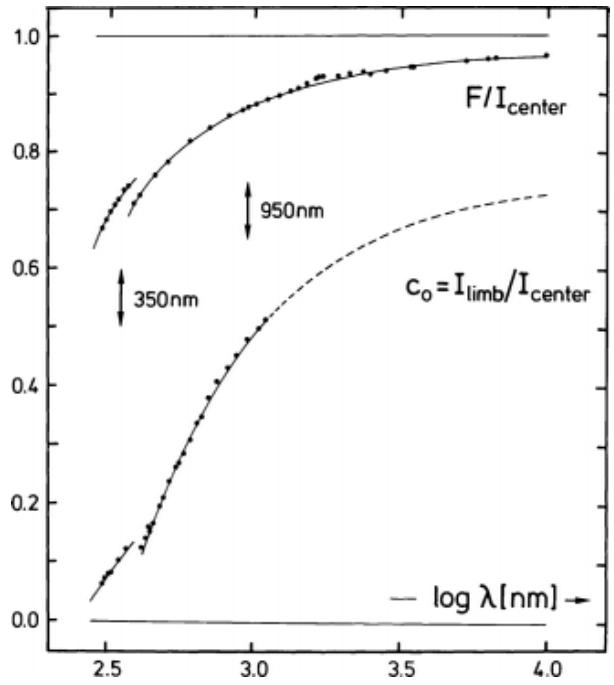

Figure 4. λ dependence of the coefficient c_0 and of the ratio $F/I(0)$ in the case of the limb darkening function L_4; c_0 from observations made in two 1 month seasons in 1986 and 1987; the smoothing functions are: $c_0 = 0.400-103\lambda^{-1}$ ($\log \lambda < 2.6$), and $c_0 = 0.756-268\lambda^{-1}$ ($\log \lambda > 2.6$, for $\log \lambda > 3.04$ extrapolated). $F/I(0)$ adopted from a compilation of 14 independent observations published from 1946 to 1983 ($\log \lambda \leq 3.38$), and from a recent paper published in 1996 (log;$\lambda > 3.38$); the smoothing functions are: $F/I(0) = 0.861-34\lambda^{-1}-18.10^{10}\lambda^{-5}$ ($\log \lambda < 2.58$) and $F/I(0) = 0.975-91\lambda^{-1}-24.10^{10}\lambda^{-5}$, ($\log \lambda > 2.58$). Arrows mark the two wavelengths with data in figures 2 and 3(*a*).

$P_n(\mu)$ (e.g. with $n = 5$), even minor variations in the true intensity distribution (granulation!) may cause large responses in the coefficients a_i. But different signs lead here to an almost complete compensation in the corresponding λ plots of $I(\mu)/I(0)$ and $F/I(0)$.

However, a significant scatter was also found in λ plots of the coefficients c_j of the functions L_3, which resulted from observations obtained over long periods of time (months, years). This is possibly a hint that even the 'average' solar limb darkening may be slightly variable in time, with time-scales larger than a month. The fact that also in this case the scatter of the coefficients c_j is not transferred to the λ plots of the corresponding ratios $F/I(0)$ would then indicate that limb darkening variations occur in such a way as to leave these ratios nearly constant.

Other hints for possible limb darkening variations come from special, systematic searches. But the question of whether the observed effects just reflect well-known characteristics of the solar photosphere (random fluctuations in distribution, size and brightness of the granules, variable structure of the supergranulation network, all sorts of oscillation patterns, intensity excesses of deficits connected to active regions), or do indicate occasional variations of the temperature distribution in the upper photosphere, cannot yet be answered definitively.

Solar Photosphere: Faculae

Photospheric faculae, often called white-light faculae, are best seen away from the center of the solar disk beginning at a heliocentric angle of about 60°. They appear as irregular bright patches whose contrast increases towards the solar LIMB, and are more extensive when they accompany sunspot groups. Near the limb they tend to appear as facular granules. The facular granules consist of aggregations of mostly vertical magnetic flux tubes.

Figure 1 shows half of a photometric image obtained on 1 July 1998 at a wavelength of 672.3 nm using a filter with a bandwidth of 10 nm. The limb darkening of the quiet sun has been removed to show more clearly the increasing contrast of the faculae as the limb is approached. The patchy or intermittent nature is obvious.

Faculae consist of magnetic flux tubes with a typical magnetic field strength of approximately 1.5 kG. Magnetograms of facular regions usually do not resolve these flux tubes and the observed magnetic field strengths depend on the filling factor and SEEING conditions at the time of observation.

The increasing continuum contrast of faculae with decreasing distance from the limb suggests an increasing temperature difference between faculae and the quiet sun. Models of facular flux tubes are unable to completely account for this steadily increasing contrast of faculae as the limb is approached. The contrast of faculae increases toward the limb for continuum wavelengths as well as for many absorption lines that are formed well below the temperature minimum. When viewed in the center of absorption lines, faculae are seen all across the solar disk in a photospheric network. Faculae seen near the limb in white light are morphologically identical to those seen in absorption lines. This behavior suggests that the appearance of faculae at different wavelengths and different positions is due to an interplay of geometry and thermal structure of the individual flux tubes.

Figure 2 shows the observed contrast of faculae from several sources (see Chapman 1994 for references). The scales are affected by the differing spatial resolution of the observations. Some progress in untangling the effects of filling factor on the contrast has been made by the Lockheed solar group by sorting their observations of facular contrast against the observed magnetic flux.

The source of the excess emission is not well understood. The emission appears to be a combination of the 'hot-wall' effect and an elevated temperature in the upper photosphere. The hot-wall effect is caused by the deeper layers of the photosphere shining through the partially evacuated flux tube (see SOLAR PHOTOSPHERIC MAGNETIC FLUX TUBES: OBSERVATIONS for more details). It has even been suggested by Stenflo and others that electric currents could be responsible for heating of the flux tubes.

Faculae and sunspots both contribute significantly to variations in the total solar irradiance which is the amount of energy reaching the Earth. Sunspots produce the largest short-term decrease because of their high contrast.

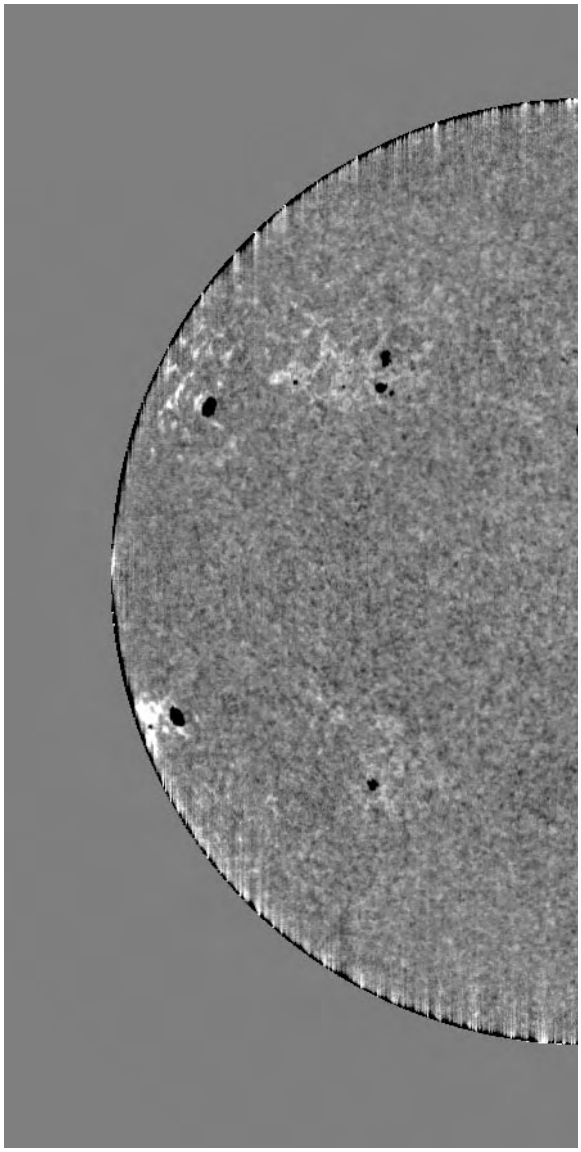

Figure 1. Photometric half-image of the Sun at 672.3 nm with a 10 nm bandpass filter on 1 July 1998. Facular contrast, seen with broad-band filters, increases towards the limb. This increase is especially notable between the limb and the sunspot near the lower left limb. Limb darkening has been removed to more clearly reveal the presence of faculae. Pixel size is 2.5 arcsec.

However, because faculae have a much larger area (at least a factor of 15 larger than sunspots) they make a positive contribution to solar irradiance variability that is approximately the same magnitude as the negative contribution of sunspots (Chapman *et al* 1996).

Figure 3 shows the change in facular area during the descending part of solar cycle 22 and the beginning phase of solar cycle 23. The data are from the Cartesian Full Disk Photometric Telescope No 2 (CFDT2), which has square pixels with a size of 2.5 arcsec. Both filters are near the

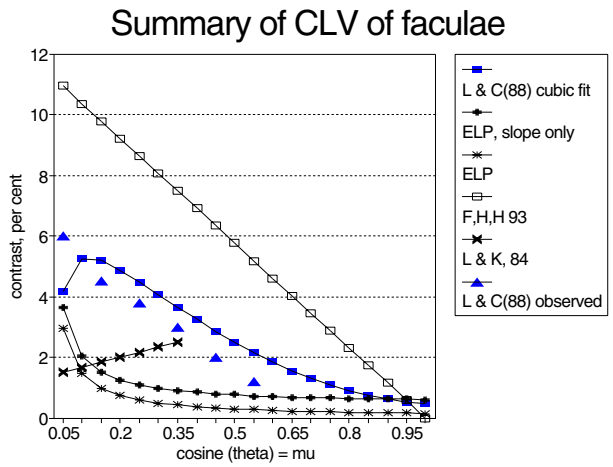

Figure 2. Facular contrast from a variety of sources versus μ. The vertical scale has not been adjusted for the different filling factors of the observations.

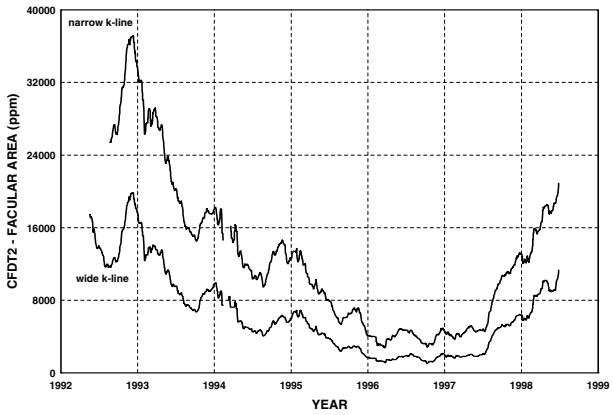

Figure 3. Facular area as measured with the Cartesian Full Disk Photometric Telescope, no 2. The narrow K line area was measured with a 0.3 nm bandpass filter. The wide K line area was measured with a 1 nm bandpass filter.

center of the calcium K line at 393.5 nm. The narrow filter has a bandwidth of 0.3 nm and the wide filter has a bandwith of 1 nm. One can see that the detected area of faculae is strongly dependent on the bandwidth of the observations. The areas shown here are much greater than one would detect in white light.

White-light faculae near the limb are morphologically identical to the photospheric network seen in absorption lines. However, the faculae seen in absorption lines have a higher contrast than white-light faculae. The identical morphology near the limb shown by Wilson supports the view that both thermal structure and geometry determine the appearance of faculae at different positions and different wavelengths. Above the photosphere, the field lines expand in the chromosphere, and the contrast increases in selected wavelengths. If there is a large concentration of flux, such as in an ACTIVE REGION, the area is called a PLAGE when seen in the light of strong FRAUNHOFER LINES.

The lifetime of an individual facula is not well established as it depends strongly on the spatial resolution of the observation as well as the evolution of the individual magnetic flux tubes that make up the facula. At moderate resolution, the lifetime is of the order of tens of hours but at higher resolution away from the solar limb (where foreshortening is less) the lifetime is less, from minutes to tens of minutes as smaller elements such as filigree and bright points are seen (see SOLAR PHOTOSPHERE: FILIGREE). Unfortunately, the determination of the lifetimes of individual faculae is difficult because the flux tubes can move and merge as the granulation buffets them (see SOLAR PHOTOSPHERE: GRANULATION).

Models of facular flux tubes have been reviewed by Spruit *et al* and have been compared with observations by Grossman-Doerth *et al* (1994) and, more recently, by Topka *et al* (1997) who conclude that a high contrast very near the solar limb requires something besides emission from hot walls.

Solar Photosphere: Filigree

The SOLAR FILIGREE (figure 1) is a pattern of strings of small bright points, visible in the SOLAR PHOTOSPHERE located in the dark lanes which separate granules. Its origin is magnetic, and each bright point is the site of a magnetic flux tube (see the fourth section). The solar filigree was first observed in the wings of the Hα line at 6563 Å, at the Sacramento Peak Observatory, in 1972, by Dunn and Zirker (1973).

The pattern is found in the quiet Sun (at the boundaries of the supergranular cells, where it forms the so-called photospheric network), as well as in ACTIVE REGIONS, where it corresponds to the photospheric faculae, visible near the LIMB as bright extended PLAGES. In active regions, they often form rings, 2–3″ in diameter, which surround a single or a few granules.

The bright points forming the filigree are very clearly visible in wideband (about 10 Å) filtergrams taken in the Fraunhofer G-band lines of the CH molecule, centered at 4307 Å, where they appear much brighter than the surrounding granules (Muller 1985). They can also be seen in white-light images, but with a lower contrast. The difference of contrast observed in G-band (or Hα) filtergrams and in white-light images is due to the fact that the light comes from different layers in the photosphere: G-band filtergrams are formed in upper layers, near the middle of the photosphere, where the difference of temperature between the filigree elements and the surrounding atmosphere is larger than in deeper layers.

Size and shape

Although a majority of bright points forming the filigree are nearly circular, many of them are significantly elongated. One does not find bright points larger than 0"6 (450 km). Their size distribution has a peak at 0"3 (220 km) at λ 4307 Å and at 0"33 (240 km) at λ 5750. It must be noted, however, that the size distributions have been obtained with the finite resolution of 50 cm telescopes, which means that a much larger number of bright points of size smaller than 0"3 could be revealed by larger telescopes, and that the lower size limit is still unknown.

Brightness

The brightness of the real bright points is not well known either, because they are so small that they are strongly blurred by the finite size of the telescope, even when the seeing degradation is negligible. The fact that they are embedded in dark lanes makes the situation even worse: their contrast drops to zero for a resolution of 0"4. In white light, at 5750 Å, their brightness is, on average, 1.08 times the brightness of the mean photosphere, when the observation is made with a 50 cm telescope; maxima of 1.25 are measured for the brightest points. The mean relative brightness increases toward the limb, and reaches a maximum of 1.25 at $\mu = \cos\theta = 0.25$; closer to the limb, it decreases. The brightness, corrected for the finite size of the telescope, is 1.25 at the solar disk centre and 1.40 at $\mu = 0.25$.

In the G-band, which is formed higher in the atmosphere, the contrast is larger: it is 1.30 at the disk center, relative to the surrounding photosphere; this value is not corrected for blurring. For more details about the filigree bright points contrast, see the review by Muller (1994).

Dynamics of filigree bright points

The filigree bright points are always constrained to stay in the intergranular lanes, by converging granular flows. Because of this strong interaction with the dynamic and energetic granules, they are very unstable: their timescale is of the order of the lifetime of granulation (typically 10 min) and they often split and merge (see SOLAR PHOTOSPHERE: GRANULATION). However, they usually first appear in a relatively wide dark space at the junction of several converging granules. It thus seems that converging granules concentrate the magnetic flux into a flux tube of small cross section and high field strength, giving rise to a bright point. The maximum brightness is reached after 4 to 5 min, on average. The mean lifetime is about 10 min, but a few bright points can be identified for nearly one hour.

They are continuously buffeted by the moving expanding granules to speeds reaching several kilometers per second. Such large velocities reflect, in fact, the expansion rate of granules.

The magnetic origin of filigree bright points

The filigree bright points are closely associated with the small-size magnetic elements visible in high resolution magnetograms: each point is spatially associated to a magnetic element, which has nearly the same size. However, the magnetic elements do not always show up as a brightening, suggesting that the magnetic flux is more stable than the bright points, which may correspond to occasional flashes. The bright points are believed to be cross sections of nearly vertical magnetic flux tubes of field strength 1–1.5 kG, which extend from the top of the convection zone to the CORONA, through the CHROMOSPHERE and the TRANSITION REGION. Flux tube diameters are smaller than 400 km at the photospheric level; they expand upward. In the models, simplified flux tubes are considered, with sharp walls separating the magnetic plasma inside, from a magnetic-free atmosphere outside. The magnetic configuration of a real flux tube is certainly more complex (see SOLAR PHOTOSPHERIC MAGNETIC FLUX TUBES).

The flux tubes are in quasi-static equilibrium; consequently, the existence of a magnetic pressure makes the gas pressure inside the field smaller than outside: the tube is partly evacuated. Because of the lower density inside, the gas is heated by the hotter atmosphere outside, through the walls, on the one hand, and one sees deeper layers on the other hand: the combination of these two effects makes the magnetic elements appear brighter than the surrounding atmosphere. The more the field is concentrated, the more it is shining. In fact,

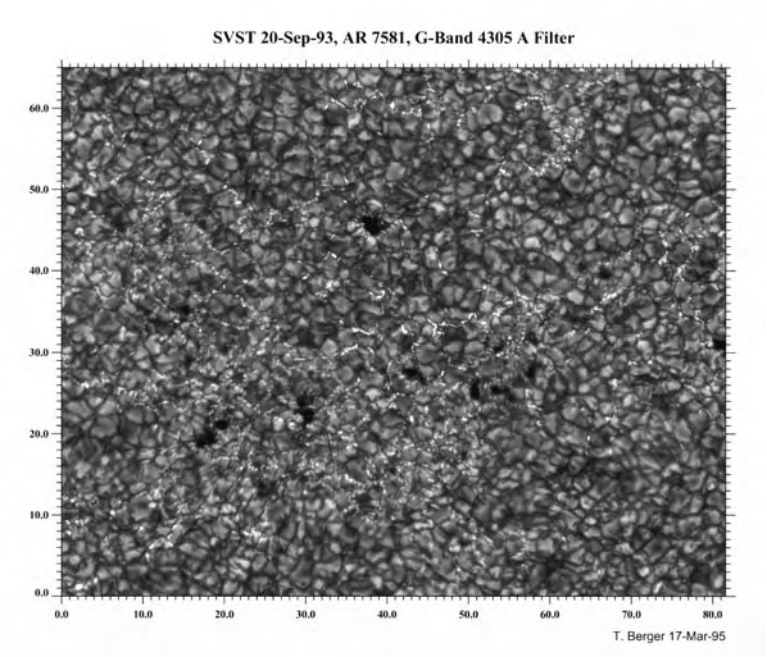

Figure 1. The solar filigree visible against the granulation pattern in a 4305 Å G-band filtergram of an active region; it is formed with more or less elongated bright grains located in intergranular lanes. Tickmarks are arcseconds. The filtergram was taken with the Swedish Vacuum Solar Telescope at La Palma, Canary Islands (courtesy of T Berger and the Lockheed Palo Alto Research Laboratory).

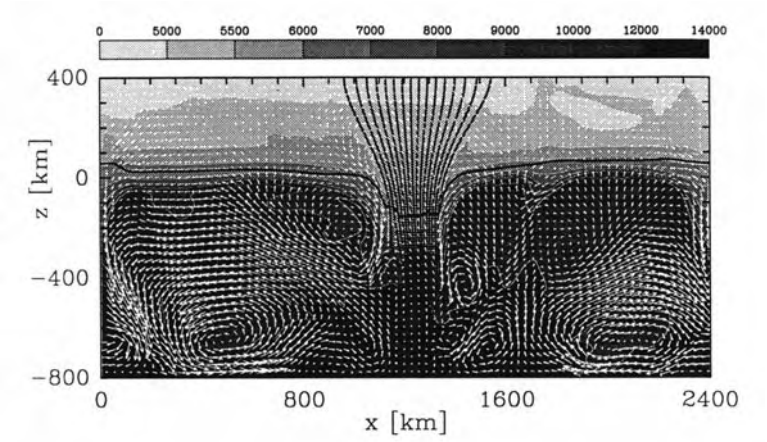

Figure 2. A schematic presentation of a nearly vertical magnetic flux tube, crossing the surface of the Sun (from a two-dimensional theoretical model computed by Steiner *et al* (1998)). The vertical lines represent the magnetic field lines. The horizontal line is the surface of the Sun, separating the convection zone below from the photosphere above. The white short vectors represent the convective flows, corresponding to granular cells. The gas pressure is lower inside the tube than outside; it is heated by the radiation from the hot, non-magnetic, atmosphere surrounding the tube. A filigree bright point corresponds to the cross section near the surface of the Sun, of a nearly vertical magnetic flux tube.

some observational details like the non-exact coincidence between the location of bright points and magnetic elements, or like the non-exact coincidence between the time of maximum brightness and of maximum field strength, is better explained with dynamical rather than static models (Steiner *et al* 1998). The rapid evolution and structural changes also demonstrate, of course, that the magnetic flux tubes are not static.

The physical origin of the magnetic flux tubes is still unknown: are they formed locally by some mechanism at work near the surface, and destroyed within a short time interval, or are they small fragments of SUNSPOTS, pulled out by convective flows, and spread over the surface of the Sun by large-scale convective motions ? But, whatever

Dirac House, Temple Back, Bristol, BS1 6BE, UK

the formation process may be, it seems that the magnetic flux, which is of the order of 10^{17}–10^{18} Mx, is temporarily concentrated into a flux tube, visible as a small bright point in high resolution filtergrams, by the compression of converging granules; during this phase it is visible as a filigree bright point.

Filigree bright points, magnetic flux tubes and the heating of the solar corona and chromospheric features

The bright points visible in high-resolution filtergrams are used to track the chaotic motion of magnetic flux at the surface of the Sun. Magnetic waves, transverse to the magnetic field, are generated by these motions in the top of the convection zone (see SOLAR INTERIOR: CONVECTION ZONE), and propagate upward, through the chromosphere, the transition region and the corona, with an exponential growth of the amplitude. The dissipation of this energy (various kinds of dissipation processes have been proposed) may heat the solar corona and some chromospheric features as well.

Distribution at the surface of the Sun

Filigree bright points are found everywhere, in SOLAR ACTIVE REGIONS as well as in the quiet sun, where they are concentrated at the boundaries of supergranules by the convective supergranular flows, forming the photospheric network. Further, the density (number of bright points by surface unit) of the network is not uniform at the surface of the Sun: it is minimum at the sunspot belt latitudes (where the filigree is present mainly in active regions) and maximum at the poles. Polar faculae consist of bright point concentrations (see SOLAR PHOTOSPHERE: FACULAE). The surface distribution is not constant in time: it varies with an 11 y period. More precisely, the density at the equator and at the poles varies almost in antiphase to the sunspot number, with a 1–2 y shift.

The size and field strength histograms of the observed bright points in the network are narrow; this means that each bright point carries nearly the same amount of magnetic flux, of the order of 2.5×10^{17} Mx. The spatial density of bright points is thus equivalent to a magnetic flux, and their spatial and temporal variations reflect magnetic flux variations in the quiet atmosphere of the Sun. Neither this weak network flux, corresponding to the very quiet Sun, nor its time variation are detectable with conventional full disk SOLAR MAGNETOGRAPHS.

Solar Photosphere: Granulation

Under good atmospheric seeing conditions observations of the Sun's surface with a telescope of at least 30 cm aperture reveal a rugged or polygonal pattern of bright elements separated by darker lanes that form an interconnected network; this pattern is called GRANULATION and was first described by Sir William Herschel in 1801. The granulation represents the top of the solar convection zone (see SOLAR PHOTOSPHERE), where hot gas rises to the surface, cools by radiation and sinks back into deeper layers. The observed size of granules ranges from approximately 150 km (the observational limit of ground-based telescopes) to approximately 2500 km, with 1.3×10^6 km^2 mean cell area of the granular elements including one-half of the surrounding dark lanes. The root-mean-square contrast of the granular pattern, after correction for degradation by telescope, stray light and seeing, is about 13% at a wavelength of 550 nm. Horizontal and vertical motions measured in granules and intergranular lanes are of the order of 2 km s^{-1} peak to peak. Granules change their shape and identity on time scales of 8–16 min; they evolve mainly by expansion, fragmentation, merging or dissolution. Numerical simulations of convection at the solar surface are capable of predicting many details of the granular structure (horizontal and vertical velocity, temperature and size distribution, evolution, vorticity etc) that agree rather well with the observations—one has to keep in mind, however, that the smallest structure of the models is not accessible to observation.

Observations of the granulation

Ground-based observations of the solar granulation (see SOLAR TELESCOPES AND INSTRUMENTS: GROUND) are hampered by two basic effects: the limited resolution of the telescopes employed and the image degradation due to refractive index inhomogeneities in the terrestrial atmosphere called SEEING. An order-of-magnitude consideration illustrates the difficulties. A telescope of $D = 60$ cm aperture, working at $\lambda = 500$ nm under diffraction-limited conditions, offers a resolution, defined as $r = 1.22\lambda D^{-1}$, of 0.21 arcsec or 150 km on the Sun. This means that, because of the telescope's optical modulation transfer function, the contrast of features of 0.2 arcsec extent is reduced by a factor of order 10. Any optical aberration in the telescope increases this factor. Moreover, daytime atmospheric conditions usually limit the attainable resolution to values larger than 1 arcsec. Only the combination of carefully selected sites with optically nearly perfect telescopes and refined observing techniques, such as real-time frame selection or speckle interferometry (see INTERFEROMETRY: GROUND), makes quantitative studies of the granulation down to the smallest scales possible. Only a few telescopes in the US (Sacramento Peak), France (Pic du Midi) and Spain (Canary Islands) are capable of doing such work. Figure 1 shows the granular pattern observed with speckle interferometric techniques; here details of approximately 150 km diameter can be studied.

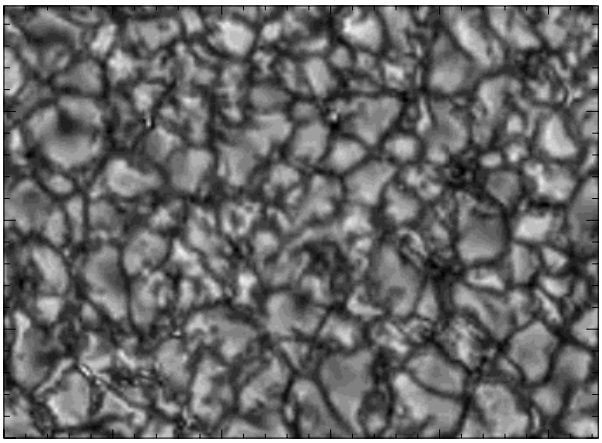

Figure 1. Solar granulation at disk center, observed with the German Vacuum Tower Telescope (VTT) at the Observatorio del Teide (Tenerife), and restored with speckle interferometric techniques by V Wilken and coworkers (Göttingen) 1997. Field of view 20×14.5 Mm^2.

Size distribution, shape and structure of the granulation

The solar granulation represents a continually changing pattern on the Sun. Nevertheless, most observers select individual granules for further study; to this end different algorithms are applied (cf Muller 1999). One consists of a combination of high-pass and low-pass filtering in the spatial frequency domain with subsequent thresholding close to the mean photospheric intensity; this defines iso-intensity contour lines and thus segments the image into granules and intergranular lanes. Alternative procedures are 'lane-finding' schemes (cf Spruit *et al* 1990), algorithms based on local gradients of the intensity, or the determination of the intensity inflection points which mark the edges of granules. As an example, figure 2 gives the size distribution of granules derived with the latter technique. The smallest granules, near the observation limit, here 0.4 arcsec or 290 km on the Sun, are the most frequent ones with a slow decline in number up to a diameter near 2 arcsec, and a subsequent rapid decline towards the largest granules. Counting the number of granules per unit area on the quiet Sun, different authors arrive at similar values: on average a granule with the surrounding half of the intergranular lane covers 1.3×10^6 km^2; this is called the mean cell area.

Intensity contrast and temperature fluctuations

The best images taken from the ground exhibit a root-mean-square intensity contrast (without correction for the telescope point spread function and scattered light) of $\simeq$10.7% at $\lambda = 468 \pm 5$ nm. Contrasts of up to 8–9% rms have been measured at 570 nm. After correction for the above-mentioned effects, values between 11% and 20% were obtained. Conservative estimates, e.g. from speckle-reconstructed images like figure 1, arrive at a contrast around 13% at 550 nm. This would correspond to rms

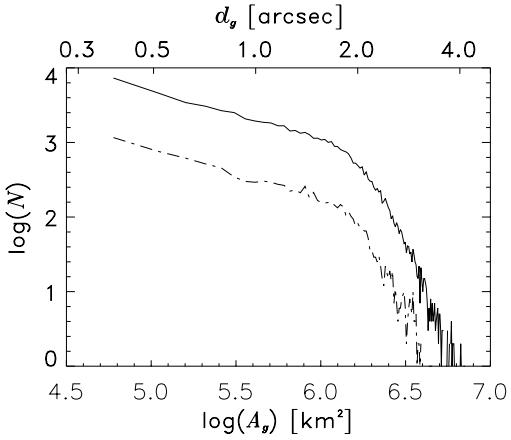

Figure 2. Plots of the granular areas and diameters published in 1997 by J Hirzberger and coworkers (Graz, La Laguna, Ondřejov). Full line, whole sample of 61 138 granules; dash-dotted line, 9656 granules from images with granular contrasts $\Delta I_{\rm rms}/I > 5.5\%$.

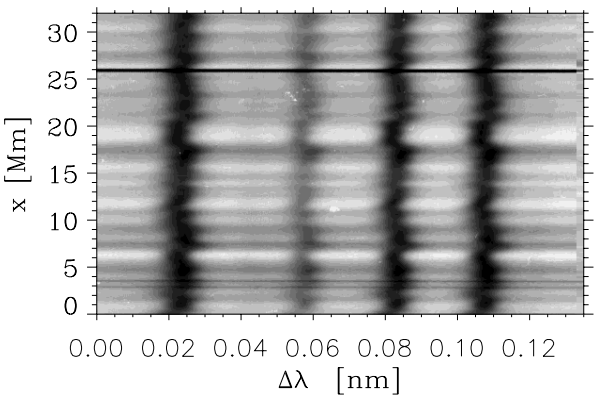

Figure 3. High-resolution slit spectrogram taken with the German VTT at Izaña (Tenerife). The weak line near $\Delta\lambda = 0.057$ nm is the Fe I line at $\lambda = 491.15$ nm. Note the strong blueshifts in the granules (bright horizontal streaks) and the redshifts, frequently connected with line broadenings, in the intergranular lanes. First published in 1996 by A Nesis and coworkers (Freiburg).

temperature fluctuations of order 200 K; according to a rule of thumb the peak-to-peak differences are 3 times larger, i.e. 600 K (see also figure 4).

On the other hand, numerical models predict temperatures around 10 000 K for the granular upflows and of 6000 K for the intergranular downflows, if one refers to the same geometrical depth level near the surface. Why does one not observe this? The reason is the very high temperature sensitivity of the H^- opacity ($\propto T^{10}$): at the same optical depth ($\tau = 1$) the temperature fluctuations are much smaller than at the same geometrical levels. Additionally, the limited spatial resolution of the observations plays a role.

Evolution, lifetime and horizontal proper motions

The study of granular evolution and lifetime requires time series of high spatial resolution that are available from space, e.g. from the Solar Optical Universal Polarimeter (SOUP) instrument on Spacelab 2, or from exceptional ground-based observations (cf Brandt and Wöhl 1998). Granules evolve in several different ways. Frequently they expand and split into smaller components that drift apart, thus forming an exploding granule. The fragments may in turn grow and fragment, or merge with others; shrinking and dissolution of granules are also observed. Again, the numerical simulations help us to understand the basic physics behind this: when a fluid parcel approaches the solar surface, radiative cooling carries away its energy; in a few tens of seconds the density increases above that of its surroundings. Then the vertical motion is decelerated and diverted horizontally. Further cooling lets the density grow further, and finally gravity pulls the parcel back down in the lanes between granules. This whole process takes several minutes.

Experimentally determined values of the granular lifetime depend on the method used. If the intensity pattern is autocorrelated, then (after removal of oscillatory intensity variations) lifetimes around 8 min are obtained; here, lifetime is defined as drop to $1/e$ of the autocorrelation function. If individual granules are followed throughout their evolution, then visual identification schemes yield a mean lifetime of approximately 16 min (with a standard deviation $\simeq$5 min), whereas objective algorithms again give values of 8–10 min. The reason for this large discrepancy is not clear; on the other hand it should not be taken too seriously, since each identification scheme involves some arbitrariness of the definitions: e.g. when two granules merge, which of the predecessors 'continues to live'?

An important feature of granular evolution is the horizontal proper motion of granules. It can be determined by local correlation tracking, a method that searches for the best spatial correlation in small subfields of consecutive granulation pictures. With this method a larger pattern of 4000–8000 km mesh width was found, the mesogranulation (see SOLAR PHOTOSPHERE: MESOGRANULATION). In certain parts of the mesogranulation granules consistently move horizontally towards a common center (converging region) while in other parts diverging motions prevail; the typical speed of the horizontal motion is 0.5 km s^{-1}. The lifetime of the mesogranulation appears to be of the order of hours—but is not well established yet. There are indications that some properties of granules, such as area, brightness, lifetime and expansion or shrinking rate, depend on their position in the mesogranular field.

Vertical and horizontal velocities

At photospheric levels and above the whole Sun is covered by a pattern of oscillatory elements with vertical

amplitudes of several 100 m s^{-1} and a wide range of sizes (see SOLAR INTERIOR: LOCAL HELIOSEISMOLOGY); these also show up as intensity oscillations. For studies of the granulation the effects of these oscillations have to be separated from the intensity and velocity variations of the granulation pattern. From high-resolution slit spectrograms taken at disk center (like the one shown in figure 3) one can measure the vertical velocity related to granular motion and obtain peak-to-peak values in the range 1.5–2 km s^{-1}, after removal of the velocity components due to the oscillation. The horizontal velocity components can be investigated by observations near the solar limb where they show up as line-of-sight velocities. In this way values are found that are a factor of $\simeq$1.5 larger than the vertical components.

The vertically ascending material does not stop its motion at the very surface but penetrates into higher layers owing to excess momentum; this is known as convective overshooting. Velocity measurements in lines of different strength reveal that the convective overshooting at granular scales extends several hundred km above the photosphere but the exact height dependence of the velocities is still not well established. Figure 4 shows an empirical model of an average granule derived from 2-dimensional spectroscopic observations of a large number of granules. An inversion technique was used to obtain the height dependence of temperature, density and line-of-sight velocity; horizontal velocities were derived from mass conservation considerations. Between the upflow in the center of the granule and the downflow in the intergranular lane there is a velocity difference of $\simeq$2 km s^{-1}; also the decrease of velocity with height is clearly visible from this figure. At height levels below 140 km, upward velocity is correlated with higher temperature near the granule center, which implies upward transport of energy, and lower temperature with downward motion above the intergranular lane. Above 140 km the temperature stratification reverses.

Granulation in active regions and near sunspots

The granular pattern in magnetic regions near sunspots and in ACTIVE REGIONS (see SOLAR CHROMOSPHERIC PLAGE) exhibits lower contrast and reduced vertical velocity as well as smaller mean cell area; it is called abnormal granulation. Also the temporal evolution is slower, and horizontal flow speeds as measured by local correlation tracking are one-half those in the quiet photosphere. When observed in the wings of strong lines, such as Hα, or in the band head of the CH radical at 430 $\pm$ 5 nm (the G-band) these regions show small bright features of $\simeq$200 km extent that frequently sit in the spaces between granules. They were first seen in 1973 by R Dunn and J Zirker and were called filigree (see SOLAR PHOTOSPHERE: FILIGREE). Apparently, the presence of a magnetic field (see SOLAR PHOTOSPHERE: INTRANETWORK AND MAGNETIC FIELDS) modifies the convective energy transport in these regions.

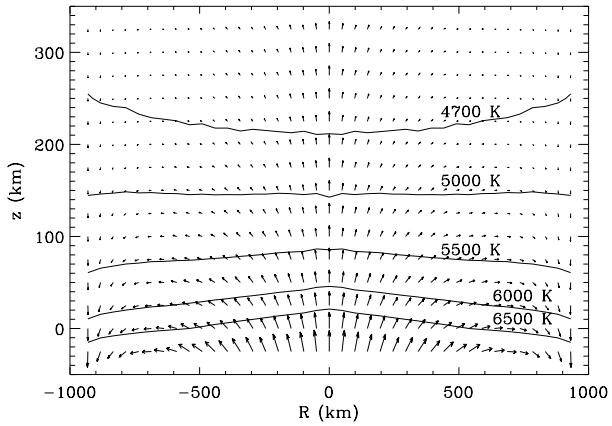

Figure 4. Velocity and temperature field measured for an average granule. The arrow length is proportional to the velocity, with a maximum vertical upward velocity of 1.6 km s^{-1}. The distance from granule center to the intergranular lane center has been scaled to 940 km. Published in 1996 by B Ruiz Cobo and coworkers (La Laguna).

Numerical simulations—agreement with observations

In the recent decade numerical simulations of the solar convection, particularly of the granulation, have attained a high degree of sophistication (SOLAR INTERIOR: CONVECTION THEORY). Despite their limitations, e.g. in the very small volume that can be modelled, some ambiguity in the boundary conditions, in the treatment of viscosity etc, the simulations are capable of describing many aspects that are confirmed by observations. For example, spatial intensity distribution and size spectrum, amplitudes of horizontal and vertical motion, evolution and topology of the granular pattern are rather well reproduced—for comparison the numerical results have to be slightly degraded spatially in order to account for the limited spatial resolution of the observations. Simulations help us to arrive at a basic understanding of the top of the solar convection zone and to infer details that are not accessible by observation. We learn that solar convection is driven by both buoyancy forces at subphotospheric levels and by radiative cooling at the surface thermal boundary layer, that the cooled plasma turns over and converges into the dark intergranular lanes and further into the vertices between granulation cells forming narrow 'fingers' of high-velocity downdrafts, which penetrate many scale heights. Recent observations have shown that some intergranular vertices are much more stable in space and time than the rest of the granular pattern. Such persistent intergranular features may mark at the photospheric level the locations of the high velocity downdrafts.

Moreover, the numerical simulations suggest that downdrafts are surrounded by high-vorticity regions while upflows are essentially laminar. Spectrograms of very high spatial resolution (cf figure 3) frequently exhibit increased linewidth near the edges of granules

where vertical velocity gradients are large. Here shear flows are surmised to create turbulence—more cautiously, some authors use the term unresolved velocities. When measured in lines that originate 70–200 km above the photosphere values of the rms turbulent velocity $w_{\rm turb} \approx 0.5$ km s^{-1} are found, which increase with decreasing height; extrapolation to photospheric levels yields $w_{\rm turb} \approx 1.5$ km s^{-1}. In this case the turbulent pressure associated with the turbulent velocity: $P_{\rm turb} = (1/2)\rho w_{\rm turb}^2$, where ρ is the density, may locally attain a significant fraction (of order 0.3) of the gas pressure, and thus play an important role in the dynamics of granular evolution.

Solar Photosphere: Intranetwork and Turbulent Magnetic Fields

The names 'intranetwork' and 'turbulent magnetic fields' are used to represent the solar magnetic fields of mixed polarities at the smallest scales of the spatial spectrum. Since the spatial separation of the opposite polarities is small, and since the magnetic flux of each small-scale magnetic element is tiny, they can only be made partly visible in 'deep' magnetograms obtained with both high spatial resolution and long integration times. If the magnetic elements are much smaller than the photon mean free path (optically thin regime) they may not be spatially resolved even in principle. Yet such optically thin magnetic structures may be diagnosed by indirect methods, in particular with the Hanle effect (see SOLAR MAGNETIC FIELD: ZEEMAN AND HANLE EFFECTS).

While the word 'intranetwork' generally refers to the spatially resolved mixed-polarity field, the phrase 'turbulent field', when used in the context of interpreting spectro-polarimetric observations, usually refers to the spatially unresolved, 'hidden' mixed-polarity field, which remains practically invisible in solar magnetograms owing to cancellation of the contributions from the opposite-polarity elements within the spatial resolution element.

Figure 1 illustrates the typical spatial distribution of the resolved mixed-polarity magnetic fields on the quiet Sun in the form of a 'deep' magnetogram of the line-of-sight component of the magnetic field. Such a magnetogram is a map of the circular polarization that is produced by the longitudinal Zeeman effect in a selected spectral line. The opposite polarities are represented by the brighter and darker patches against a neutral background, giving a 'salt and pepper' appearance when the polarities are mixed.

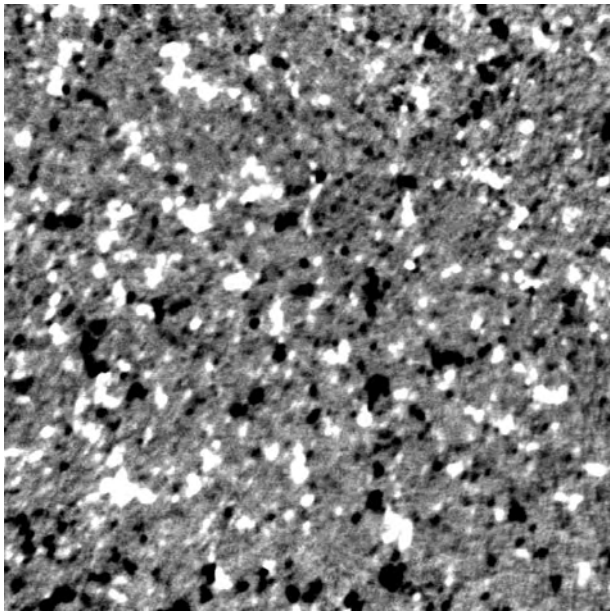

Figure 1. 'Deep' magnetogram of a 280 × 280 arcsec^2 portion of the quiet Sun at the center of the solar disk, obtained on 1 July 1998, by Jongchul Chae at BBSO. The opposite-polarity magnetic fluxes are represented by the brighter and darker patches against a neutral grey background. 4096 separate frames have been added to enhance the sensitivity and bring out the weaker magnetic fluxes. Courtesy of Big Bear Solar Observatory/New Jersey Institute of Technology.

Intranetwork fields

The choice of the word 'intranetwork' is made to contrast these magnetic fields with those that are related to the emission network that is seen as a brightness pattern in chromospheric and TRANSITION REGION spectral lines (see CHROMOSPHERE: NETWORK). This emission is located at the boundaries of the velocity cells of the supergranulation (with a cell diameter of 30 000 km) (see SOLAR PHOTOSPHERE: SUPERGRANULATION). Since the magnetic field is frozen into the plasma, it is carried by the flow pattern of the supergranulation and converges to the downdraft regions at the cell boundaries. The supergranulation flow thus organizes the large-scale pattern of magnetic flux and emission.

Because of the organizing effect of the supergranulation flow, most of the magnetic flux becomes concentrated in the network, and it is this network flux that is the source of the large-scale magnetic field that reaches up in the CORONA and beyond. The magnetic fluxes in the network are predominantly of one polarity over scales of the supergranulation size. This flux occurs in the form of highly intermittent magnetic flux tubes, which occupy typically 1% of the volume in the photosphere and have field strengths on the order of 1 kG.

In magnetograms with insufficient polarimetric sensitivity and spatial resolution one may get the impression that *all* the photospheric magnetic flux is in the form of network flux with a typical magnetic filling factor of 1% , while the remaining 99% appears as if it were field free. No portions of the solar plasma can, however, be strictly field free, since the flux concentration by the supergranular and granular flows is of finite efficiency (see SOLAR PHOTOSPHERE: GRANULATION), and any left-over, unconcentrated weak magnetic flux will be acted upon by the convective and turbulent motions and tangled up until some magnetoturbulent equilibrium between magnetic and kinetic energies is reached. Many of these magnetoturbulent processes may also take place deep in the convection zone before the fluxes emerge at the solar surface (see SOLAR INTERIOR: CONVECTION ZONE).

What we see in figure 1 is actually a mixture of network and intranetwork fields. The more prominent flux patches are due to the network, while the rather inconspicuous dot-like features represent the intranetwork field. These features can only be seen in 'deep' magnetograms under good seeing conditions.

If an observed magnetic element carries a small magnetic flux, this does not necessarily imply that the field strength is also small, since the measured flux is a product

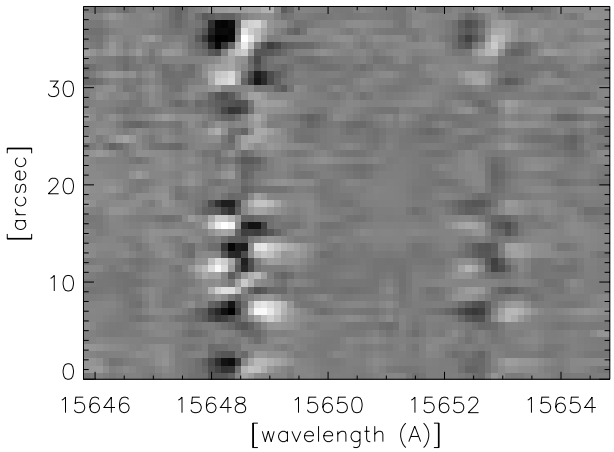

Figure 2. Spectral image in the near-infrared of the circular polarization, recorded in 1997 at the National Solar Observatory (Sunspot, New Mexico) with the spectrograph slit positioned at the center of the solar disk. The two spectral lines of neutral iron at 15 648 and 15 652 Å show the characteristic Zeeman-effect signatures of a magnetic field that exhibits variations of sign or polarity on scales of a few arcsec along the spectrograph slit. At each spatial position the circularly polarized line profile is antisymmetric, but the sense of the antisymmetry depends on the polarity. Courtesy H Lin and T Rimmele, NSO/Sacramento Peak.

of field strength and magnetic filling factor. For fluxes larger than about 2×10^{17} Mx (corresponding to 20 G Mm^2; 1 Mm = 1000 km, corresponding to 1.4 arcsec on the Sun) the field strength depends very weakly on flux (and is about 1.0–1.5 kG), which may be understood in terms of the convective collapse mechanism for the formation of kG flux tubes. For smaller fluxes the field strength decreases rapidly with decreasing flux, since the diameter of kG flux tubes with such small flux would be optically thin, which would prevent the collapse mechanism from working (owing to damping by the effective heat exchange between flux tube interior and exterior).

In the visible spectral range the Zeeman splitting is generally incomplete (smaller than the spectral line width), which has the consequence that the observed circular polarization mainly carries information on the magnetic *flux* but not directly on the field strength or filling factor. To extract information on the field strength one has had to develop indirect methods by forming ratios between the circular-polarization amplitudes measured in spectral lines with different sensitivities to the Zeeman effect. In the infrared, however, the Zeeman splitting is much larger and becomes complete even for moderately strong fields. This allows us to extract direct information on both flux and field strength (and thus also on magnetic filling factor) without having to use tricks such as polarized line ratios. Figure 2 gives an example of a spectro-polarimetric recording of intranetwork magnetic fields in the wavelength region around 1.565 μm. The spectrograph slit has been placed at the center of the solar disk, and the spectrogram shows the characteristic antisymmetric circularly polarized line profiles due to the longitudinal Zeeman effect. The polarity reversals occur on a scale of a few arcsec, close to the scale of the solar granulation. Such recordings allow the magnetic flux, field strength, and filling factor to be determined for each spatial location along the spectrograph slit.

The relation between the network and intranetwork magnetic fields is not clear. It is generally believed that the magnetic flux that is the source of solar activity originates by dynamo processes inside the Sun (see DYNAMOS: SOLAR AND STELLAR), preferentially near the bottom of the Sun's convection zone. New magnetic flux emerges from the interior in bipolar form on different scales. The bipolar regions with the largest amount of flux form the ACTIVE REGIONS with SUNSPOTS and appear at low heliographic latitudes. Smaller bipolar regions without sunspots on typical scales of 10–20 arcsec are called ephemeral active regions because of their shorter lifetimes. They are more abundant with a larger latitudinal spread. It is possible, although controversial, that the still smaller-scale and ubiquitous intranetwork fields with scales of a few arcsec may be considered as the small-scale portion of a continuous spectrum of bipolar magnetic regions that includes active regions in its large-scale portion. While the flux emergence rate for active regions is 10^{20} Mx day^{-1}, it is 10^{22} Mx day^{-1} for ephemeral regions and 10^{24} Mx day^{-1} for intranetwork fields (Zirin 1987). The smallest scales thus dominate the flux budget.

The large bipolar magnetic regions (active regions) are highly organized, with the magnetic polarities being oriented in the east–west direction and evolving with the 22 year solar magnetic cycle according to Hale's polarity law (see SOLAR CYCLE). The ephemeral active regions also obey Hale's polarity law in a statistical sense, but with a much larger spread in their orientations. It is not yet known whether the orientations of the intranetwork fields are entirely random or not. If their directional distribution contains a non-random component, they could even be the dominating contributor to the global magnetic flux pattern owing to their extremely high flux emergence rate (which is 10 000 times that of active regions). Their possible role in the operation of the solar dynamo is still a controversial subject.

The large emergence rate needs to be balanced by a similar rate of flux removal, otherwise the photosphere would become 'choked' by all the emerging flux. Flux removal can occur mainly either by (i) submergence, whereby flux ropes are retracted down below the solar surface, or by (ii) annihilation, when opposite-polarity fields meet and reconnect on the Ohmic diffusion scale (on the order of 1 km). Reconnection can also release field lines from being anchored to the solar body and allow the liberated flux loops to be convected into the heliosphere. It has not yet been possible to determine the relative role of these various mechanisms for the overall flux budget.

Large active regions as well as ephemeral active regions are localized bipolar structures that only cover a

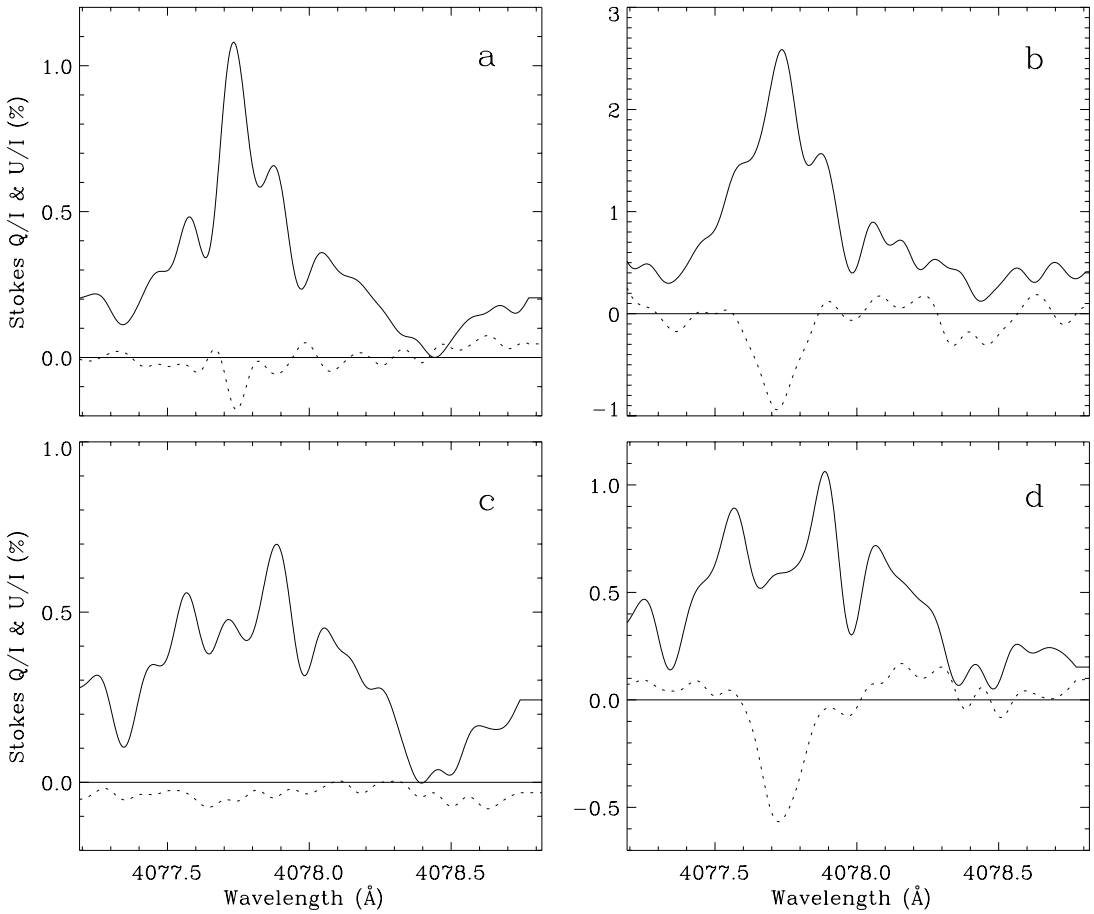

Figure 3. Illustration of spectral signatures of the Hanle effect in the Sr II 4077.7 Å line at four locations on the solar disk. The curves represent the degree of linear polarization oriented parallel to the nearest solar limb (Stokes Q/I, full curves) and at 45° to the limb (Stokes U/I, dotted curves). The shapes of the polarized line profiles change from place to place on the Sun because of varying Hanle depolarization in the line core of the Q/I profiles (while the line wings are almost unaffected). Partially resolved magnetic fields with a net orientation cause a rotation of the plane of linear polarization, which shows up as a U/I signal in the line core. From Bianda *et al* (1998).

small fraction of the solar surface. Likewise the network magnetic fields, which represent the footpoints of the large-scale coronal field, are highly intermittent in the photosphere with kG fields and a magnetic filling factor on the order of 1%. The intranetwork magnetic fields retain some degree of intermittency, although much less pronounced, and have substantially lower field strengths (in the range of hundreds of G or less). Other properties of the small-scale and intranetwork fields are discussed in Stenflo (1989), Martin (1990) and Wang *et al* (1995).

Turbulent fields: beyond the spatial resolution limit

It is not known to what extent the magnetic field retains some degree of intermittency when going to still smaller scales. The theory of magnetoconvection (see MAGNETOHYDRODYNAMICS: MAGNETOCONVECTION) in a highly stratified medium is not in a position to make any clear prediction about this, and the scales that we are now considering are too small to be spatially resolved. Still it is possible to obtain information on the spatially unresolved turbulent magnetic fields via spectro-polarimetric methods involving the Hanle effect.

Spectral lines are linearly polarized by coherent scattering processes, but in the presence of a turbulent magnetic field the amount of polarization is reduced depending on the strength and degree of intermittency of the turbulent field. To apply this method one first has to describe the spatially unresolved field with an idealized model that is characterized by some free parameters, the values of which are constrained or determined by the amount of observed Hanle depolarization. With a one-parameter model, characterized by a volume-filling field with a random orientation of the field vectors (note, however, that the spatial topology is not constrained to be random) and a single-valued field strength as the free parameter, one finds field strengths in the range of 4–40 G, depending on position on the solar disk. If the field would

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

be intermittent with a filling factor smaller than unity, the field strength would be correspondingly larger.

Figure 3 illustrates the kinds of spectral signatures used to extract information on both spatially unresolved and partially resolved magnetic fields via the Hanle effect. The figure shows four recordings at four different locations on the solar disk of the linear polarization produced by coherent scattering in the spectral line Sr II 4077.7 Å. The Hanle effect is only effective in the line core but not in the wings, and it manifests itself in the form of depolarization and rotation of the plane of polarization. The four full curves show various degrees of depolarization, while the dotted curves show a polarization signal in the line core if the plane of polarization has been rotated. The interpretation of the observations is complicated, but such data give access to a different parameter regime than can be studied via the ordinary Zeeman effect.

It is natural to expect that the field would become ubiquitously tangled by the turbulent motions until some equipartition between the magnetic and kinetic energies is reached at the smallest scales, where the convective collapse mechanism is inoperative and magnetic diffusion plays an increasing role. The nature of the magnetoturbulent spectrum, however, remains unknown. With future multiline applications of Hanle diagnostics it should be possible to make the interpretative models more sophisticated and realistic.

If the turbulent field strength is determined by the kinetic energy spectrum of the granulation and smaller-scale turbulence, and if this kinetic spectrum is the same at all places on the quiet solar disk, then one would expect the turbulent field strength to be independent of position on the quiet Sun (outside active regions). Hanle observations, however, show (Stenflo *et al* 1998) that the turbulent field strength is not spatially invariant but exhibits variations by an order of magnitude. It is a quantity that needs to be mapped across the solar disk.

Outlook

Progress in understanding the intranetwork and turbulent magnetic fields requires improved spatial resolution combined with high polarimetric accuracy and spectral resolution. The near-infrared spectral region is particularly suited for Zeeman diagnostics of the spatially resolved fields, since the large Zeeman splitting of infrared lines allows a determination of both field strength and magnetic filling factor (cf Solanki 1995). The Hanle effect as a diagnostic of spatially unresolved turbulent magnetic fields is best applied with lines at shorter wavelengths in the visible domain, where scattering polarization occurs with larger amplitudes.

Small-scale structures evolve on small time scales, so high spatial resolution also demands moderately high temporal resolution. The four observational parameters of spatial, temporal and spectral resolution as well as polarimetric accuracy form a 4D parameter space that characterizes the observations. The observations will always be photon starved, since it will always be necessary to make trade-offs between these four parameters, even with the largest foreseeable future telescopes. The chosen trade-offs depend on the emphases and objectives of the particular observing program. With adaptive optics it will become possible to combine high spatial resolution with high-precision spectro-polarimetry requiring relatively long integration times. This, in combination with larger telescope apertures, will provide access to unexplored territory in the 4D parameter space, allowing for major advances in understanding magnetoconvection and the operation of the solar dynamo.

Solar Photosphere: Mesogranulation

Mesogranulation is a horizontal cellular pattern in the convective motions at the surface of the Sun with sizes of 5–10 Mm. Convection is the transport of energy by rising warm fluid and sinking cool fluid. How convection appears at the solar surface depends on how it is viewed. In the emergent intensity, solar convection is visible as a cellular pattern called granulation (see SOLAR PHOTOSPHERE: GRANULATION). Observed as quasi-steady fluid velocity averaged over times of order 1 h, a larger-size cellular pattern of diverging horizontal flows appears, called mesogranulation, with diameters of 5–10 Mm. Horizontal velocity flows also reveal an even larger pattern of supergranulation (see SOLAR PHOTOSPHERE: SUPERGRANULATION).

Mesogranulation was first observed as a pattern in the persistent (time-averaged) vertical velocity observed as a Doppler shift in photospheric and chromospheric spectral lines. It is most clearly seen in the quasi-steady divergence of the horizontal surface velocity, which can be determined by following the motion across the surface of features in the granulation using local correlation tracking. This technique calculates the cross correlation between images at two different times as a function of their displacement. The local motion between the two times is taken to be the displacement that maximizes the cross correlation at each location in the image. Using the quasi-steady horizontal motions to calculate the trajectories of markers in the flow shows that they end up after a few hours in thin lanes surrounding the mesogranule cells (figure 1). Magnetic fields are shuffled about in a similar fashion by the fluid motions and as a result are observed to collect on the mesogranule boundaries and then be swept to the supergranule boundaries where the magnetic field produces the chromospheric network (see CHROMOSPHERE: NETWORK).

The mesogranular component of solar convection affects the properties of the smaller-scale granules. By conservation of mass, regions of horizontally diverging flow are regions of upflowing fluid and regions of horizontally converging flow are regions of downflowing fluid. Bright, long-lived, rapidly expanding granules are found preferentially in upflowing, diverging interiors of mesogranule cells. Small, faint, short-lived granules are found preferentially in the downflow lanes of converging flow at the edges of the mesogranule cells.

Solar convection is driven by radiative cooling in a very thin layer at the solar surface of that small fraction of fluid that reaches the surface. This cool fluid forms the low-entropy cores of downdrafts that descend into the interior and is the primary site of the buoyancy work that produces the convective motions. The convective flow pattern is determined by mass conservation. Warm fluid ascending into lower-density layers is like a fountain (figure 2). Most of it must turn over and become entrained in the downdrafts within a density scale height (the distance in which the density decreases by a factor of $e = 2.7$). With increasing depth, the temperature increases and the scale height increases, which leads to larger-size cells of ascending fluid (figure 3). Thus mesogranular-scale upflows become dominant about 2 Mm below the surface and supergranular-scale upflows dominate at about 10 Mm below the surface.

Solar Photosphere: Supergranulation

The surface of the Sun is covered by convection cells called GRANULATION, which can easily be seen in white light through a telescope under good SEEING conditions. These cells, typically 1 Mm in diameter, are visible because their centers are hotter (brighter) than their cooler (darker) boundaries. Granules float on top of a much larger convection pattern called supergranulation. Supergranules, with diameters of about 20 Mm, are the tops of plumes (bubbles) which probably form 5–10 Mm below the solar surface in the Sun's convection zone (see SOLAR INTERIOR: CONVECTION ZONE). Supergranulation is invisible in ordinary photographs, but can be seen in Dopplergrams. In a supergranule gas flows radially outward from its center to its periphery. This motion drags with it magnetic flux tubes, which pile up at the supergranule boundary to form a magnetic network (see SOLAR PHOTOSPHERIC MAGNETIC FLUX TUBES) and define the locus of the Sun's chromospheric network (see CHROMOSPHERE: NETWORK).

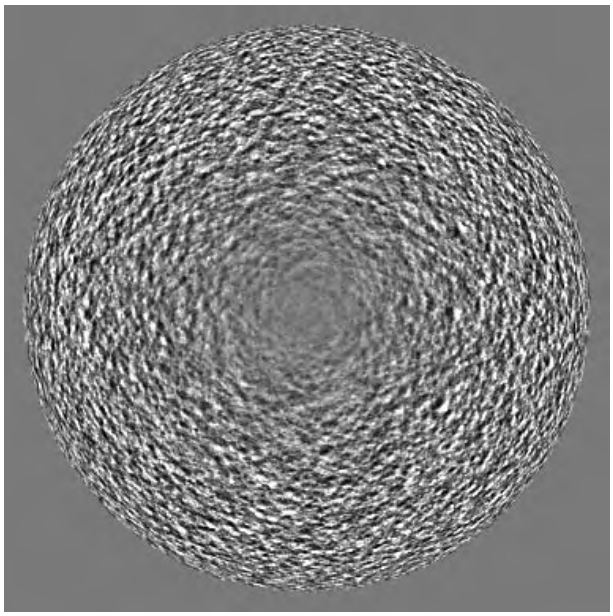

Figure 1. A full-disk Dopplergram of the Sun obtained by MDI. Dark and bright features indicate line-of-sight approaching and receding velocities. Supergranules, not visible at disk center, appear as elliptical structures, each with a dark and a bright half. (Courtesy of R Bogart, Stanford University, and G Simon, Air Force Research Lab.)

Solar convection and mixing-length theory

In 1801 the great English astronomer William Herschel first observed that the Sun's visible surface, the SOLAR PHOTOSPHERE, has a granular appearance. Seventy-five years later the first high-resolution photographs of the Sun revealed that this granulation was composed of closely packed cells having bright (hot) centers surrounded by dark (cool) lanes. In the 1930s the German theoretician Ludwig Biermann realized that, in the outer 30% of the Sun, heat from the interior is transported to the surface by convection, and granules are the surface manifestation (the boiling bubbles) of this convective process. However, theory was incompatible with the observations. According to then-accepted mixing-length theory, convective bubbles should have sizes proportional to the local scale height H (the distance in which density or pressure changes by a factor e $\approx$ 2.7). Thus a large range of cell sizes was expected. Why was it then that only granular-sized bubbles ($\approx$ 1 Mm) were seen, while H ranged over three orders of magnitude, from 100 km at the Sun's surface to 100 Mm at the base of the convection zone?

Discovery of supergranulation

Not until the 1960s was this mystery finally solved, thanks first to an invention by the brilliant American physicist Robert Leighton and second to a simple theory of heat transport through the convection zone. Leighton modified the well-known SPECTROHELIOGRAPH so that it could not only take ordinary brightness photographs of the Sun but also obtain Dopplergrams and Zeemangrams. That is, with the new instrument, he was able to visualize line-of-sight velocities and magnetic fields at the solar surface. Immediately thereafter (in 1961) he and his colleagues made two major discoveries that spawned two new disciplines of solar research. The first was the Sun's five-minute oscillations which opened the field of HELIOSEISMOLOGY. The second was supergranulation, which started the study of solar magnetoconvection. Supergranules were the second scale of solar convection to be discovered. Their area is 400 times that of granules. Mixing-length theory, already seriously weakened because only one scale of convection (granulation) had been observed, was further destroyed by the discovery of supergranulation. Instead of many convective size scales, now two discrete scales of widely disparate sizes had been seen. In 1968 Nigel Weiss and George Simon suggested a model of rising plumes which predicted the existence of three or four cell sizes, the two that had been observed, a giant cell formed at the base of the convection zone and perhaps an intermediate scale. Lawrence November discovered the last of these scales in 1981, calling it mesogranulation, and giant cells were first observed in 1997.

Properties of supergranules

Convection cells typically have depths from 1/4 to 1/2 the size of their diameters; they look like very thick pancakes. So supergranules, which have mean diameters of 20 Mm, are generally believed to originate 5–10 Mm below the solar surface. By the time these hot bubbles reach the surface they have given up their excess heat to the surrounding gas. Hence they show so little brightness contrast between their warmer centers and cooler boundaries that they are invisible in ordinary

photographs. Only their motions, revealed in the Dopplergrams, can be observed. Recent helioseismology measurements, by the MDI instrument on the SOHO spacecraft (launched in 1995), indicate that supergranules extend about 8 Mm below the surface, exactly in the expected depth range. Helioseismology is permitting the first three-dimensional view of the Sun's subsurface layers and holds much promise for understanding convection processes below the Sun's visible surface. In stark contrast to pancake observations, one theoretical model suggests that supergranules may be tall vertical cylinders, extending from the bottom to the top of the convection zone. Future helioseismological data may be able to discriminate between pancake and cylinder models of supergranules.

Hot gas rises (50–100 m s^{-1}) at a supergranule's center, flows horizontally outwards (200–500 m s^{-1}) and then sinks (100–200 m s^{-1}) at the cell boundary. Most of the downflow occurs at vertices of the irregular polygonal structure of supergranulation. At the Sun's surface one sees primarily the horizontal flow pattern. In a full-disk Dopplergram (figure 1), supergranules are elliptical features, half-bright, half-dark. None is seen at disk center. The round supergranules appear elongated owing to foreshortening. This photograph is explained schematically in figure 2. Since Dopplergrams show only line-of-sight motions, horizontal motions will not be visible at disk center. Away from center, one observes supergranules at a slant angle, so a component of the horizontal motion projects into the line of sight, and appears either dark (approaching) or light (receding). The slant angle of view produces the geometrical foreshortening such that, when viewed from Earth, the supergranule looks smaller (broken arrows) than at disk center. The gas circulation within the supergranulation is shown schematically by the solid arrows. In figure 3 we show a high-resolution Dopplergram, taken at the Sun's south limb by MDI. Here we have enclosed eight typical supergranules in boxes. Each has its darker half closer to disk center (located above the image, at x, $y = 300$ arcsec, 975 arcsec). If the supergranule has a circular cross-section and a horizontal radial outflow from its center, the Doppler effect and foreshortening give it an elliptical shape, with its long axis dividing the dark and bright halves. This long axis is parallel to the solar limb and perpendicular to the line we have drawn along a solar radius from the supergranule toward disk center.

Until recently it has been impossible to measure accurately the lifetime of supergranules, since they were known to live 1 day or longer. Because of the day–night cycle, ground-based observations of supergranules were interrupted at sunset, and by the following sunrise the cell had either died or changed shape sufficiently so that identification was uncertain or impossible. Now the space-based MDI instrument has, on several occasions, provided uninterrupted Dopplergrams (at a 1 min cadence) for 60–90 days. Special feature-tracking algorithms have been applied to these data sets. From measurements of many thousands of supergranules it has been learned that, while most supergranules live between 15 and 30 h, a small number have lifetimes exceeding 2 days, a few even over 4 days.

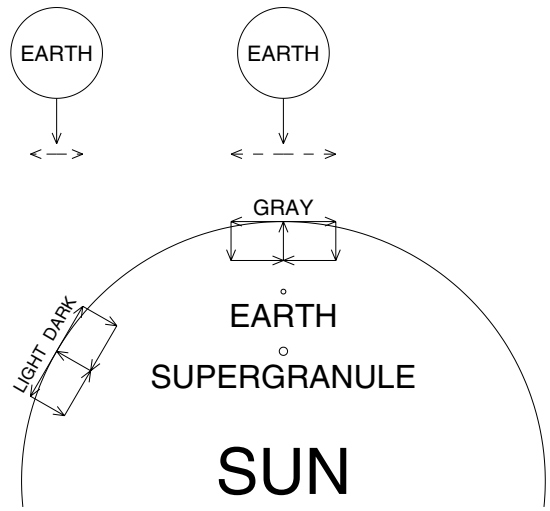

Figure 2. Schematic diagram (enlarged) of supergranules, at and away from disk center, to explain features seen in figure 1. and figure 3. The actual sizes of supergranules and the Earth, relative to the Sun, are shown as small circles.

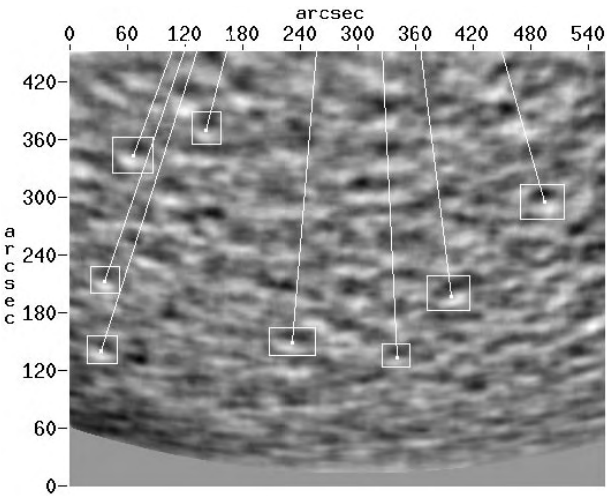

Figure 3. Appearance of supergranules near the solar limb. Eight are enclosed in boxes. Lines connect the centers of these supergranules with Sun center. Note that each line is approximately perpendicular to the line (not drawn) that separates the dark and bright halves of that supergranule. Supergranular advection of granules

The supergranular flows carry granules, much like flotsam is transported in a river. Thus it is possible to observe these flows indirectly, by measuring the motions of the granules,

using the technique of local correlation tracking (LCT), first developed in the 1980s and since then a powerful tool for describing the Sun's surface velocity structure. Since granules are such small features, LCT only works with ground-based observations under very good seeing conditions (times of low atmospheric turbulence) or with space-based telescopes. Otherwise the granule shapes are distorted or even disappear and cannot be used as supergranular tracers. LCT wonderfully complements Doppler measurements, since it works best at disk center, where Dopplergrams are ineffective. Because LCT can also be used far from disk center where the Doppler signal is strong, it has been possible to confirm that the two techniques give consistent values for supergranular velocities.

The magnetic network

Not only granules but also small magnetic flux tubes are carried by the supergranular flow field. Since supergranules cover the solar surface in a close-packed polygonal-shaped cellular structure, this topology requires that the outflows from adjacent supergranules meet at their common boundary. Some of this gas, which had risen to the surface at the supergranule centers, falls back down along this boundary line. The remainder moves along the boundary to vertices in the pattern, where the downflow is concentrated into small plumes, and often shows a vortex (twisting) motion. The magnetic flux is forced to the cell boundaries by the flows, where it gathers into a network pattern, which is especially concentrated at the vertices. The study of such interactions between convective gas motions and magnetic field is called magnetoconvection. Models of solar magnetoconvection attempt to describe how magnetic flux is carried, concentrated, dispersed, diffused, twisted and stretched by motions of the ionized solar gas and how, at the same time, the magnetic field reacts against this motion, thus altering the nature of the gas flow. While the supergranular interactions described here occur probably at and within 10 Mm of the solar surface, similar forces acting far below the surface, near the base of the convection zone (200 Mm depth), are probably responsible for the formation of SUNSPOTS and the solar dynamo (see DYNAMOS: SOLAR AND STELLAR) which produces the solar activity cycle (see SOLAR CYCLE).

The magnetic network causes localized heating at the solar surface and directly above it in the chromosphere. A chromospheric network, consisting of rising and falling jets of hot gas called spicules, forms at the loci of the magnetic flux. In figure 4, a filtergram taken in the light of Hα, a spectral line of hydrogen that originates in the chromosphere, the spicules correspond to the dark elongated structures. The distinct network pattern resembles hedgerows that separate farm fields. (The complex bright and dark region in the foreground is an ACTIVE REGION containing two small sunspots. This is not part of the network pattern which is visible in the central and upper portions of the filtergram.)

Figure 4. The chromospheric network (seen in this Hα filtergram) is coincident with a network of magnetic flux elements and marks the boundaries of supergranules. The network consists of dark fibrillar vertical structures (spicules). Black crossed lines indicate the long and short axes of two foreshortened supergranules. (Courtesy of R Dunn, National Solar Observatory.)

Magnetic diffusion and kinematic modeling

Knowledge of the supergranule lifetime is important for studies of solar magnetoconvection. It is believed that large-scale long-term transport of magnetic field across the Sun is related to the solar activity cycle. This transport may be due to a diffusion mechanism controlled by the supergranulation. As we have pointed out, the supergranular flow concentrates magnetic flux into a network pattern. This pattern undergoes little change during the supergranule's life, but when the cell disappears it is replaced by a new supergranule 5, 10 or 20 Mm removed from the former cell. The magnetic network must now rearrange itself to conform to the flow pattern of this new supergranule. The continual birth and death of supergranules creates a random-walk diffusion that steps the magnetic field across the Sun. This diffusion is directly proportional to the square of the step size, and inversely to the time between steps, i.e. to the area of a supergranule divided by its lifetime.

Kinematic modeling of solar magnetoconvection (in

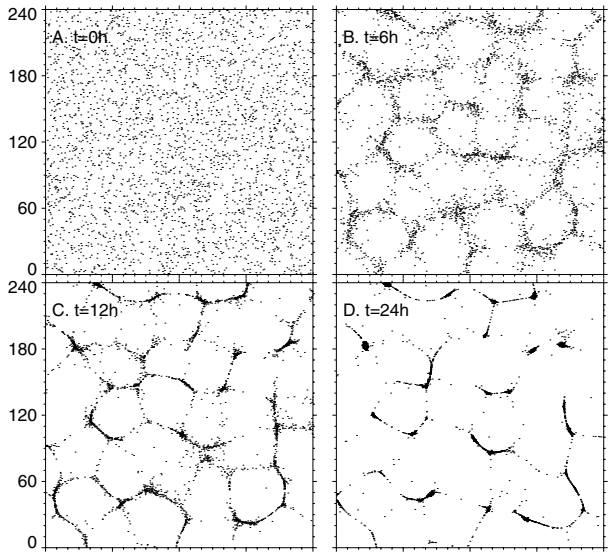

Figure 5. Formation of the magnetic network. In this numerical simulation, supergranular flows carry an initially uniform distribution (A) of tracer particles (representing magnetic flux tubes) to the boundaries of the supergranules. After 6 h (B) the evolving network can easily be recognized, and it is almost fully formed in 12 h (C). After 24 h (D) the network is very thin, and beginning to concentrate into small clumps at vertices of the pattern.

which the magnetic field does *not* react back against the velocity field, and thus the magnetic flux tubes act as simple tracers of the flow) can be used to illustrate the concentration, dispersal and diffusion of magnetic flux at the solar surface. If one uses the observed sizes, lifetimes and velocity field of supergranules to create a slowly changing artificial grid of convection cells, one can observe the effect of this evolving flow pattern on an initially uniform randomly distributed set of tracer particles (called *corks*) and compute the rate of diffusion. Results from such a model calculation by Simon, Title and Weiss are shown in figure 5. The visualization shows the evolution of the cork pattern over 1 day, from a uniform random distribution to a well-defined network structure, with concentrations of particles forming at vertices of the flow pattern. While they are not correct representations of magnetoconvection of strong magnetic fields, these models are sufficiently accurate for weak fields. They can be quickly computed for large areas of the solar surface and thus provide useful descriptions of magnetoconvection and magnetic diffusion on the quiet Sun, away from sunspots and active regions.

Solar Photosphere: The Limb Effect and Gravitational Redshift

The 'limb effect' is the observational finding that many spectral absorption lines formed in the photosphere (FRAUNHOFER LINES) show a REDSHIFT of their mean wavelength when comparing limb observations with observations from the solar disk center. The magnitude of this effect is different for each spectral line and equals some 100 m s^{-1} when explained as a DOPPLER EFFECT.

The 'gravitational redshift' is the redshift of spectral lines originating near a mass concentration as described by Einstein's theory of GENERAL RELATIVITY.

Both historic terms are related to wavelength shifts and spectral line shape changes when analysing the center-to-limb variation of the spectral absorption lines formed in the photosphere (see SOLAR PHOTOSPHERE: CENTER-TO-LIMB VARIATION), which is the topic of this article.

Wavelength shifts and line shapes

Using present knowledge of the physical conditions within the SOLAR PHOTOSPHERE one expects several effects on the wavelengths and line shapes of the spectral lines formed there, which depend on each other:

(a) Due to the gravitational force on the Sun, which is much larger than that on the Earth, the wavelengths of spectral lines are shifted to longer wavelengths as compared with the same spectral lines on Earth. The effect amounts to an equivalent Doppler shift of 636 m s^{-1}. This amount is the same at the disk center and at the solar limb because the gravitational redshift depends on the gravitational potential energy at the emitting location. This energy is the same everywhere on the surface of the Sun (which is an equipotential surface).

(b) The convective motions, especially those of the GRANULATION, which exhibit upward motions of about 2 km s^{-1} in their centers and downflows in the intergranulation, cause spectral line wavelength shifts. A shift towards shorter wavelengths due to the Doppler effect can be expected for spectral lines originating in the central region of the disk, because most of the light originates from bright granules moving upward.

(c) Each solar absorption line is formed within a certain layer of the photosphere. The line centers are formed higher in the atmosphere than the wings. Since the pattern of convective motions in the photosphere depends on the depth in this atmosphere and the velocity components depend on the position on the solar disk, besides wavelength shifts spectral line asymmetries also occur. These effects depend on the selected spectral line and in addition show a center-to-limb variation, which means that the spectral line shape is most often different in the central disk region as compared with that observed near the limb.

To investigate the line shifts, those caused by large-scale motions, like solar rotation or supergranulation, have to be removed, either by correction or by averaging in space or time.

Several methods are used to determine spectral line positions from digital line profile data, only two of which are mentioned here: (i) a parabola can be fitted to the lower third of the spectral line and the deepest point of that parabola represents the position of the spectral line; (ii) the bisector points (a definition and examples are given in this article) can be used to fit the spectral line position.

Historic observations

The first detection related to these effects was published by J Halm in 1907, who found that the wavelengths of two iron lines in the solar spectrum were larger at the solar limb as compared with the disk center. The shifts found by Halm amounted to Doppler velocities of about 600 m s^{-1} and had the same magnitude at the poles and at the equator of the Sun. This finding is nowadays called the 'limb effect'. It was confirmed in 1907 by W S Adams, who later measured the limb effect for many other spectral lines.

After the successful testing of Einstein's theory of general relativity, attempts were made to measure the redshift of solar spectral lines as compared with the same lines produced on Earth. Indeed C E St John found in 1928 that the spectral lines observed at the solar limb showed about the expected redshift due to the gravitation, but the redshift in the disk center was only about half of that amount. He was the first to explain the observed limb effect as compared with a reference wavelength on Earth as a combination of convective motions and gravitational redshift.

After 1950 when the first models, which included convective motion, were created to compute solar spectral lines, it became evident that besides the upward motion of hot gas within the granules, downward motion of cooler gas also had to be taken into account. At that time these different motions could not yet be detected by spectroscopic methods, but the models suggested that another effect should be the result of the mixture of upward and downward motions, namely the asymmetry of most solar spectral lines and in addition a center-to-limb variation of the asymmetry. When the detection of the asymmetry of solar spectral lines was reported, it was first doubted. Only after 1960 was the observational material good enough to determine more precisely the amount of asymmetry: the bisector of a spectral line, which is the average of the wavelengths at which the line flanks on the blue and the red side have the same measured intensities, exhibits for many spectral lines a shape like the character 'C'. Therefore it was later called the 'C shape' of a spectral line. When taking the deepest point of the spectral line, where the bisector crosses the spectral line profile, as the wavelength reference, the bisector shows a maximum difference of less than 1 ppm towards the shorter wavelength. Such small deviations from the symmetric profile could only be measured by electronic

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

methods and taking into account possible falsifications of the spectrometer used. In 1975 a first collection of line shapes and their center-to-limb variation for about 100 different solar spectral lines in the wavelength range from 575 nm to 660 nm was published by E A Gurtovenko *et al*.

Historic models

The Einstein shift of solar spectral lines is given by

$$\Delta\lambda\,\lambda^{-1} = GMR^{-1}c^{-2} = 2.12 \times 10^{-6}$$

with G the constant of gravitation, M the solar mass, R the solar radius and c the velocity of light. For all absolute wavelength comparisons this effect has to be included in the computations. Since the absolute comparison of wavelengths with a precision of better than 1 ppm is still a problem, in general only relative comparisons of wavelengths are performed.

In 1954 K H Böhm included the convection in a model for computing solar spectral lines in the photosphere, as Doppler shifts of upward moving gas, downward moving gas and static gas. H H Voigt in 1956 added a higher layer without vertical motions to this model. This model allowed spectral line asymmetries to be computed. In 1957 E H Schröter published a model, which could explain the limb effect with only two moving components of gases. The static component was not necessary in his model.

All these models support the basic idea that the observed limb effect as compared to laboratory reference wavelengths is caused by the gravitational redshift, which is reduced on the disk, especially near its center, by the vertical upward motion of the hot granules. For strong Fraunhofer lines, like for example Na D, Mg b and the K line at 770 nm, no limb effect is found, because they are formed in higher layers, where no vertical motions are present. But these lines exhibit the gravitational redshift.

Although the explanation of the solar spectral line asymmetry and the relative limb effect by mainly convective motions seems to be rather successful, other mechanisms have been discussed. A few of them will be given in historical order:

(a) When J Halm published the detection of the limb effect in 1907 he also gave his explanation that pressure differences should be the cause of the limb effect and that these pressure differences should change during the SOLAR CYCLE. He explicitly argued against the possibility of explaining the limb effect by gas motions.
(b) In 1967 G Erikson and P Maltby discussed the influence of sound waves on the spectral line wavelengths, but they could only reduce the gravitational redshift at solar disk center and did not obtain the observed blueshifts for any line.
(c) In 1974 M H Hart tried to include a Lennard-Jones potential for the pressure to explain the limb effect. It was only possible to explain some sodium lines using his model, but it failed for all other spectral lines. Directly related to Hart's publication was a publication by J M Beckers and P de Vegvar in 1978. They showed that pressure effects could not be used to explain the limb effect of iron lines.
(d) In 1977 H H Plaskett combined several mechanisms: the motions were the most important, but he included also a pressure effect and correction for a gravitational effect.

Further investigations

Besides the vertical motions of the solar granular gas, horizontal motions were also detected. By including these horizontal motions of granular gas in their model, J M Beckers and G D Nelson could explain in 1978 two special details of the limb effect of spectral lines:

(a) The limb effect shows for many lines a minimum of the wavelength not in the disk center but near to the center-to-limb position of $\cos\theta = 0.8$, where θ is the angle between the line-of-sight and the vertical direction on the Sun. This will be discussed again later and is also shown in figure 3.
(b) Often a redshift of the spectral lines is found at the solar limb, which is larger than the Einstein shift. This effect is called supergravitational redshift.

Only after 1980 was it possible, as for example in work by Å Nordlund, to solve numerically the hydrodynamic equations under conditions typical of the solar photosphere and compute the convective motions self-consistently, including their depth dependence. Using these models it was possible to compute spectral lines which show the observed C shapes and also their center-to-limb variation. Some details of these models and an investigation of the C shape of many iron lines from a digital solar spectral atlas were published by Dravins *et al* in 1981 and also presented in a review on spectral line asymmetries and wavelengths shifts by Dravins in 1982.

Within more recent investigations, the number of spectral lines used from different elements and of different excitation potentials increased. In addition, the investigations concentrated on the formation heights of the spectral lines. Balthasar (1984) published results from analyses of 143 selected lines, which were observed with a Fourier transform spectrometer (FTS) in the wavelength region 500 nm to 630 nm: he described three different classes of C shapes and center-to-limb variations. In figures 1 and 2 examples of typical spectral line C shapes of the three classes are given for the disk center and a limb position respectively.

Although the number of spectral lines within each class was quite different, he found a convincing dependence on their formation heights and their lower excitation potentials. Some general findings are:

(a) There are a few spectral lines formed in deep layers, which show a red asymmetry (right part of figure 2).
(b) Lines formed in higher layers show larger asymmetries in the disk center.

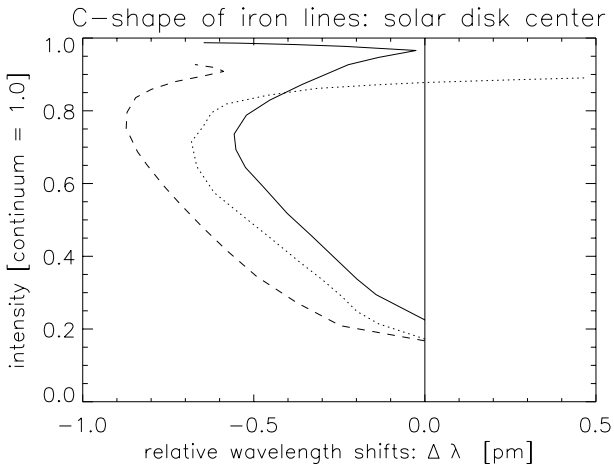

Figure 1. The C shapes of typical iron lines in the disk center: Fe 524.25 nm (full curve), Fe 507.47 nm (dotted curve), and Fe 507.97 nm (dashed curve). The wavelength positions of the deepest points in the spectral lines are taken as reference. The spectral lines are typical examples of classes I, II and III of Balthasar (1984). The plot was produced using data obtained from Balthasar.

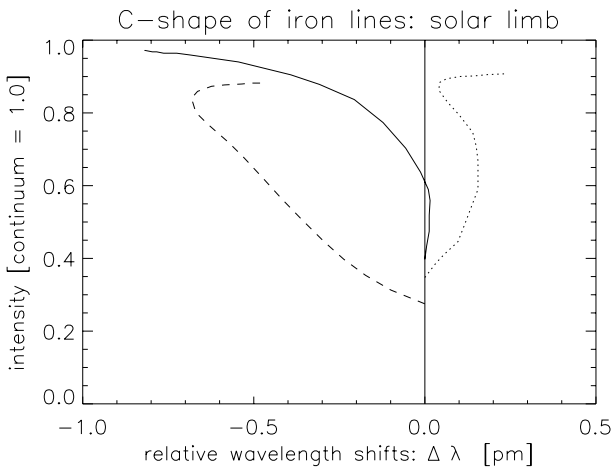

Figure 2. The C shapes of typical iron lines at the solar limb (at a position of $\cos\theta = 0.112$): Fe 524.25 nm (full curve), Fe 507.47 nm (dotted curve), and Fe 507.97 nm (dashed curve). The wavelength positions of the deepest points in the spectral lines are taken as reference. The spectral lines are typical examples of classes I, II, and III of Balthasar (1984). The plot was produced using data obtained from Balthasar.

(c) When reducing all wavelength shifts to 500 nm it was possible to determine a limb effect curve for 96 lines of neutral iron. The best fit was possible for a variable $(1-\cos\theta)$:

$$\Delta\lambda(\theta) = -0.027 - 0.320(1-\cos\theta) + 1.212(1-\cos\theta)^2,$$

with the shifts given in pm. This relation and that of subsamples of spectral lines formed deeper and higher in the photosphere is given in figure 3. (The fit procedure allowed small deviations from a zero value in the disk center.)

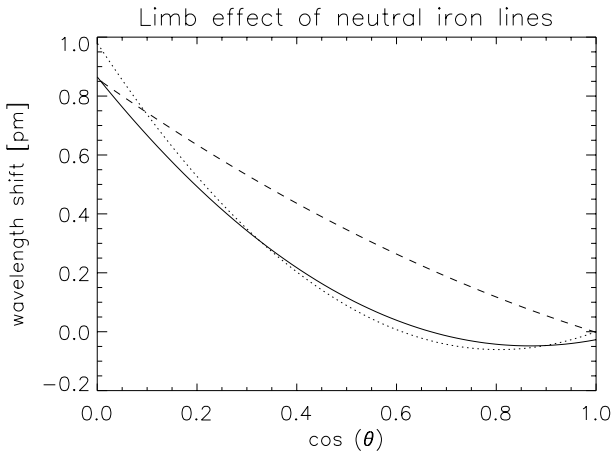

Figure 3. The mean limb effect for the 96 spectral lines of neutral iron is given as the full curve. The mean limb effect of a subsample of 21 lines formed in deep layers ($\log\tau = 0$ to -1) is given as the dotted curve. The mean limb effect of another subsample of 10 lines formed in high layers ($\log\tau = -3$ to -5) is given by the dashed curve. The plot was produced using data from Balthasar (1984).

In 1985 Balthasar published another paper, where he used a subsample of 20 iron lines from the FTS spectra at disk center, which are formed at different depths. He corrected their wavelengths for a laboratory reference wavelength. For this sample he found the following numerical value of the vertical velocities, depending on their formation depths:

$$v_{\rm ver} = 684 - 1922.8\exp(1.3577\log(\tau))({\rm m\ s^{-1}})$$

It is interesting that there are already some spectral lines showing a redshift larger than the gravitational redshift. For the horizontal velocities, depending on their formation depths, he found from this sample

$$v_{\rm hor} = (510 \pm 23) - (199 \pm 8)\log(\tau)({\rm m\ s^{-1}}).$$

The contribution of the horizontal motions to the line asymmetries is explained by a geometrical model, taking the roughness of the atmosphere into account.

Further problems

Although the occurrence of solar spectral line shifts and their C shapes is now quite well understood, there are several findings which need further investigation:

(a) For the non-split iron line at 557.61 nm P N Brandt and E H Schröter in 1982 found a more pronounced limb effect on the east–west diameter as compared with the north–south diameter of the Sun, while J M Beckers and W R Taylor had found in 1980

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

just the opposite relation—which they explained as a meridional motion towards the poles.

(b) Since reports exist about changes of the granulation during the solar activity cycle, it can be speculated that there should also be changes of the limb effect, the C shapes of spectral lines and their center-to-limb variation during the activity cycle. Maybe the finding described under (a) is an example.

(c) For the modeling of C shapes the real formation heights of spectral lines in the photosphere are still not well enough known. The atomic parameters, the physical conditions of the photosphere and their changes have to be investigated further. These uncertainties also influence the results of 3D modeling.

(d) Using the best spatial resolution available, it has been possible for some years to determine line profiles of different parts of the granules and the intergranular space separately. This topic is a very promising tool for understanding both the granulation and the spectral line formation within it much better.

Solar Photospheric Magnetic Flux Tubes: Observations

The magnetic field on the solar surface (SOLAR MAGNETIC FIELD) is highly filamentary, with a considerable fraction being in the form of flux tubes (roughly speaking bundles of concentrated field lines). Small-scale flux tubes have diameters below approximately 400 km. They appear bright and are the basic magnetic features underlying the magnetic network and active region plages (SOLAR CHROMOSPHERIC PLAGE).

Averaged over the solar disk the magnetic field strength varies between a few gauss and a few tens of gauss, whereas the field strength inside the flux tubes, B, is around 1500 G at the solar surface. Consequently, flux tubes cover only of the order of 1% of the solar surface. Although a weak and probably turbulent field (SOLAR PHOTOSPHERE: INTRANETWORK AND TURBULENT MAGNETIC FIELDS) is expected to fill the space between the flux tubes, they nevertheless contain the dominant fraction of the magnetic energy, since it is proportional to B^2. In addition, flux tubes, in particular the small-scale ones, are the main source of energy transfer from the solar interior to the Sun's outer atmosphere and hence are important players in the heating of the solar CHROMOSPHERE and solar CORONA.

Magnetic flux tubes with a wide range of sizes or cross-sectional areas are present on the Sun. The largest and best known are SUNSPOTS (diameters 4000–50000 km). Somewhat smaller flux tubes are called pores (diameters roughly in the range 400–5000 km; SUNSPOT PORES), with the smallest pores often also referred to as magnetic knots. Finally, the smallest magnetic flux tubes (with diameters less than approximately 400 km) are called magnetic elements and are the main subject of this article. Whereas sunspots are clearly distinguished from pores by the presence of a fully developed penumbra in the former, the distinction between knots and normal pores or between knots and magnetic elements is not so clear-cut. In addition to the size this distinction rests on differences in brightness. Magnetic elements are brighter than knots, which in turn are brighter than pores. Magnetic elements emit a larger radiative flux than the quiet Sun (i.e. the field-free part of the solar atmosphere), while larger flux tubes are at least slightly darker. A high-resolution magnetogram is plotted in figure 1, together with the white-light image of the corresponding region. Examples of magnetic features that are bright (e.g. at 8″ horizontal and 4″ vertical) and dark (at 11″ and 11″) are present in white light in the images.

The basic theoretical picture of each of these types of feature is that of a flux tube (or possibly a tight bundle of very small flux strands) which passes more or less vertically from the solar interior into its atmosphere, so that it is seen in cross section in magnetograms or in other images of the solar surface. In principle, the magnetic field of the flux tube may be twisted, in which case it is called a magnetic flux rope.

Flux tubes are not directly accessible to observations in the interior of the Sun, are seen in cross section at the surface at wavelengths ranging from the ultraviolet to the infrared and are outlined by x-ray emitting gas in the corona (SOLAR SPECTROSCOPY: ULTRAVIOLET AND EXTREME ULTRAVIOLET EMISSION, VISIBLE EMISSION, INFRARED EMISSION, SOLAR SPECTROSCOPY AND DIAGNOSTICS: X-RAY EMISSION). The magnetic field of flux tubes can be best studied in the photosphere due to the significant Zeeman splitting of spectral lines in the photospheric spectrum (SOLAR MAGNETIC FIELD: INFERENCE BY POLARIMETRY), the relatively simple formation physics of these spectral lines and the high spatial resolution achievable in the visible. Also, at greater heights the field from the flux tubes has expanded, so that neighboring flux tubes have generally merged, making it difficult to separate and identify individual flux tubes in these layers.

Sunspots, pores and magnetic elements differ in numerous respects. The largest sunspots possess 10^5–10^6 times as much magnetic flux as magnetic elements. Sunspots and pores are dark relative to the quiet Sun, whereas magnetic elements are on average bright, particularly when observed near the solar limb. Sunspots, and to a large extent also pores, are present only in SOLAR ACTIVE REGIONS, which are restricted to the activity belts (roughly within 30° of the solar equator), whereas magnetic elements are present at all latitudes. They are not completely homogeneously distributed, however. The number density of magnetic elements is considerably larger in active regions (where they cluster to form plages or faculae) than in the quiet Sun. Even outside active regions the magnetic elements are concentrated at the boundaries of supergranule cells (SOLAR PHOTOSPHERE: SUPERGRANULATION) forming the so-called magnetic network (CHROMOSPHERE: NETWORK). Flux tubes can also be present inside the supergranule cells, but these intranetwork fields generally have a smaller magnetic flux per flux tube and also lower intrinsic field strengths than their counterparts in the network. At a smaller spatial scale magnetic elements are observed to prefer the dark downflow lanes of the granulation (SOLAR PHOTOSPHERE: GRANULATION) and to avoid the bright, upflowing granules.

The photospheric layers of magnetic flux tubes ranging from sunspots to magnetic elements possess remarkably similar field strengths (averaged over the flux-tube cross section). At the solar surface the field strength lies between 1200 and 1800 G, with magnetic elements having a field strength of around 1500 G.

The brightness of magnetic elements makes them important contributors to the variable component of SOLAR IRRADIANCE. The magnetic network and active region faculae or plages owe their excess brightness at all atmospheric layers to excess radiation from the magnetic elements. Numerous lines of evidence suggest that they are dominantly responsible for the fact that the Sun is brighter at the maximum of magnetic activity, although in that phase of the SOLAR CYCLE the number of dark sunspots on the solar surface is largest.

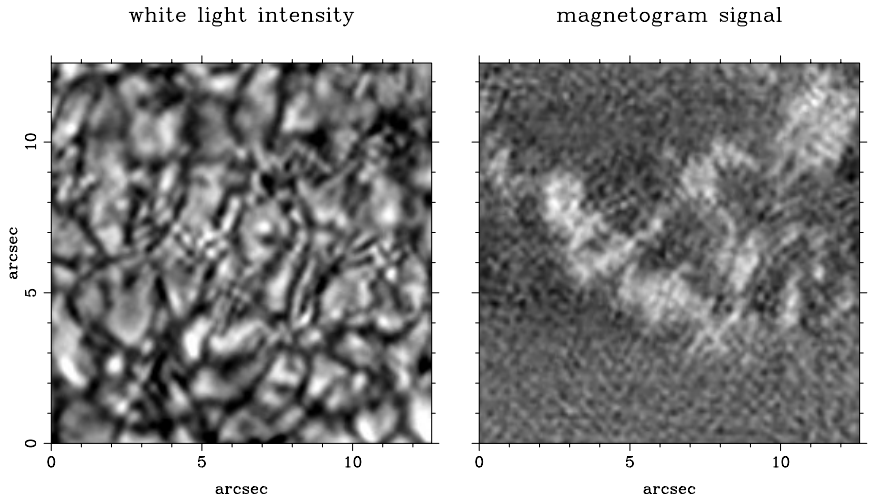

Figure 1. High-resolution white-light image (left) and magnetogram (right). Regions with a magnetic field (i.e. with significant net circular polarization) appear bright in the magnetogram. The pattern of relatively bright cells surrounded by dark lanes in the white-light image are granules. Note the increased small-scale structure at the location of the magnetic field. (Figure kindly provided by C U Keller.)

Two-component model of magnetic elements

An important parameter determining the way in which a solar feature is described by empirical modelers is its size relative to the spatial resolution element of typical observations. If the feature is spatially resolved and does not show significant internal structure then one-component, i.e. purely plane-parallel, modeling is sufficient. Solar magnetic elements, however, are usually not completely resolved, so that two components are required. The first component describes the magnetic flux tubes, the second their (relatively) field-free environment.

Since the Zeeman effect (SOLAR MAGNETIC FIELD: ZEEMAN AND HANLE EFFECTS) not only splits spectral lines, but also polarizes them, the polarization in spectral lines, described by the Stokes parameters, serves as a diagnostic of flux tubes. For a two-component model the observed Stokes profiles (which are averaged over the spatial resolution element) can be written as

$$I_{\rm obs} = \alpha I_{\rm m} + (1-\alpha) I_{\rm s} \quad (1)$$

$$P_{\rm obs} = \alpha P_{\rm m} \quad (2)$$

where $I_{\rm m}$ is the intensity profile arising from the magnetic feature, $I_{\rm s}$ is the intensity from the surroundings, α is the magnetic filling factor (i.e. the fraction of the surface area within the spatial resolution element covered by magnetic field) and $P = Q$, U or V represents in turn the two linearly and the circularly polarized Stokes parameters. It is clear from these equations that in the context of this simple model $Q_{\rm obs}$, $U_{\rm obs}$ and $V_{\rm obs}$ are formed in the magnetic element only. Hence it is possible to obtain information on unresolved flux tubes by observing one or more of the polarized Stokes parameters.

Since the magnetic filling factor is generally far smaller than unity, the intrinsic field strength B of magnetic elements is correspondingly larger than the spatially averaged field strength $\langle B \rangle$. The latter quantity is a measure of the magnetic flux in the spatial resolution element. Typical values of the filling factor α are 1% or less in the quiet Sun, 5–10% in the network and 10–30% in active-region plage.

Flux tube sizes and magnetic fluxes

The true sizes of magnetic elements are highly controversial, since they are either close to or below the size of the spatial resolution element, which can, in the best cases, be as small as 150 km on the Sun, corresponding to an angular resolution of roughly 0.2″. One problem is that achieving this high a resolution in magnetograms is extremely difficult. Standard techniques such as freezing the distortions due to the Earth's turbulent atmosphere by making short exposures fail due to the low signal level in magnetograms (these receive orders of magnitude fewer photons than the brightness images, which can have a much broader wavelength band). Hence most estimates of the sizes of magnetic elements are indirect, based on the sizes of features in an image taken in some proxy of the magnetic field (e.g. bright points in a filtergram taken in the core of a spectral line) under the assumption that there is a one-to-one correspondence between the two sizes. This assumption is difficult to test and is, due to the strong dependence of the contrast of magnetic features on their size, at the most only partly correct.

Magnetic elements probably have no unique size. For example, the sizes of bright points in an active region have been found to be log-normally distributed (just as the sizes of sunspots), with an average value of 220 km. Also, the center-to-limb variation (SOLAR PHOTOSPHERE: CENTER-TO-LIMB VARIATION) of the continuum contrast of faculae (SOLAR PHOTOSPHERE: FACULAE) is best reproduced if they are

composed of a mixture of flux tubes of different sizes (see the section on thermal structure). Direct observations with as high a spatial resolution as possible as well as the comparison of spectral diagnostics with theoretical models suggest that on average magnetic elements are somewhat larger in regions with a greater magnetic filling factor (e.g. in active-region plage) than in regions with a lower average field strength (e.g. in the quiet Sun network). In other words the average diameter of magnetic elements increases with α or $\langle B \rangle$. This relation may break down for the smallest $\langle B \rangle$ values, where the intrinsic field strength, B, instead depends on $\langle B \rangle$.

An open question is whether individual magnetic elements are themselves formed of smaller flux strands and, if yes, what the size of these flux strands is. It has been argued that such flux strands are indeed present and that they are far below the photon mean-free-path in diameter, making them less than 10–20 km broad. At present there is insufficient evidence to confirm or reject this hypothesis.

The magnetic flux per element varies between typically 5×10^{16} Mx for intranetwork elements (i.e. weak magnetic features present within supergranules) over 5×10^{17}–5×10^{18} Mx for typical (bright) magnetic elements to increasingly larger values for points, knots, pores and sunspots. Note that because the intrinsic field strength is almost the same for differently sized flux tubes there is an almost linear relation between flux tube size and magnetic flux. Therefore, the flux per magnetic element also slowly increases with $\langle B \rangle$.

Magnetic field strength and orientation

The most accurate field strength values are probably provided by observations in the infrared (at 1.5648 μm) due to the linear dependence of the Zeeman sensitivity of spectral lines on wavelength. (The Zeeman sensitivity is given by the ratio of Zeeman splitting to Doppler width of the line.) Recent inversions of spectral lines in the visible should also give relatively accurate results. The greatest currently achievable accuracy is roughly 20 G at a given geometrical height in the atmosphere, corresponding to a relative uncertainty of 1–2%. This accuracy allows the small variations in field strength as a function of magnetic filling factor α to be measured. In figure 2 the intrinsic field strength B of magnetic features is plotted versus the spatially averaged field strength $\langle B \rangle$, which is proportional to α over most of the plotted range.

In active regions, i.e. for $\langle B \rangle \gtrsim 100$ G, B increases very slowly with $\langle B \rangle$. At significantly smaller fluxes (below approximately 25 G, corresponding to the network and intranetwork), however, B depends strongly on $\langle B \rangle$. The features with smallest $\langle B \rangle$ are most likely intranetwork magnetic elements. They have field strengths of only a few hundred gauss.

This observed dependence of B on $\langle B \rangle$ is predicted relatively accurately by models describing the formation of intense photospheric flux tubes by the convective collapse mechanism (SOLAR PHOTOSPHERIC MAGNETIC FLUX TUBES: THEORY).

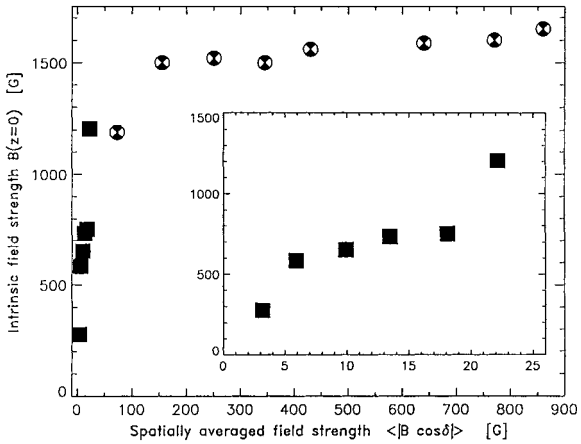

Figure 2. Intrinsic magnetic field strength at the solar surface $B(z = 0)$ versus the unsigned, spatially averaged longitudinal field strength $\langle |B \cos \delta| \rangle$, where δ is the angle between the magnetic vector and the line-of-sight. Plotted are binned values resulting from quiet Sun (squares) and active region plage observations (circles). The inset shows only the leftmost part of the main figure, with the squares being identical to those in the main figure.

Due to the requirement of horizontal pressure balance (which is a consequence of the so-called thin-tube approximation) field strengths of 1500–1700 G at the solar surface imply that the flux tubes are significantly evacuated, i.e. that the gas pressure and density is less than roughly 20–30% of that in the surroundings (at the same geometrical height). Hence, like sunspots, magnetic elements are also thought to possess a Wilson depression, although this has not been directly confirmed (SUNSPOTS: WILSON EFFECT).

This large evacuation implies that the magnetic energy density, $B^2/8\pi$, in the flux tubes is considerably larger than the energy density of the gas inside the flux tube. Equivalently, the plasma beta $\beta = 8\pi p/B^2 < 1$ in the flux tube (where p is the gas pressure). The measured B implies $\beta \approx 0.3$. On the other hand, the high evacuation of the flux tubes also means that the magnetic energy density in the flux tubes is similar to the energy density of the gas in the surroundings and much larger than the average kinetic energy density of photospheric motions. For the intranetwork elements the situation is quite different. The intranetwork fields are in equipartition with the kinetic energy density (i.e. equality of magnetic and kinetic energy density) and thus only weakly evacuated.

The 1.56 μm lines of neutral iron, on which figure 2 is based, are formed deep in the solar atmosphere, near the continuum-forming layer. When spectral lines formed at greater heights are observed then lower values of B are obtained. Consider lines formed at increasingly greater heights in active region plage: the Fe I 6302 Å line gives on average 1400 G, Fe I 5250.2 Å gives 1000–1200 G and the Mg I 12.32 μm line (formed in the upper photosphere just

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

below the traditional temperature minimum) gives 200–500 G. This decrease of B with height is consistent with the roughly exponential height dependence predicted by horizontal pressure balance, suggesting that this is indeed the confining mechanism of the field. The observations therefore suggest that the thin-tube approximation is a good description of magnetic elements.

Theory also predicts that the magnetic field expands with height. This follows from the decrease of the field strength with height and magnetic flux conservation. Various observations confirm this prediction. For example, magnetograms recorded in lines formed at chromospheric heights are far more homogeneous than those recorded in lower-lying, photospheric lines. Also, the spectral shapes of the polarized Stokes profiles of Zeeman sensitive lines formed in the upper photosphere or over a large height range reveal the expansion of the field.

All in all, measurements of the magnetic field strength support the description of magnetic elements as flux tubes shaped by pressure equilibrium.

By using all four Stokes parameters it is possible to determine the orientation of the magnetic vector (with some remaining ambiguity in the orientation of the field component perpendicular to the line of sight). Such observations reveal that magnetic elements have an average inclination of approximately 10° or less to the vertical in both active region plages and the network. Isolated, compact groups of magnetic elements, particularly in active regions, appear to form rosettes, i.e. the flux tubes near the center of the group are vertical, while with increasing distance from the center the flux tubes become increasingly inclined to the vertical. These rosettes have been called azimuth centers. In active regions they are often associated with considerably larger filling factors than the average plage.

There is also evidence that flux tubes with weaker magnetic fields are often considerably more inclined than the kG flux tubes. Thus the weaker intranetwork fields appear to be directed almost isotropically.

A special case of weak fields that are predominantly horizontal are freshly emerging fields. The tops of loops just emerging from the convection zone into the atmosphere are horizontal and have a strength of a few hundred gauss. These freshly emerged fields exhibit a nearly linear relationship between B and inclination. It is speculated that the field intensifies and becomes increasingly vertical as time elapses after its emergence.

Thermal structure

The following three points summarize the main observed thermal properties of magnetic elements.

(a) Small flux tubes are hotter and brighter than larger flux tubes. Equivalently, magnetic elements in regions with small magnetic filling factor are hotter than in regions with large filling factor.
(b) In the continuum-forming layers magnetic elements are cooler than the average quiet Sun *at the same geometrical depth*, but are hotter in the higher layers of the photosphere and in the chromosphere. When converted to equal optical depth, however, the smaller magnetic elements turn out to be brighter than the quiet Sun in all observable layers.
(c) The chromospheres of magnetic elements are particularly hot and bright. The chromospheric temperature rise starts 200–300 km below where it is located in standard models of the average quiet Sun atmosphere.

In the following the above points are discussed in greater detail. The thermal structure of magnetic elements depends sensitively on their size, particularly in the lower photosphere. The continuum-forming layer in small flux tubes is generally hotter than the average quiet Sun. Consequently, these flux tubes appear bright. This is the case, for example, in the magnetic network. As the magnetic flux and hence the average size of the magnetic features increases they become increasingly darker (examples of bright and dark magnetic features are visible in figure 1). Although this qualitative dependence of continuum or white-light brightness on size has been confirmed by different types of observations the absolute value of the brightness is far more controversial. Values of the continuum contrast (i.e. the ratio of the continuum brightness of flux tubes to that of the quiet Sun) range between 1.8 and 0.9 for typical flux tubes. This is because the contrast also depends strongly on other properties such as wavelength, position on the disk and spatial resolution. The highest contrast values are usually obtained at high spatial resolution in broader and bluer wavelength bands, which are more contaminated by spectral lines and thus do not entirely reflect the continuum contrast. A critical assessment of the different determinations in the literature suggests that continuum contrast values of magnetic elements at 500 nm probably lie between 0.9 and 1.3.

Spectral lines are formed at greater height in the atmosphere than the continuum and they clearly indicate an increased contrast. This is illustrated by the G-band (430 nm) image shown in figure 3. At least some of the flux tubes are visible as small bright points. This increased contrast in spectral lines is due to three main reasons. Firstly, it is due to an increasing temperature difference between flux tubes and surroundings with height. A second contributing factor is the large temperature sensitivity of some lines, for example lines of minor ions or molecular lines. Finally, the increased contrast at greater height is due to the expansion of the flux tube with height, so that the atmosphere is increasingly filled with hot gas at greater heights. Since individual flux tubes are usually not resolved this increased filling enhances the brightness.

Figure 4 shows the empirically derived temperature of active region plage and network flux tubes as a function of $\log(\tau_{500})$, the logarithmic continuum optical depth at 500 nm. In this representation the network flux tube model is hotter than the quiet Sun in all layers, whereas the plage

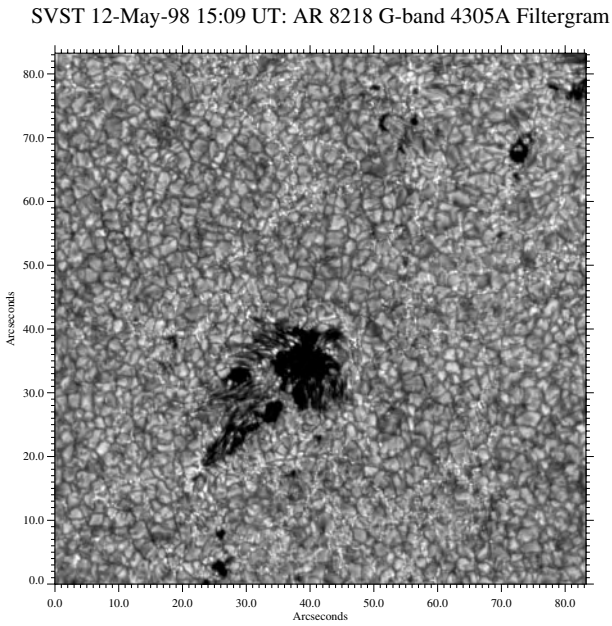

Figure 3. Image of a part of the solar surface obtained in the G-band at 430 nm. In addition to the granulation and the dark sunspot, numerous small bright points are visible. These correspond to magnetic elements or small flux tubes. The high contrast in this image is due to the presence of spectral lines due to the CH molecule in the imaged wavelength band. (Figure kindly provided by T E Berger.)

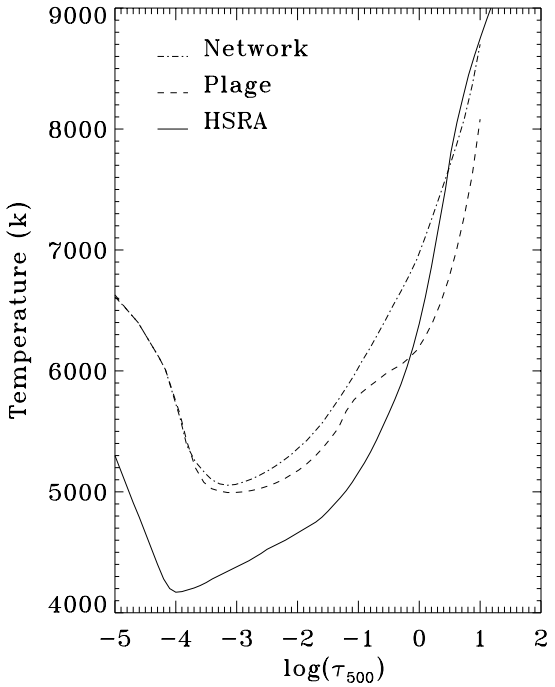

Figure 4. Temperature versus logarithmic continuum optical depth (log τ_{500}) of three empirical model atmospheres. Solid curve: quiet Sun model HSRA; dashed curve: model describing the magnetic elements found in active region plage; dot-dashed curve: magnetic elements forming the network.

flux tube model, which describes somewhat larger flux tubes, is cooler in the lowest layers. If geometrical height were to be used instead of optical depth, then the flux tube curves would have to be moved to the right due to the Wilson depression, so that in the lower photosphere the temperatures of both flux tubes would lie below that of the quiet Sun.

The difference between the two flux tube curves is mainly restricted to the lower photosphere. In the upper photosphere the models are relatively similar. In particular, they show almost identical chromospheric temperature rises. Other observations also suggest that the size dependence of the thermal structure is primarily a property of the lower layers, as long as we don't consider very large flux tubes and extremely high filling factors. In sunspots, for example, the chromosphere starts decidedly higher in the atmosphere than in magnetic elements.

The chromospheric temperature rise seen in figure 4 within the flux tubes sets in 200–300 km lower than in the quiet Sun. This explains the high contrasts seen, for example in Ca II K. The contrast continues to increase with height, so that the contrast in transition region lines (observed in the EUV) is larger than in the visible.

One observation that needs to be reproduced by theory is that whereas the flux tube magnetic field expands rapidly with height in chromospheric layers (forming a magnetic canopy), the brightness structures associated with the field in the chromosphere and transition region are much more compact than expected from such an expansion, partly lying at the resolution limit of 1″ of EUV observations (see CHROMOSPHERE: MAGNETIC CANOPY). Only the central parts of the flux tubes appear to get significantly heated.

Magnetic regions exhibit a definite center-to-limb variation of the continuum intensity. At low and intermediate resolution the continuum contrast is small at the center of the solar disk, but increases rapidly towards the limb. This dependence can be explained by a hot cloud model, in which the temperature difference at a given optical depth increases rapidly with height in the lower and middle photosphere. This, however, does not agree with the temperature stratification derived from Stokes profiles, in particular for network flux tubes (indicated by the dot-dashed curve in figure 4). The center-to-limb variation can also be explained by a geometrical effect, such as the change in visibility of the hot walls of a partially evacuated flux tube as it moves across the disk. In order to reproduce the observations in this manner a mixture of flux tubes of different sizes needs to be present, with smaller flux tubes being bright closer to the center of the disk, while larger flux tubes exhibit the largest contrast near the limb. High-resolution filtergrams support this view. Whereas near the center of the disk the bright features associated with network or facular flux tubes are mainly bright points, often lying at the limit of the spatial resolution, the bright

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

structures forming faculae near the limb are dominantly the considerably larger facular granules.

Lifetimes

The lifetime of a magnetic flux tube can be defined as the time that it exists as a coherent structure before it either splits, merges with others, submerges, etc. Note that the question of a flux tube's lifetime is distinct from the question of how long magnetic flux remains on the solar surface before it is expelled or submerges again.

Determining lifetimes of individual flux tubes is even more difficult than determining their sizes, since the lifetime of a magnetic feature can only be determined if it can be resolved, or at least separated from its neighbors over its whole lifetime. As pointed out in the section on flux tube sizes and magnetic fluxes this is generally not the case, even on individual frames of magnetograms, not to say for whole time series.

Therefore, mainly two types of observations are used to estimate flux tube lifetimes; those which determine the lifetime of a group of flux tubes (e.g. a part of the magnetic network) since only the whole group can be resolved, and those which determine the lifetime of some proxy of the magnetic field (such as bright points seen in filtergrams).

Both methods have their problems, since neither the lifetimes of flux-tube groups nor of proxies need correspond to the actual lifetimes of individual flux tubes (not even by an order of magnitude). For example, the brightness of a magnetic element can fluctuate, due to dynamic processes, in the course of its lifetime (only some fraction of the flux appears bright at any given time).

The former method generally gives relatively long lifetimes for stable structures such as network features (50–100 h), whereas the latter gives extremely short durations (5–20 min). Therefore there is an uncertainty of almost three orders of magnitude in our knowledge of flux tube lifetimes.

Time series of proxies and, in particular, images in the G-band at 430 nm, show a continual motion of bright points along intergranular lanes, together with splittings and mergings, apparently driven by the evolution of the neighboring granules.

Dynamics

Flux tubes harbour a wide variety of dynamic phenomena, such as lateral motions of the whole flux tube, steady flows along the field lines and waves supported and guided by the flux tubes.

Stationary flows in flux tubes

A direct indicator of flows within magnetic elements is the zero-crossing wavelength λ_V of Stokes V. Stokes V is the difference between right and left circularly polarized light and λ_V corresponds to its central wavelength, at which Stokes V becomes zero.

In active region plage no average λ_V shifts greater than 250 m s^{-1} are observed. This is true for all lines formed between the low photosphere and the lower to middle chromosphere. There is, however, also evidence for a small redshift in the magnetic features of approximately 100 m s^{-1} at large μ, with indications of a small blueshift at small μ. Evidence also exists for an increase of the average λ_V shift with decreasing magnetic filling factor.

In contrast to spatially averaged values of λ_V, the spatially localized snapshots of λ_V often show significant blue and redshifts (up to 1 km s^{-1}).

The largest line shifts in the photospheric layers of small-scale magnetic features are, however, associated with magnetic neutral lines. Simultaneous observations of the field strength and flow speed on both sides of the neutral line suggest that these shifts are due to siphon flows along small magnetic loops connecting the opposite polarities, with the flow becoming supersonic near the top of the loop. Siphon flows along magnetic loops are driven by the difference in gas pressure in the two footpoints of the loop, which in turn is coupled to a difference in field strength.

The origin of the line shifts (of both signs) seen in high-resolution spectra is less clear. One explanation also invokes siphon flows along many thin (but probably long) loops. Since matter flows from the footpoint of the weaker field to the more intense field, a distribution of field strengths among neighboring flux tubes could produce up- and downflows in the neighboring flux tubes. Another possibility, namely that these shifts represent snapshots of non-stationary motions, is discussed in the next subsection. Finally, at present we also do not know the cause of the small shifts ($\approx$100 m s^{-1}) of the spatially averaged V profiles. Even such small velocities would drain the corona on a time scale of hours to days in open-field regions unless sufficient matter can diffuse across the field lines into the flux tube, which appears unlikely according to current understanding. An alternative explanation involves a net Doppler shift produced by non-stationary velocities within the flux tube.

Another diagnostic is the observed strong blue–red asymmetry of Stokes V profiles. Both the absolute value of the area, A_b, and amplitude, a_b, of the blue Stokes V wing differ from the absolute value of the red wing area, A_r, and amplitude, a_r, respectively. An asymmetric Stokes V profile is illustrated in figure 5. Quantitatively, this asymmetry may be expressed by the relative amplitude, δa, and area, δA, asymmetry defined as

$$\delta a = \frac{a_b - a_r}{a_b + a_r} \quad \text{and} \quad \delta A = \frac{A_b - A_r}{A_b + A_r}. \tag{3}$$

Close to solar disk center both δa and δA are positive for photospheric lines, although δA almost disappears for the strongest lines. In general, $\delta a > \delta A$. Closer to the limb both δa and δA change sign, i.e. the red Stokes V wing becomes stronger than the blue wing.

It is now generally accepted that for photospheric lines cospatial gradients of the line-of-sight velocity and magnetic vector produce the Stokes V asymmetry. Downflows of 1–2 km s^{-1} in the immediate surroundings

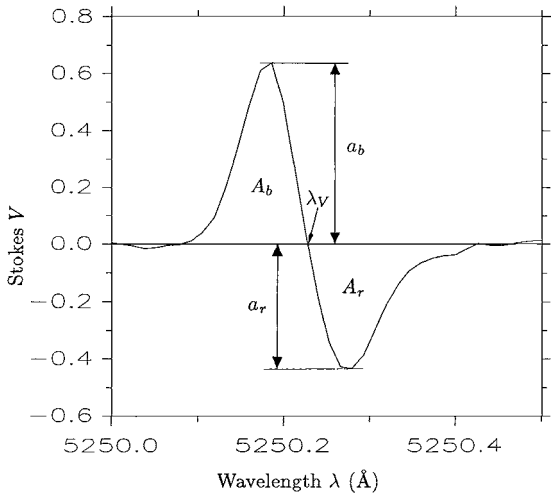

Figure 5. Stokes V profile, i.e. net circularly polarized light, of the Fe I line at 525.2 nm observed in the magnetic network near the center of the solar disk. The zero-crossing wavelength, λ_V, the amplitude, a_b, and area, A_b, of the blue wing of Stokes V and the corresponding red wing parameters, a_r and A_r, are indicated. Note the larger amplitude and area of the blue lobe than of the red lobe.

of the magnetic elements can reproduce the observed δA values without producing any zero-crossing shift if the surroundings are also approximately 200–300 K cooler than the average quiet Sun, highly suggestive of intergranular lanes. This picture of magnetic elements located in the downflowing intergranular lanes is confirmed by direct imaging.

A different view of the production of Stokes V asymmetry is based on the picture that magnetic features are composed of many narrow strands of field, each thinner than the horizontal photon mean-free path. These strands are interleaved with flowing material. Such a model can also reproduce δA and even δa, if two different sets of velocities are assumed to be present in the surroundings.

Traditional flux-tube models with downflows in the surroundings can also simultaneously reproduce δA and δa if flows inside the flux tubes are also allowed. The internal flows may be either a downflow increasing rapidly with depth, or a combination of up- and downflow, suggestive of oscillatory or wavelike motion. Both of these models reproduce the observations equally well, but the latter is to be preferred since it fulfils mass conservation in the flux tube.

In summary, the δA observed in magnetic elements appears to be largely a product of the granulation surrounding the magnetic elements. Conversely, δA can constrain the velocity and the temperature of the convection in active regions, so-called abnormal granulation.

Non-stationary velocities inside flux tubes

The detection of MHD waves in flux tubes is of particular interest, since these are one prime candidate for transporting the energy which heats the chromosphere and which may contribute to the heating of the corona.

A number of diagnostics support the presence of non-stationary velocities in magnetic elements, for example flux tube waves. The most direct of these, time-series of λ_V, have so far mainly uncovered oscillations or waves with a period close to 5 min and an amplitude of 0.2–0.3 km s^{-1} in photospheric spectral lines that increases slowly with height. There are indications that the waves are propagating upwards with a phase velocity of approximately 100 km s^{-1}. The results appear to be relatively independent of the spatial resolution of the observations, which varies between 1″ and 8″.

There is one significant exception to the 5 min periods, however. In an isolated magnetic feature near disk center 100 s periods in λ_V, with a 280 m s^{-1} amplitude have been detected, corresponding to an estimated energy flux of $(1.6–2.3)\times10^7$ erg cm^{-2} s^{-1}, sufficient to heat the associated chromospheric network if the wave is not significantly radiatively or acoustically damped on the way. According to linear theory this period corresponds to propagating longitudinal tube waves, i.e. acoustic waves modified by the magnetic field propagating along the flux tube. Unfortunately, only a single magnetic feature was found to exhibit such oscillations and confirmation is important.

The widths of the V profiles of relatively Zeeman-insensitive lines suggest that non-stationary velocities with much larger amplitudes than those deduced from time-series of λ_V are present in magnetic elements. Typical rms values of such velocities lie around 1.5–2.5 km s^{-1} for photospheric and lower chromospheric lines. These values are equivalent to or larger than those obtained from fits to quiet Sun Stokes I profiles. In the quiet Sun, however, most of the line broadening comes from the granulation, which is, of course, not present within the magnetic features. Therefore, the broadening must be due to an oscillatory or wave-like velocity field, or due to the presence of stationary up- and downflows within different spatially unresolved magnetic elements (e.g. siphon flows on small scales). A fraction of the broadening velocity (10–20%) is detected as the rms of the λ_V spatial fluctuations seen in high-resolution observations (see the section on stationary flows in flux tubes).

The velocity amplitudes deduced from line broadening near the limb are almost the same as near disk center. Similarly, the rms of the λ_V of high-resolution observations does not decrease towards the limb. These two observations suggest that transverse wave modes (e.g. kink mode, torsional Alfvén mode) are just as strongly excited as longitudinal modes (e.g. sausage or tube mode, overstable oscillations). Some evidence of quasi-periodic transverse motions of small-scale magnetic features has indeed been determined (although only for a single feature).

Another possible source of horizontal velocity visible in Stokes V is the motion of complete magnetic elements

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

that are continually being shuffled around by the evolving granulation. Velocities of 0.5–5 km s^{-1} are mentioned in the literature. These have been derived by tracking features in time series of filtergrams or magnetograms. Of interest in this respect are the observations of short-duration rapid horizontal movements of bright points. If bright points are identified with flux tubes the amount of energy generated in the form of an upward-propagating kink-wave pulse along a slender flux tube by the observed rapid horizontal movements may be estimated. It turns out to be sufficient to heat the quiet solar corona, even in the presence of reflections at the SOLAR TRANSITION REGION.

The final parameter indicating non-stationary velocities in magnetic features is the Stokes V amplitude asymmetry, δa. It can be reproduced along with δA and λ_V by a simple representation of a nonlinear wave with different up- and downflow velocity amplitudes, along with a downflow outside the flux tube (see the section on stationary flows in flux tubes).

In summary, some diagnostics indicate the presence of broadening velocities up to 3 km s^{-1} (both Stokes V line broadening and δa give similar velocity amplitudes), but λ_V time series only show rather low-amplitude perturbations, while snapshots at high spatial resolution yield λ_V with an intermediate rms. These results suggest that (a) many flux tubes with tube waves having different phases are present in the resolution element of a given observation, or (b) the tube waves have a very short wavelength and consequently also a short period (if it becomes smaller than the half-width of the Stokes V contribution function of a particular line, the waves become invisible in the λ_V time series of that line), or (c) the dynamical thin-tube approximation breaks down and most of the power is present in higher-order modes having multiple nodes or at least different phases across the cross section of the tube. Such waves are extremely difficult to detect, due to the cancellation of phases when averaging over even a single flux tube.

Bibliography

Photospheric flux tubes are fascinating and heavily investigated objects, so that only some of the many observational results on them could be included in the present article. There are a number of reviews which provide a good introduction to the subject and the literature, some of which also go into greater detail then the present article. General introductory reviews covering both magnetic elements and sunspots have been written by Stenflo (1989, 1994) and Solanki (1998), while reviews dealing with magnetic elements alone (but including both observational and theoretical aspects) have been published by Spruit *et al* (1992), Schüssler (1992) and Solanki (1993), with the last being the most comprehensive in its literature coverage.

Solar Photospheric Magnetic Flux Tubes: Theory

The magnetic field in the photospheric layers of the Sun is found to occur not in a homogeneous form but in discrete concentrations of intense field. The most obvious form of magnetic flux (magnetic field strength times surface area occupied by the field) is seen in SUNSPOTS but it turns out that much smaller arrangements of magnetic field are to be found in the lanes between granules where downdraughts occur (see SOLAR PHOTOSPHERE: GRANULATION). These are the photospheric flux tubes: small-scale concentrations of intense magnetic field. The tubes have diameters of a few hundred kilometers or smaller and field strengths of 1–2 kG. Generally found in intergranular lanes, they are subject to the dynamical nature of the photospheric environment with its sound waves and flows. The tubes are isolated flux tubes in that their immediate surroundings are essentially field-free. See SOLAR PHOTOSPHERIC MAGNETIC FLUX TUBES: OBSERVATIONS.

The small-scale tubes of the photosphere may be thought of as the elemental building blocks of solar magnetism, so an understanding of intense flux tubes has implications for a wider understanding of solar and stellar magnetic phenomena. Theoretical progress in modelling small-scale flux tubes builds on the fact that in such tubes variations across the interior of a tube are less important than variations along the tube.

The elemental photospheric flux tube is taken to be a cylinder of magnetic flux embedded in a field-free environment; the photospheric flux tube is thus a region of locally high Alfvén speed. Two basic speeds prove central to an understanding of tube dynamics: the slow tube speed c_t and the kink speed c_k. These speeds are in turn defined in terms of the sound speed and Alfvén speed. For a tube of magnetic field strength B_0 with plasma density ρ_0 and pressure p_0, the sound speed c_s and Alfvén speed v_A of the tube are defined by

$$c_s = \left(\frac{\gamma p_0}{\rho_0}\right)^{1/2} \qquad v_A = \left(\frac{B_0^2}{\mu\rho_0}\right)^{1/2} \tag{1}$$

where γ (generally taken to be 5/3) is the ratio of specific heats of the plasma and μ is its magnetic permeability.

From the speeds c_s and v_A we may construct the slow magnetoacoustic speed c_t and the kink speed c_k of a tube:

$$c_t = \frac{c_s v_A}{(c_s^2 + v_A^2)^{1/2}} \qquad c_k = \left(\frac{\rho_0}{\rho_0 + \rho_e}\right)^{1/2} v_A \tag{2}$$

here ρ_e denotes the plasma density of the field-free environment of the tube. The slow tube speed and the kink speed are important in coronal flux tubes too (see MAGNETOHYDRODYNAMIC WAVES).

A photospheric flux tube is typically a region of plasma density depletion: the presence of the magnetic field leads to a plasma pressure reduction inside the tube, in keeping with the requirement of transverse pressure balance, and unless there are substantial temperature differences between the tube and its environment then this reduction in plasma pressure is accompanied by a reduction in plasma density. In other words, the magnetic field of a photospheric flux tube partially evaculates the plasma. This is in contrast to the coronal flux tube which is generally a region of plasma enhancement and reduced Alfvén speed, achieved without violation of pressure balance because the strong and pervasive magnetic field of the solar corona can easily accommodate any enhancements or reductions in the plasma pressure.

The thermal structure of a photospheric flux tube is complicated. The tube may exchange heat with its surroundings, through radiative transport and convective energy transport. Detailed numerical studies suggest that photospheric magnetic flux tubes are hotter than their surroundings in their upper layers but cooler than their surroundings in their deeper layers.

The speeds c_t and c_k of a photospheric flux tube are sub-Alfvénic, and the slow speed is also sub-sonic; whether the kink speed is sub-sonic depends on the specific parameters of the tube. A numerical illustration is of interest. In a photospheric flux tube with $B_0 = 2$ kG and plasma density $\rho_0 = 2.2 \times 10^{-4}$ kg m^{-3}, the Alfvén speed is $v_A = 12$ km s^{-1}. Taking the sound speed c_s of the photosphere to be 8 km s^{-1} then gives a slow speed of $c_t = 6.7$ km s^{-1}. For a flux tube that has depleted its plasma density to some 50% of its environment (so that $\rho_0 = \rho_e/2$, consistent with an environment sound speed of 9.6 km s^{-1}), we obtain $c_k = 6.9$ km s^{-1}. Thus the slow speed c_t is some 56% of the Alfvén speed and the kink speed c_k is about 57% of the Alfvén speed. The precise ordering of the two speeds depends on the details of the modelling.

The speeds c_t and c_k are associated with the dynamics of flux tubes, arising in both wave phenomena and flows in tubes. The speed c_t, made up in equal measure of the sound speed and the Alfvén speed, is evidentally associated with the compressibility of the tube. Any squeezing of a tube results in increases in the magnetic pressure and plasma pressure in the tube, which act to restore the undisturbed state. This is a feature shared by all elastic tubes and consequently the equivalent of the speed c_t arises in a variety of other physical situations, with the role of the Alfvén speed being played by the appropriate elastic speed of an elastic tube. For example, in the case of a blood vessel the equivalent of the speed v_A is simply the elastic speed in the membrane of the blood vessel. The speed of sound c_s in blood is much larger than the elastic speed and so the slow speed is close to the elastic speed of the blood vessel. For water in a pipe, the relative magnitudes of the two basic speeds depend on the material of the pipe. In a metal pipe, the elastic speed is much larger than the sound speed in water and so the effective slow speed is close to the sound speed in water (about 1.4 km s^{-1}). By contrast, in a plastic pipe the orderings in the two speeds are reversed and the effective propagation speed is close to the elastic speed in plastic

(about 10 m s^{-1}), lying far below the speed of sound in water.

The kink speed involves both the tube and its environment. The kink wave which propagates with this speed (see below) involves the magnetic tension force in the tube and the kink wave displaces both the tube and its surroundings by about equal measures, hence the combined occurrence of the densities ρ_0 and ρ_e. The speed also arises in the description of magnetoacoustic surface waves on an interface between two plasmas of different properties.

An important question in the physics of photospheric flux tubes is how are they formed. A flux tube with kilogauss field strength requires strong forces to bring about its intense state, with the magnetic pressure $B_0^2/2\mu$ being far in excess of the pressure of converging flows that granulation may provide; the tube finds equilibrium through evacuation of its interior, reducing the plasma pressure and thus allowing magnetostatic pressure balance between the flux tube and its environment to occur. It is envisaged that granulation acts to 'shepherd' flux tubes into the regions where downdraughts between the granules occur. The process is an example of flux expulsion (by advection), whereby the convective flows of the photosphere move magnetic field into intergranular lanes, in keeping with the frozen flux concept of ideal MAGNETOHYDRODYNAMICS. The process is not of itself sufficient to account for the observed field strengths; it brings about the 'seedlings' of photospheric flux tubes but other effects are needed to produce the observationally determined intense field strengths. The additional process that comes into play is driven by the super-adiabatic temperature gradient of the solar convection zone (see SOLAR INTERIOR: CONVECTION ZONE), which in field-free regions drives the convective flows (granules and supergranules; see SOLAR PHOTOSPHERE: SUPERGRANULATION) that distinguish the Sun's convection. In flux tubes, convectively driven flows are channelled by the tubes. The fact that photospheric flux tubes reside in a plasma that is stratified by gravity means that any downdraught generated within a flux tube brings less dense plasma from the higher reaches of the stratified tube to the deeper layers within the tube, allowing the high plasma pressure of the environment to squeeze the tube further. An increase in magnetic field strength results. The process is referred to as convective collapse. It may be described in mathematical detail for a thin flux tube (see below).

A flow in a magnetic flux tube may also develop because of pressure differences between the footpoints of the tube. For example, if the footpoints of a tube are rooted in regions that are magnetically distinct from one another, such as one footpoint in a sunspot and the other in a field-free region, then plasma pressure differences arise and a flow may be driven in the tube. Such motions of the plasma within the tube are called siphon flows.

Waves in photospheric flux tubes

To give a detailed description of the magnetohydrodyanmic waves that an isolated photospheric flux tube supports we consider the equations of ideal MHD. Consider an equilibrium magnetic field $\boldsymbol{B}_0 = B_0(r)\hat{\boldsymbol{z}}$ aligned with the z-axis of a cylindrical polar coordinate system (r, θ, z). To begin with we will ignore the effects of gravity. Then the equilibrium plasma pressure $p_0(r)$ of a radially structured magnetic atmosphere is such as to maintain total pressure balance: the sum of the plasma pressure $p_0(r)$ and the magnetic pressure $B_0^2(r)/2\mu$ is a constant. Where the field is strong, as in the center of a flux tube, the plasma pressure is correspondingly reduced.

Small-amplitude motions $\boldsymbol{v} = (v_r, v_\theta, v_z)$ about a structured equilibrium state satisfy the coupled wave equations

$$\rho_0(r)\left(\frac{\partial^2}{\partial t^2} - v_A^2(r)\frac{\partial^2}{\partial z^2}\right)v_r + \frac{\partial^2 p_T}{\partial r \partial t} = 0 \qquad (3)$$

$$\rho_0(r)\left(\frac{\partial^2}{\partial t^2} - v_A^2(r)\frac{\partial^2}{\partial z^2}\right)v_\theta + \frac{1}{r}\frac{\partial^2 p_T}{\partial \theta \partial t} = 0 \qquad (4)$$

$$\left(\frac{\partial^2}{\partial t^2} - c_t^2(r)\frac{\partial^2}{\partial z^2}\right)v_z = -\frac{c_s^2(r)}{c_s^2(r) + v_A^2(r)}\frac{1}{\rho_0(r)}\frac{\partial^2 p_T}{\partial z \partial t} \qquad (5)$$

with the evolution of $p_T(r, \theta, z)$ described by

$$\frac{\partial p_T}{\partial t} = \rho_0(r)v_A^2(r)\frac{\partial v_z}{\partial z} - \rho_0(r)[c_s^2(r) + v_A^2(r)]\mathrm{div}\,\boldsymbol{v}. \qquad (6)$$

Here $c_t(r)$, $c_s(r)$ and $v_A(r)$ denote the slow speed, sound speed and Alfvén speed within the radially structured plasma, of density $\rho_0(r)$. Equations (3)–(5) come from the components of the momentum equation in which the magnetic force has been expressed in terms of the perturbation in total pressure p_T, defined as the sum of the perturbation p in the dynamical plasma pressure and the magnetic pressure perturbation $B_0(r)B_z/\mu$, with B_z being the component of the perturbed magnetic field in the direction of the applied magnetic field $\boldsymbol{B}_0$. Equation (6) results from a combination of the isentropic (adiabatic) equation and the induction equation of ideal MHD.

One solution of the above equations is the torsional Alfvén wave, which propagates motions v_θ, independent of θ, according to the wave equation

$$\frac{\partial^2 v_\theta}{\partial t^2} = v_A^2(r)\frac{\partial^2 v_\theta}{\partial z^2}. \qquad (7)$$

Torsional oscillations, which have $v_r = 0$, $v_z = 0$ and $p_T = 0$, have a radial dependence determined by the manner in which the oscillations are generated. The oscillations exhibit phase mixing by which radial gradients of the motion grow rapidly in regions where the Alfvén speed $v_A(r)$ varies sharply in r.

In addition to torsional Alfvén waves there are motions that are compressive, with $p \neq 0$ and $p_T \neq 0$. We examine the elemental magnetic flux tube that models photospheric conditions, taking the applied magnetic field

Dirac House, Temple Back, Bristol, BS1 6BE, UK

$B_0(r)\hat{z}$ to be confined within a cylindrical tube of radius a. The plasma pressure and density within the tube are p_0 and ρ_0; the corresponding plasma pressure and density in the tube's field-free environment are p_e and ρ_e. The tube is in magnetostatic pressure balance with its surroundings: $p_e = p_0 + B_0^2/2\mu$. With c_s and v_A now denoting the sound speed and Alfvén speed within the tube and c_e the sound speed in the tube's environment, pressure balance combined with the ideal gas law then shows that the plasma density ρ_0 within the tube is related to the density ρ_e in the tube's environment through

$$\frac{\rho_0}{\rho_e} = \frac{c_e^2}{c_s^2 + \frac{1}{2}\gamma v_A^2}. \tag{8}$$

Thus, for sound speeds c_s and c_e that are roughly comparable, a photospheric flux tube is a region of density depletion (i.e. $\rho_0 < \rho_e$).

Now the media inside and outside the elemental flux tube are uniform, and this affords a considerable simplification. In a uniform medium, the wave equations (3)–(6) may be combined to yield an equation for p_T. Writing

$$p_T(r, \theta, z, t) = p_T(r) \exp \mathrm{i}(\omega t + n\theta - k_z z)$$

provides a Fourier description of the motions, of frequency ω, longitudinal wavenumber k_z and azimuthal number n. The integer $n(= 0, 1, 2, \ldots)$ describes the geometrical form of the perturbations. The case $n = 0$ gives the sausage wave and corresponds to symmetric squeezings and rarefactions of the tube; these are compressional ($p_T \neq 0$) oscillations. The case $n = 1$ describes the kink wave of the tube; in such waves the motion of the tube resembles a wriggling snake, with the whole tube being displaced without changing its cross-sectional shape. Finally, there are also waves with $n \geq 2$; these are the fluting waves.

For a uniform tube, p_T satisfies

$$r^2 \frac{\mathrm{d}^2 p_T}{\mathrm{d}r^2} + r \frac{\mathrm{d}p_T}{\mathrm{d}r} - (m_0^2 r^2 + n^2) p_T = 0 \tag{9}$$

where

$$m_0^2 = \frac{(k_z^2 c_s^2 - \omega^2)(k_z^2 v_A^2 - \omega^2)}{(c_s^2 + v_A^2)(k_z^2 c_t^2 - \omega^2)}.$$

This is a form of Bessel's equation with solution $p_T = I_n(m_0 r)$ inside ($r < a$) the tube; I_n is a modified Bessel function. Similarly, in the field-free environment ($r > a$) of the flux tube, where the sound speed is c_e, a solution p_T proportional to the modified Bessel function $K_n(m_e r)$ arises, where

$$m_e^2 = k_z^2 - \frac{\omega^2}{c_e^2}.$$

It is usual to examine modes for which m_e^2 is positive, corresponding to selecting waves that are confined to near the tube. Then, matching p_T and v_r across $r = a$ results in

$$\frac{1}{\rho_0(k_z^2 v_A^2 - \omega^2)} m_0 \frac{I_n'(m_0 a)}{I_n(m_0 a)} + \frac{1}{\rho_e \omega^2} m_e \frac{K_n'(m_e a)}{K_n(m_e a)} = 0 \tag{10}$$

where a prime ($'$) denotes the derivative of a modified Bessel function (e.g. $I_n'(m_0 a) \equiv \mathrm{d}I_n(x)/\mathrm{d}x$ evaluated at $x = m_0 a$, etc). This is the dispersion relation for tube waves in an isolated magnetic flux tube, requiring that $m_e > 0$; surface waves arise whenever $m_0^2 > 0$, and body waves occur if $m_0^2 < 0$. It is evident that tube waves are dispersive, their phase speed $c(\equiv \omega/k_z)$ depending on the wavenumber (in the combination $k_z a$).

Solution of the dispersion relation (10), for conditions appropriate for an isolated photospheric flux tube, show that there are slow body waves (both sausage and kink) with phase speeds c that lie between c_t and c_s and slow surface waves which have phase speeds that are less than c_t. Also, there is a surface wave with a phase speed close to the kink speed c_k and another surface wave with phase speed near c_e. Fluting modes also have speeds close to c_k.

There is particular interest in waves that are much longer than a tube diameter, corresponding to $k_z a \ll 1$. This is the thin flux tube limit, of special interest for photospheric flux tubes. Since generally $\omega \sim k_z v_A$, the condition $k_z a \ll 1$ corresponds to requiring that periods $\tau(\equiv 2\pi/\omega)$ are such that $\tau \gg 2\pi a/v_A$, giving $\tau \gg 50$ s for a tube of radius $a = 100$ km. P-modes, for example, have periods around 300 s, roughly meeting this criterion. With $k_z a \ll 1$, the slow surface wave has phase speed close to c_t.

Dispersion relations such as equation (10) are important in the development of a nonlinear wave theory for a tube. Indeed, it has been shown that slow (sausage) surface waves have motions $v(z, t)$ along a thin tube which satisfy the nonlinear integrodifferential equation

$$\frac{\partial v}{\partial t} + c_t \frac{\partial v}{\partial z} + \beta_0 v \frac{\partial v}{\partial z} + \alpha_0 \frac{\partial^3}{\partial z^3} \int_{-\infty}^{\infty} \frac{v(s, t)\, \mathrm{d}s}{[\lambda^2 a^2 + (z - s)^2]^{1/2}} = 0. \tag{11}$$

The constants α_0, β_0 and λ depend on the various parameters of the tube.

Equation (11) is sometimes referred to as the Leibovich–Roberts equation. An explicit form of its solution is not known although it is amenable to numerical solution. It is of particular interest because it is associated with soliton behavior. Solitons are nonlinear waves with specific interaction properties that make them worthy of special study. For the related problem of a magnetic slab—the Cartesian equivalent of a flux tube—the equation describing the weakly nonlinear slow surface wave is the Benjamin–Ono equation, i.e.

$$\frac{\partial v}{\partial t} + c_t \frac{\partial v}{\partial z} + \beta_0 v \frac{\partial v}{\partial z} + \alpha_1 \frac{\partial^2}{\partial z^2} \int_{-\infty}^{\infty} \frac{v(s, t)}{s - z}\, \mathrm{d}s = 0 \tag{12}$$

for constant α_1. The Benjamin–Ono equation has been studied extensively and its soliton solution is known explicitly. Equations (11) and (12) may be derived using thin flux tube theory (see below) or from the full equations of ideal MHD, assuming that motions are weakly nonlinear and weakly dispersive.

Thin flux tube theory

The restriction to thin tubes, in the sense that waves are much longer than a tube radius (so that $k_z a \ll 1$), leads to a considerable simplification in the description of the dynamics of photospheric flux tubes, so much so that it becomes possible to include a number of other effects ignored in the discussion of an elemental magnetic flux tube. Of particular importance is the influence of stratification brought about by gravity. The pressure scale height in the photosphere is comparable with a tube radius so the effects of gravity are particularly significant in the photospheric layers of a tube. Other effects, such as radiative transport, may also in principle be included in thin flux tube theory.

To describe motions in a thin tube in the presence of gravity the so-called thin flux tube equations are used. These equations have been used extensively for both analytical and numerical investigations of flux tube dynamics. The sausage and kink modes are treated separately. The thin tube equations for the *sausage mode* (in ideal MHD) are

$$\frac{\partial}{\partial t}\rho A + \frac{\partial}{\partial z}\rho v A = 0 \tag{13}$$

$$\frac{\partial v}{\partial t} + v\frac{\partial v}{\partial z} = -\frac{1}{\rho}\frac{\partial p}{\partial z} - g \tag{14}$$

$$\frac{\partial p}{\partial t} + v\frac{\partial p}{\partial z} = \frac{\gamma p}{\rho}\left(\frac{\partial \rho}{\partial t} + v\frac{\partial \rho}{\partial z}\right) \tag{15}$$

$$BA = \text{constant} \tag{16}$$

$$p + \frac{B^2}{2\mu} = p_\mathrm{e}. \tag{17}$$

In these equations, $B(z,t)$ is the field strength of a thin tube with cross-sectional area $A(z,t)$, and $v(z,t)$ is the longitudinal flow speed within the tube, where the plasma pressure and density are $p(z,t)$ and $\rho(z,t)$. The gravitational acceleration is $g(=274\ \mathrm{m\ s^{-2}})$, acting in the negative z-direction. The external gas pressure $p_\mathrm{e}(z,t)$ is calculated on the boundary of the tube and may vary in response to motions in the tube or its environment; pressure balance across the tube is maintained at all times (as expressed by equation (17)).

In equilibrium ($v = 0, \partial/\partial t = 0$) the thin tube equations for a magnetic flux tube in temperature balance with its surroundings (so that $c_\mathrm{s} = c_\mathrm{e}$) yield

$$p_0(z) = p_0(0)\,\mathrm{e}^{-N} \qquad \rho_0(z) = \rho_0(0)\frac{\Lambda_0(0)}{\Lambda_0(z)}\,\mathrm{e}^{-N}$$

$$A_0(z) = A_0(0)\,\mathrm{e}^{N/2} \qquad B_0(z) = B_0(0)\,\mathrm{e}^{-N/2} \tag{18}$$

where

$$N(z) = \int_0^z \frac{\mathrm{d}z}{\Lambda_0(z)}$$

is the integrated pressure scale height; $\Lambda_0(z)(\equiv p_0(z)g\rho_0(z))$ is the pressure scale height inside the tube. See figure 1.

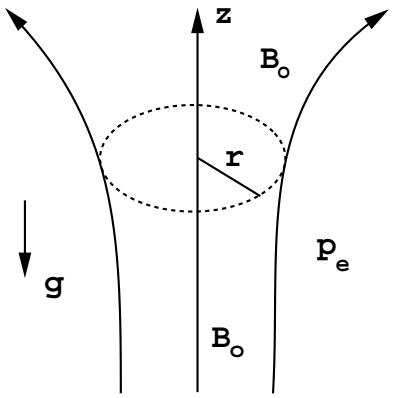

Figure 1. Equilibrium state of a thin magnetic flux tube in a stratified plasma. The tube is confined by the external plasma pressure p_e in the field-free environment of the tube. The region within the tube is generally of lower plasma density than the environment.

The linear form of the thin tube equations is readily found for the equilibrium (18). Ignoring contributions from *variations* in p_e, longitudinal motions are found to satisfy the Klein–Gordon equation

$$\frac{\partial^2 Q}{\partial t^2} - c_\mathrm{t}^2(z)\frac{\partial^2 Q}{\partial z^2} + \Omega_\mathrm{S}^2(z)Q = 0 \tag{19}$$

where $Q(z,t)$ is related to the flow $v(z,t)$ and $\Omega_\mathrm{S}^2(z)$ depends on the details of the equilibrium state.

In an isothermal atmosphere, Λ_0, c_t and Ω_S^2 are all constants, with

$$\Omega_\mathrm{S}^2 = \frac{c_\mathrm{t}^2}{4\Lambda_0^2}\left[\left(\frac{9}{4} - \frac{2}{\gamma}\right) + \frac{4c_\mathrm{s}^2}{\gamma v_\mathrm{A}^2}\left(1 - \frac{1}{\gamma}\right)\right]. \tag{20}$$

The Klein–Gordon equation (19) then yields the dispersion relation

$$\omega^2 = k_z^2 c_\mathrm{t}^2 + \Omega_\mathrm{S}^2 \tag{21}$$

which shows that Ω_S is a cutoff frequency (for sausage waves in a thin tube). Ω_S^2 may be viewed as made up of two contributions, the first (corresponding to the first term on the right-hand side of equation (20)) arising from the geometrical shape of the undisturbed tube and the second (corresponding to the second term on the right of equation (20)) being determined by the tube's elasticity. A rigid tube with exponential cross-sectional area (determined according to the equilibrium (18) with Λ_0 constant) has cutoff frequency $(9/4 - 2/\gamma)^{1/2}c_\mathrm{s}/2\Lambda_0$, whereas a straight and vertical rigid tube has cutoff frequency $c_\mathrm{s}/2\Lambda_0$. In general the cutoff frequency for the sausage mode in a tube is less than the cutoff frequency of a rigid tube.

The Klein–Gordon equation also describes the kink mode in a thin tube. Thin tube equations for the kink mode may be used to describe the transverse displacements $\xi(z,t)$ of a vertical tube, leading to the wave equation

$$\frac{\partial^2 \xi}{\partial t^2} = c_\mathrm{k}^2(z)\frac{\partial^2 \xi}{\partial z^2} + g\left(\frac{\rho_0 - \rho_\mathrm{e}}{\rho_0 + \rho_\mathrm{e}}\right)\frac{\partial \xi}{\partial z}. \tag{22}$$

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

Equation (22) may be cast into an equation of the Klein–Gordon form, just as for the sausage mode. For an isothermal medium, the dispersion relation for the kink mode is

$$\omega^2 = k_z^2 c_k^2 + \Omega_K^2 \tag{23}$$

where the cutoff frequency for the kink mode is

$$\Omega_K = \frac{c_k}{4\Lambda_0}. \tag{24}$$

The forms (19)–(24) allow a direct comparison between sausage and kink modes. For example, with again $v_A = 12$ km s^{-1}, $c_s = 8$ km s^{-1} and $\Lambda_0 = 140$ km, sausage and kink modes both grow in amplitude by a factor of e in propagating a distance of 560 km (four scale heights). The sausage wave, propagating with a speed $c_t = 6.7$ km s^{-1}, has a cyclic cutoff frequency, $\Omega_S/2\pi$, of 4.2 mHz (period 240 s). The kink wave has a speed of $c_k = 6.9$ km s^{-1}, close to the sausage mode's, but its cutoff frequency at 2 mHz (period 500 s) is very different. The sausage mode's behavior is similar to that of a vertically propagating sound wave, which has a propagation speed of 8 km s^{-1} and cutoff frequency of 4.5 mHz (period 220 s), although it e-folds in just 280 km (two scale heights); consequently, sound waves are expected to form shocks lower in the atmosphere than tube waves. The fact that the cutoff frequency of the kink mode is considerably smaller than the cutoff frequency of the sausage wave or a sound wave suggests that kink waves may survive to higher levels in the solar atmosphere than sausage waves or sound waves.

The dispersion relations (21) and (23) imply that an impulsively generated wave (sausage or kink) results in a wavefront which propagates with the speed c_t or c_k, the wavefront supporting an oscillating wake which rises and falls with the frequency Ω_S or Ω_K.

Convective collapse

Convective collapse, the process by which a photospheric flux tube may be formed with kilogauss field strengths, may be demonstrated from the thin flux tube equations for the sausage mode. The differential equation satisfied by the longitudinal flow, Fourier analyzed by writing $v(z, t) = u(z)\exp(i\omega t)$, is

$$\frac{B_0}{\rho_0}\frac{d}{dz}\left(\frac{\rho_0 c_t^2}{B_0}\frac{du}{dz}\right) + \left[\omega^2 - \omega_g^2\left(\frac{c_t^2}{v_A^2} + \frac{\gamma c_t^2}{2c_s^2}\right)\right]u = 0 \tag{25}$$

where

$$\omega_g^2 = \frac{g}{\Lambda_0}\left(\Lambda_0' + \frac{\gamma - 1}{\gamma}\right)$$

is the square of the Brunt–Väisäla (or buoyancy) frequency of a plasma element in a stratified atmosphere. In the atmosphere of a flux tube embedded within the solar convection zone, ω_g^2 is negative and this drives an instability within the tube. The magnetic field may quench the instability if it is sufficiently strong. This is readily illustrated by an approximate solution of equation (25). With the illustrative boundary conditions that $u = 0$ at levels $z = 0$ and $z = -d$, we obtain the approximate solution

$$u(z) = u_0 \exp\left(\frac{z}{4\Lambda_0}\right)\sin\left(\frac{\pi z}{d}\right) \tag{26}$$

with

$$\omega^2 = c_t^2\left[\frac{\pi^2}{d^2} + \frac{1}{16\Lambda_0^2} + \left(\frac{1}{v_A^2} + \frac{\gamma}{2c_s^2}\right)\omega_g^2\right].$$

Hence, if $\omega_g^2 < 0$ then a mode with $\omega^2 < 0$ may arise, corresponding to an instability. The instability amounts to a flow of plasma within the stratified tube; a downdraught brings the more tenuous plasma in the higher levels of the tube to layers deeper within the tube, allowing the external plasma pressure to squeeze the tube. A stronger field results. This is convective collapse. The process is halted when the field strength B_0 is sufficiently large to resist the compression of the tube, and so quench the instability (reducing ω^2 to zero). A flux tube with only moderate field strength finds itself subject to the instability until it has strengthened itself, through convective collapse, to a state where it may resist the process. Consequently, intense and isolated magnetic flux tubes are the expected norm in any medium such as the solar photosphere where convective effects operate in the presence of magnetic field.

A determination of the field strength necessary to quench the instability depends on the precise details of the modelling. Studies of the process under conditions appropriate for the solar convection zone show that kilogauss field strengths are required before the collapse is halted. However, what precisely is the ensuing state of a collapsed flux tube remains uncertain, mainly as a result of the need to take into account a number of detailed and complicated effects ignored in the above treatment. In particular, it is necessary to include the effects of RADIATIVE TRANSFER, nonlinearity and a more realistic choice of flow boundary conditions.

Numerical simulations

Numerical simulations allow the inclusion of a variety of effects that complicate the description of the basic modes of behavior of photospheric flux tubes, and this promotes a more direct comparison with solar observations. By following the motion of a parcel of magnetized fluid (using a so-called Lagrangian approach), it proves possible, for example, to explore the linear and nonlinear sausage and kink modes in a vertical tube or to simulate the convective collapse process. These problems are usually addressed through numerical solution of thin flux tube equations, allowing for the important effects of stratification. Broadly, analytic theory for an ideal plasma has provided valuable insights for the more complex modelling of flux tubes under conditions representative of the solar photosphere. Thin flux tube theory for the kink mode has also been applied to modelling the behaviour of a nonvertical flux tube, addressing in particular the important question of

how magnetic field stored below the convection zone is transported to the solar surface.

An important question still under active consideration is how to incorporate the environment's back-reaction on a moving flux tube. The effect has been explored for the sausage mode and leads to the formation of solitons; the influence of stratification on flux tube solitons has not so far been explored. The back-reaction of the environment on the kink mode is somewhat uncertain, with several alternative possibilities suggested in the literature.

The behaviour of shocks excited within tubes and also the formation of shocks and downflows as a result of the convective collapse of a tube have been modelled in two-dimensional simulations. Numerical simulations have also permitted realistic estimates of the energy flux carried by the various waves, allowing applications to the Sun and stellar atmospheres more generally to be explored.

Solar Probe

Proposed NASA mission to fly through the Sun's corona. Planned launch date 2007. Inserted into an eccentric orbit, it would approach within 3 solar radii of the surface to take *in situ* measurements of the corona, flying from pole to pole. A second flyby may occur in 2015.

Solar Prominence Chirality

A prominence is a relatively cool sheet of dense plasma embedded in the hot tenuous corona. They are easily seen as bright clouds at the 'limb' or edge of the solar disk. When viewed on the solar disk, prominences are long narrow features, i.e. 'FILAMENTS'. Prominences are permeated by weak magnetic fields that are thought to support the plasma against the pull of gravity, and to guide its flows.

In recent years, a global pattern has been recognized in the orientation of magnetic fields inside prominences, especially those 'quiescents' located far away from sunspots. The pattern is characterized by a preferred chirality or handedness in the northern and southern solar hemispheres. The origin of the pattern is controversial at the time of writing, but may shed some light on the large-scale processes involved in the 11-year SOLAR CYCLE.

D Rust discovered the pattern in 1967 from his measurements of the Zeeman effect in prominences that form an east–west chain or crown at high latitudes around the poles of the Sun. (In a magnetic field some spectral lines split into two or more circularly polarized components. This is the ZEEMAN EFFECT.)

Those prominences at the northeast limb had negative field components along the line of sight, those at the northwest limb, positive fields. So both suggested that the component of the field along the long axis of the prominences pointed from east to west. At the same time axial fields in the southern hemisphere pointed east. Rust predicted this pattern would reverse in the next sunspot cycle, cycle 21.

In 1970, J-L Leroy, V Bommier and S Sahal-Brechot, at the Pic du Midi Observatory, began a long series of observations of prominence magnetic fields. They measured the Hanle effect in a strong spectral line of neutral helium, the so-called D3 line at 587.6 nm. This line is emitted by the chromosphere that surrounds and lies under a prominence. When the light in the line is scattered by the helium atoms in the prominence, it becomes linearly polarized. But the magnetic field in the prominence tends to *depolarize* the scattered light. By measuring the amount of depolarization, the French group was able to determine the direction and strength of the magnetic fields.

Leroy's group confirmed Rust's finding of a hemispheric pattern for the axial component of the field in a large sample of quiescent prominences and also confirmed his prediction that the directions of the axial fields would reverse with the onset of cycle 21. Figure 1 is an example of the French group's results. It is a map that shows all the filaments visible on the solar disk during a solar rotation. The arrows show axial field components pointing to the west in the northern hemisphere and to the east in the southern hemisphere. The + and − signs designate the polarity of the weak magnetic fields around the filaments, and the shadings indicate bright Hα active regions.

S F Martin and her associates at Big Bear Observatory extended the Rust–Leroy pattern to lower-latitude prominences. In 1992 they were able to infer the direction of the axial field in a filament from the orientation of small thread-like features ('fibrils') that cluster around a filament in the neighboring chromosphere (see CHROMOSPHERE: FIBRILS).

They discovered a pattern which is implicit in figure 1. The majority of quiescent filaments are either left-handed ('sinistral') or right-handed ('dextral') depending on the direction of their axial fields as seen by a hypothetical observer who stands in the positive magnetic region adjacent to the filament (figure 2). Moreover, most dextral filaments are found in the northern hemisphere, most sinistrals in the southern hemisphere. This relationship remains unchanged, cycle after cycle. Although the absolute direction (eastward or westward) of the axial fields reverses from one cycle to the next, so does the relative position of the neighboring positive magnetic zone.

Filament channels, in which filaments form, are also either dextral or sinistral and also display this hemispheric preference (see SOLAR FILAMENT CHANNELS).

Martin and her colleagues also pointed out a *structural* pattern of chirality in filaments. As seen from above, the 'feet' or 'barbs' of a filament project from the axis in only one of two possible ways, a fact that P Foukal had noticed in 1971. Sinistral filaments are always 'left-bearing', dextral filaments are always 'right-bearing' (figure 2)

Interpretations

D Rust and A Kumar have extended a conceptual model of the solar cycle, due to H Babcock, to explain the chirality of filaments. In Babcock's model (see DYNAMO THEORY) the subsurface magnetic field at the beginning of a cycle extends north–south to connect the poles. As the cycle progresses, differential rotation of the plasma (see SOLAR INTERIOR: ROTATION) wraps the meridianal field lines around the Sun, and forms a system of subsurface magnetic 'ropes' that are inclined from northeast to southwest in the northern hemisphere and oppositely in the southern hemisphere. In the same way that Babcock used these ropes to explain Hale's laws of sunspot polarity, Rust and Kumar use them to explain the handedness of filaments. They picture a filament as a twisted magnetic rope that erupts into the atmosphere, properly oriented with the correct handedness (but see SOLAR PROMINENCE FORMATION).

In an elaboration of their filament model, Rust and Kumar discuss the generation and loss of helicity, the 'twist' of solar magnetic fields. Filaments often disappear by erupting bodily from the Sun. In many cases a helical structure in the filament is seen to unwind during the eruption. Rust and Kumar propose that this helical field is created somehow during the subsurface formation of a filament. Moreover they claim the sense of the filament's twist (clockwise or anticlockwise) is correlated with the direction of its axial field: sinistral filaments are right-handed helices and dextrals are left-handed. Rust and Kumar support their proposal by showing that interplanetary magnetic clouds, which originate in the eruption of a filament, have the same helicity as their

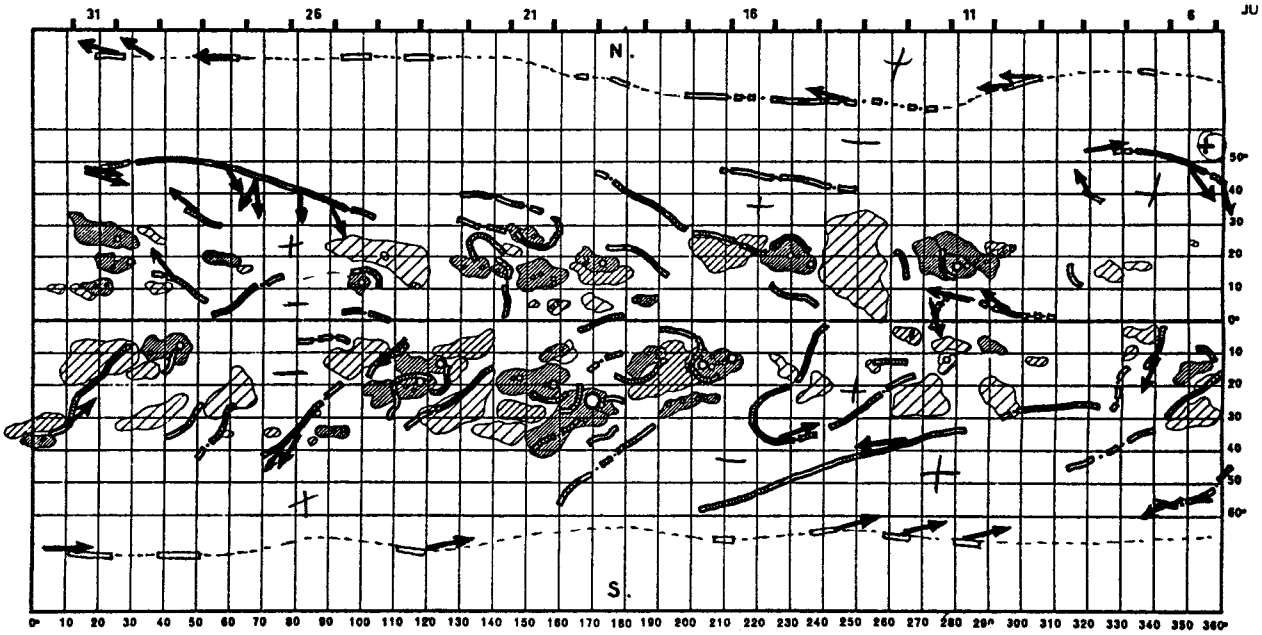

Figure 1. A map of the axial magnetic fields in filaments, over the whole Sun. (Courtesy of J-L Leroy.)

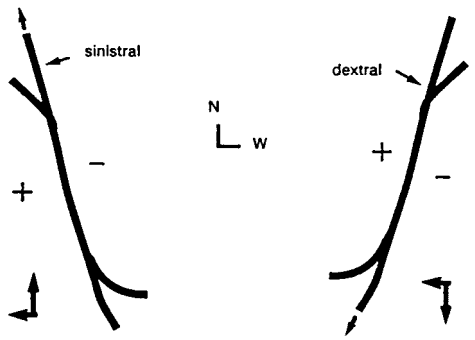

Figure 2. A diagram of sinistral and dextral filaments, showing their axial fields. The small appendages ('barbs') also indicate chirality: as seen from either side of the filament, they bear to the left in the sinistral and to the right in the dextral.

associated filaments. So not only the axial fields of filaments, but also the *twist* in these fields, may show a hemispheric preference.

E Priest and his colleagues also invoke differential rotation to form subsurface magnetic ropes in each hemisphere that have the correct orientations to explain filament handedness. But instead of postulating that the ropes emerge as a whole, they suggest that small loops bob up to the surface and link up, end to end, to form the axial field in a filament (figure 3).

Recently A Van Ballegooijen and his collaborators have explored another scheme, in which only *surface* fields and surface motions are involved. They made numerical simulations of the solar cycle, allowing bipolar active regions to emerge at the observed rates, sizes and latitudes. Simultaneously, three well-known surface flows act on these regions: differential rotation distorts the regions, supergranule cells diffuse their magnetic flux and poleward drifts carry their flux to the poles. The result is the formation of so-called switchbacks, hairpin turns in the curves that divide large areas of opposite magnetic polarity in the photosphere. The authors then examine the coronal fields these processes produce. They find that filaments forming on the preceding branches of such switchbacks would obey the hemispheric rule, but those on the following branches would not, in contradiction to the observations.

It does seem therefore that subphotospheric fields and flows are necessary to explain the observed hemispheric pattern of the chirality of filaments. Other magnetic chirality patterns have been recognized in recent years. A global view of the patterns seems to be emerging.

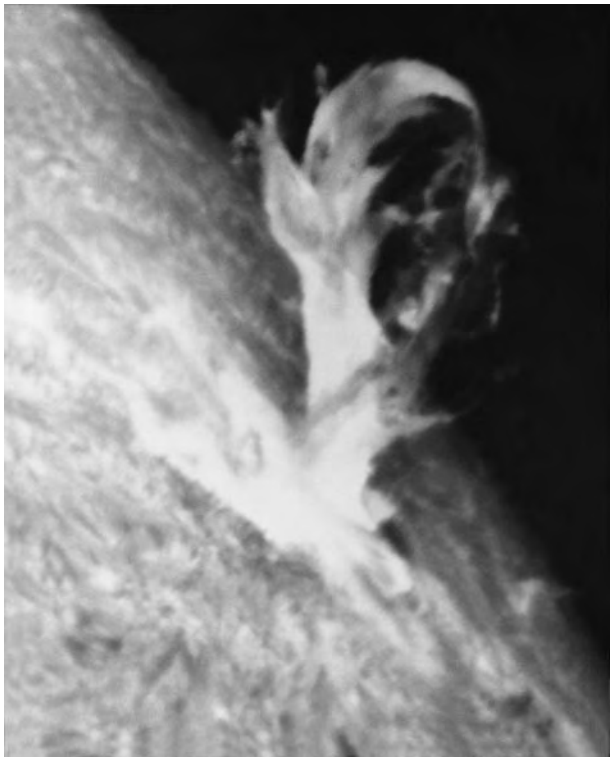

Figure 1. An ejective filament eruption exploding out of an active region near the limb. The expanding filament magnetic flux rope is seen to have overall twist and complex substructure. At this point, about 10 min into the explosion, the filament flux rope has increased in volume by a factor of ∼1000. This photograph is an Hα filtergram (from the Big Bear Solar Observatory); it shows plasma in the erupting filament that is at chromospheric temperatures (5000–10 000 K).

Solar Prominence Eruption

The prominence in a solar prominence eruption is a magnetic structure in the chromosphere and corona (see SOLAR PROMINENCES; SOLAR PROMINENCE: ACTIVE). Prior to its eruption, the prominence is visible in chromospheric images by virtue of chromospheric-temperature plasma suspended in the magnetic field, and belongs to that large class of solar magnetic structures appropriately called solar filaments because of their characteristic sinewy sigmoidal form. Hence, the term 'filament eruption' is used interchangeably with the term 'prominence eruption'. The magnetic field holding a filament is prone to undergo explosive changes in configuration. In these upheavals, because the filament material is compelled by its high conductivity to ride with the magnetic field that threads it, this material is a visible tracer of the field motion. The part of the magnetic explosion displayed by the entrained filament material is the phenomenon known as a solar filament eruption, the topic of this article. Figure 1 shows a filament eruption in progress, exploding up into the corona.

This article begins with a description of basic observed characteristics of filament eruptions, with attention to the magnetic fields, flares, and coronal mass ejections in which erupting filaments are embedded (see SOLAR FLARE OBSERVATIONS; SOLAR CORONAL MASS EJECTION: OBSERVATIONS). The present understanding of these characteristics in terms of the form and action of the magnetic field is then laid out by means of a rudimentary three-dimensional model of the field (see SOLAR FLARE MODELS; SOLAR CORONAL MASS EJECTION: THEORY). The article ends with basic questions that this picture leaves unresolved and with remarks on the observations needed to probe these questions.

Observed characteristics

Every stationary filament, whether or not it eventually erupts, stands over and tracks a neutral line (i.e. a polarity dividing line) in the photospheric magnetic flux (see SOLAR FLARE MAGNETIC FIELDS). The width of the opposite polarity flux areas bracketing the neutral line is typically considerably greater than the height of the filament, and coronal images show a magnetic arcade rooted in the opposite polarities and arching high over the filament. That is, the filament is centered low in the tunnel of the coronal arch of the overall magnetic bipole, suspended in the *core magnetic field*, the field that is rooted near the neutral line and closely envelops the neutral line. The filament and substructure striations within the filament run nearly parallel to the neutral line. This shows that the core field threading the filament runs nearly parallel to the neutral line rather than arching right over the neutral line as it would if it were near its relaxed, minimum-energy potential configuration. In contrast to the core field, the loops of the overall arch of the bipole are more nearly orthogonal to the neutral line. Thus, the form of the filament and its location within the bipole show that the core field is greatly deformed from the potential field configuration, being sheared so that it stretches along the neutral line, and that the core field is more strongly sheared than is the field farther out in the envelope of the bipole.

In a filament eruption, the active agent is the core field in and around the filament; it is the core field that explodes, exploding both itself and the filament that it carries. Thus, the size of a filament eruption is set by the length of the *sheared core field* traced by the filament at eruption onset. This length is a measure of the overall size of the closed magnetic bipole in which the filament and sheared core field are seated. Accordingly, the range of sizes of filament eruptions is more or less the range of the lengths of filaments found on the Sun, and this is roughly the range in the size of magnetic bipoles that occur on the Sun. This range extends from as large as half a solar radius (∼300 000 km) to as small or smaller than the larger bipoles found in the magnetic network ($\lesssim$10 000 km). The magnetic bipoles forming active regions with sunspots, and the filament eruptions in these regions, are usually medium sized, typically ∼30 000 km, but ranging up to as large as 100 000 km at eruption onset. The filament eruption in figure 1 is seated in an active region and is

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills, Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

larger than average: the erupting filament and sheared core field were initially ∼50 000 km long. Although the largest (in span) of all filament eruptions do not occur in active regions, the larger of the filament eruptions in active regions, in particular filament eruptions from between large impacted opposite-polarity sunspots, mark the Sun's most powerful magnetic explosions. This is so because sunspots have the strongest magnetic fields found on the Sun, and consequently the sheared core fields between the largest impacted sunspots have the largest store of non-potential magnetic energy. The very largest filaments and filament eruptions are in quiet regions, on the neutral lines of the bipolar arcades under large coronal streamers. The strength of the filament core field in these is only ∼10 G, a hundred times less than in the most powerful filament eruptions from large sunspot regions. The eruption of one of these largest quiet-region filaments is spectacular, as in the example shown in figure 2, even though the total energy of the explosion is 10 to 100 times less than for the strongest ones in active regions. While the largest filament eruptions occur in only the largest bipoles, which are all in quiet regions, small filament eruptions can occur wherever small bipoles occur, which can be within active regions as well as in quiet regions. However, most of the smallest filament eruptions (from bipoles $\lesssim$10 000 km across) occur in quiet regions, due to the ubiquity of such bipoles in the magnetic network (see CHROMOSPHERE: NETWORK). Because many macrospicules look like small versions of the filament eruptions in figures 1 and 2, it is likely that many macrospicules are small (∼10 000 km) magnetic explosions similar to filament eruptions, and this raises the possibility that many spicules (which are rooted in the network and are similar to macrospicules but smaller) are still smaller analogues of filament eruptions (see CHROMOSPHERE: SPICULES).

There is enough magnetic flux all over the Sun, in all quiet regions as well as in active regions, that the entire solar atmosphere above the photosphere is permeated with magnetic field strong enough to impose its structure on the chromosphere and corona. Consequently, none of the bipoles in which filaments and filament eruptions are seated is totally isolated; instead each is hemmed in to some degree by adjacent magnetic fields. When these adjacent fields are weak relative to the eruption bipole, the eruption proceeds about as it would if there were no adjacent field. Often, some of the adjacent fields, weak or strong, are in other bipoles that have their own sheared core fields. In these cases, a filament eruption in one bipole can trigger and interact with another eruption in one or more adjacent bipoles. The morphology and development of these multiple-bipole eruptions is naturally more complex than in single-bipole events. All of the figures in this article show examples or models of single-bipole events.

The filament eruption in any one bipole, whether or not it is part of a multiple-bipole eruption, is either ejective or confined. In an *ejective filament eruption*, the erupting core field becomes an expanding, twisted, arched magnetic flux rope, the top of which escapes far out of the originally closed bipole while the ends remain rooted in the surface. This requires that the envelope of the bipole also eject along with the filament flux rope, the filament rope riding inside the distending bubble of envelope field. The filament eruptions in figures 1 and 2 are ejective. In a *confined filament eruption*, there is no distinct formation of a monolithic rising flux rope. Instead, there is complex eruptive untwisting and restructuring of the core field as the erupting core field undergoes an overall expansion. The whole eruption is confined and arrested within the enveloping bipole, and the overall magnetic arch of the bipole remains closed throughout the eruption. Figure 3 shows a confined filament eruption from beginning to end. This eruption spans the interior of an active region; so it is of average size and is seated in strong field. As do ejective eruptions, confined filament eruptions occur in quiet regions as well as in active regions, over the same wide range of size and field strength. The factors that dictate whether an eruption is to be confined or ejective are probably specifics of the pre-eruption field configuration and the strength of the envelope field relative to the core field.

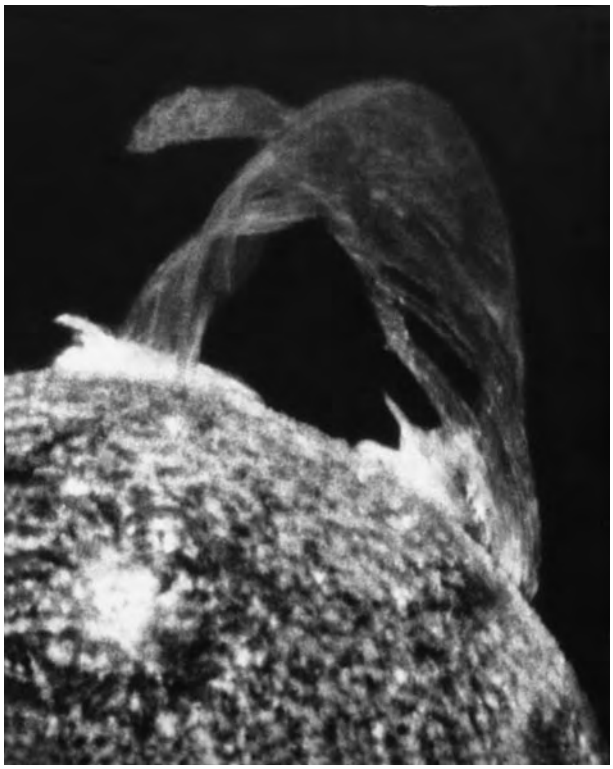

Figure 2. A large filament ejectively erupting from a quiet region on the limb. The many long striations show that the filament material is strung in a twisted magnetic flux rope. This image is an He II 304 A spectroheliogram (from the Naval Research Laboratory's extreme ultraviolet spectroheliograph on Skylab); it shows plasma at transition-region temperatures (∼80 000 K).

Every filament eruption, confined or ejective, is

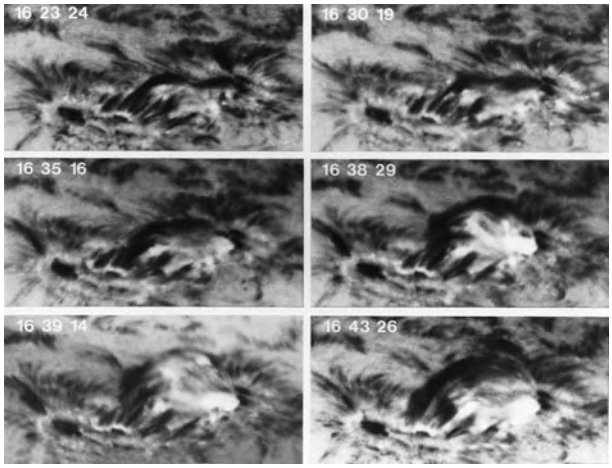

Figure 3. A confined filament eruption in an active region. In this 20 min sequence, the filament core field untwists and expands as it erupts to become a magnetic arch in the interior of this overall bipolar active region. The active-region's opposite-polarity sunspots are seen at opposite ends of the erupting filament and final arch. These images are blue-wing Hα filtergrams from the Big Bear Solar Observatory.

accompanied by increased coronal heating (see CORONAL HEATING MECHANISMS) in the bipole in which it is seated, and every ejective filament eruption, in addition, accompanies the ejection of the corona in and above the bipole, i.e. is an intrinsic part of a larger surrounding coronal mass ejection, the core of which is the ejected filament. Figure 4 shows the coronal mass ejection bubble around an ejected quiet-region filament. The bright twisted loop in the core of the bubble is the filament flux rope from a quiet-region filament eruption like that in figure 2, but at a later phase, farther out in the corona. The corresponding coronal mass ejections for ejective filament eruptions from active regions are similar in overall form to those from quiet regions, but usually accelerate more rapidly to final speeds that are two to five times faster (as fast as 1000–2000 km s^{-1}). Because these fast ejective filament eruptions are always accompanied by a strong flare in the ejective bipole, they are aptly called flare sprays. The burst of heating in any large strong-field filament eruption in an active region produces a major flare in coronal emission, increasing the Sun's total x-ray luminosity by a factor of 10 to 1000. In these eruptions and in many quiet-region eruptions, the enhanced coronal heating begins in the erupting core field at eruption onset, rendering this field visible in coronal images. Coronal images during the onset phase often show the whole core field to have the overall shape of an S or backward S. Later in ejective eruptions, after the filament flux rope has been ejected far out of the bipole, the coronal images show a bright, growing coronal arcade straddling the neutral line. In large weak-field ejective eruptions like those in figures 2 and 4, the coronal heating can be so weak as to be hardly noticeable in the global x-ray luminosity, but is usually strong enough to be

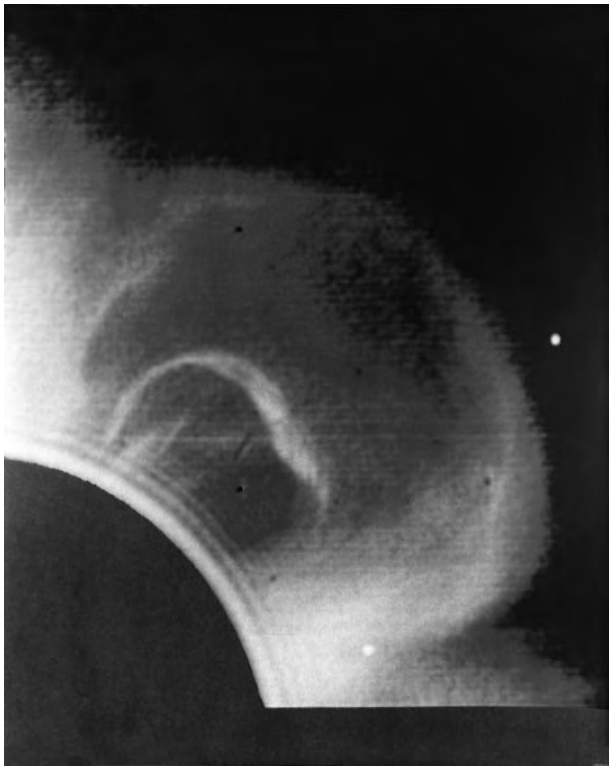

Figure 4. The filament flux rope in the core of the coronal mass ejection from a large quiet-region ejective filament eruption. The ejecting magnetic field, which is traced by and carries the ejecting plasma within it, is seen in the act of exploding out through the corona and into the solar wind. The occulting disk extends half a solar radius above the limb. This white-light image is from the High Altitude Observatory's coronagraph on the Solar Maximum Mission.

seen in coronal x-ray images, at least in the post-ejection coronal arcade. In active-region eruptions the heating also produces flare brightening of the chromosphere at the feet of the field lines threading the coronal heating. In confined eruptions and early in ejective eruptions, this chromospheric brightening occurs close along the neutral line under the filament, as the filament erupts (as in figures 1 and 3). In confined eruptions, coronal images show the filament core field brightening and expanding as it transforms into an arch standing on the chromospheric brightening, as does the chromospheric arch that appears in figure 3 as the eruption ends. In ejective eruptions after the filament is ejected, the chromospheric flare brightening is in two separating ribbons at the feet of the coronal arcade.

Form, energy and action of the magnetic field

The filament eruptions in flares and coronal mass ejections, together with magnetograms (maps of the strength and distribution of the photospheric roots of the magnetic field) reveal that these events are fundamentally magnetic explosions, and that the exploding magnetic field has

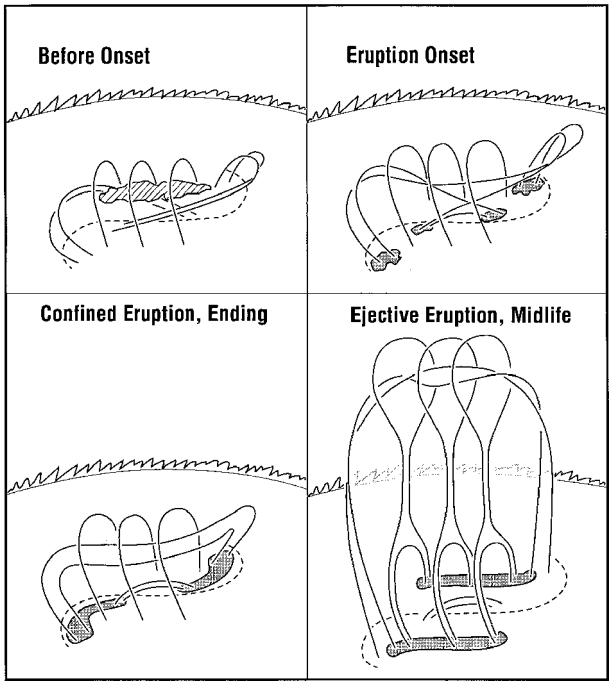

Figure 5. Three-dimensional sketches of the magnetic field before and during filament eruptions. The dashed curve is the polarity neutral line in the photosphere. The diagonally hatched object in the upper left panel is the pre-eruption filament; for clarity of the eruption of the core field that carries the erupting filament material, this material is not shown in the other panels. The gray areas are chromospheric flare brightenings. The ragged arc in the background in the chromospheric limb. Early in the eruption, reconnection occurs in the sheared core field in or under the filament, as in the upper right panel. In ejective eruptions, after the filament flux rope forms and ejects, the ejected envelope field of the pre-eruption arcade is wrapped around the filament core flux rope and forms much of the surrounding expanding coronal mass ejection bubble that envelops the filament core rope, and the stretched legs of the envelope field reconnect to form the growing coronal arcade rooted in the separating chromospheric flare ribbons, as in the lower right panel.

the following characteristics: (a) The pre-eruption field is a closed bipole. (b) The field along the neutral line through the core of the bipole is greatly sheared and has an overall sigmoidal form, so that it traces the neutral line through the bipole and has oppositely curved elbows on opposite ends. (c) The pre-eruption core field has a large store of non-potential magnetic energy. (d) Much of this energy is released by the untwisting and expansion of the filament core field as it erupts. (e) The released energy is comparable to the total energy expended in the accompanying flare and/or coronal mass ejection (up to $\sim 10^{32}$ erg in the largest active-region events).

The evidence for the field configuration and its transformation in the filament-eruption explosion is outlined in the previous section. The sketches in figure 5 show the three-dimensional form, action and reconnection of the magnetic field implied by the observed characteristics of filament eruptions and their observed involvement in flares and coronal mass ejections. In confined eruptions, the overall bipole remains closed, containing and arresting the eruption within it. In ejective eruptions, the entire bipole eruptively opens and simultaneously recloses via the sequence and topology of the reconnection. The expanding ejected filament flux rope and envelope field can continue on to become a coronal mass ejection that blasts out into the solar wind.

Current research

The model sketched in figure 5 displays, for single-bipole filament eruptions, the typical three-dimensional form of the magnetic field and its change in topology as it explodes, to the extent that these have been revealed by the best magnetograms and chromospheric images from the ground together with the best transition-region and coronal images from space. These observations indicate that reconnection occurs, beginning low in the sheared core field early in the eruption, but it is not clear why the reconnection starts or whether the reconnection is essential for the explosion. Basic questions left unresolved by present observations are:

(a) How does the metastable pre-eruption field configuration originate?
(b) How does the configuration destabilize to explode?
(c) Is reconnection necessary for either the triggering or the growth of the explosion?

The observations most needed for answering these questions are vector magnetograms of substantially better sensitivity, spatial resolution and continuity than are now possible from the ground. Vector magnetograms provide a direct measure of the shear in the magnetic field in the photosphere. To probe why and how filaments erupt, the vector magnetograms need to track the development of the entire bipole in which the sheared core field builds up and explodes. It is anticipated that the required improved vector magnetograms, along with simultaneous high-resolution images of the chromosphere, transition region and corona, will be provided from space by the Solar-B Mission currently being developed by Japan, jointly with the United States and the United Kingdom, for launch in 2004.

Solar Prominence Fine Structure

A clear feature of high-resolution observations of quiescent PROMINENCES, both on the disk and at the limb, is the presence of fine-scale fibril structures. The fine structure of prominences provides vital clues to questions such as how prominences form and how they are supported. Magnetic fields permeate the prominence plasma and play a decisive role in shaping the fine structure and its dynamics. Conversely, the shape, orientation and possibly the strength of the magnetic field may be inferred from the observed substructures.

Observations

Limb observations leave little doubt that prominences consist of thin threads and knots. The threads are typically 5000–35 000 km long, and from 200 km to 2000 km thick. The thread thickness appears to increase with height above the solar limb. Threads and bright knots are of similar sizes (figure 1). Since the observed widths of the thinnest threads are of the same size as the instrumental resolution limit, their true widths may be a lot less.

In filaments viewed from above against the disk many threads are inclined to the direction of the long axis of the filament by about 30° (figure 2). Observations near or above the limb reveal a lot of fine-structure inclined by similar amount relative to vertical.

Characteristic properties of prominence threads are listed in table 1.

Threads and the overall structure of prominences

The thin threads (fibrils) of prominences constitute characteristic medium-scale structures.

At some distance from the disk center, quiescent filaments often display a well-defined, sharp upper edge, which is called the filament *spine*. A spine often consists of several to many thin, long absorbing threads. When observed at the solar limb the threads which are associated with prominence spines are not always conspicuous, depending on the perspective from which the prominence is viewed. But overall, the threads then appear to run more or less parallel to the solar surface. They also run parallel to a polarity reversal boundary in the photospheric magnetic fields below. In addition to the threads along the top of the spine, there can be low or intermediate horizontal threads, as well.

Often the ends of a filament fan out in the shape of a thin 'shroud'. This is where the magnetic fields of the threads are thought to connect to the chromosphere; the splayed threads at ends are associated with opposite polarity magnetic fields in the photosphere below. In other cases, at the ends of filaments, the fine threads become vanishingly thin and only an occasional flowing knot of mass reveals the connection of the body of the filament to the chromosphere.

At semiregular intervals along a filament, some threads converge towards one or more points in the chromosphere to the side of the spine. These structures are identified as major 'barbs'. However, amid the multiple-thread barbs, single-thread barbs also join the spine to the chromosphere. These barbs typically curve downward to the chromosphere and, hence, have a large vertical component. Because prominences are dynamic, at any moment in time, some threads can be in transit and might not appear to connect to the chromosphere.

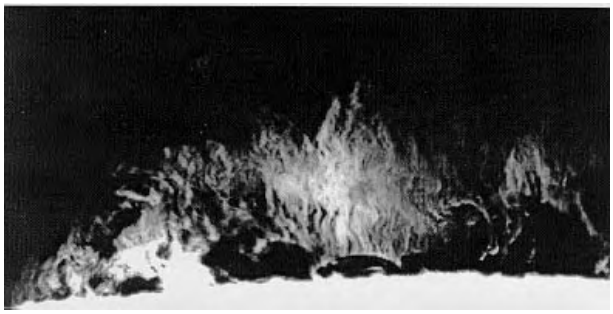

Figure 1. A quiescent prominence showing numerous vertical treads observed in the Ca II K line with the Vacuum Tower Telescope of National Solar Observatories. (Courtesy of Dr R B Dunn.)

The visibility of prominence threads

The observability of prominence threads is restricted by their contrast against the background and the resolution of the observing instrument. High-resolution Hα filtergrams from La Palma have resolved threads with thickness down to about $\frac{1}{3}$ arcsec (250 km on the Sun). However, the true visibility of a prominence thread in hydrogen Balmer lines is a function of temperature and density of the 'cold' plasma. The full length of a magnetic flux tube that forms a thread may escape detection if the plasma parameters vary along the tube.

Number density and filling factor

The number of thin and barely resolvable threads in the line of sight may be estimated by assuming that all threads have the same brightness and that the distribution of velocities is Gaussian. The observed intensity will then increase in proportion to the number of threads. Few threads in the line of sight give rise to large variations in line shift and in line widths, whereas averaging over many threads will produce less variation and wider line widths. Multithread models that are based on Hα spectral data give numbers of threads ranging from a very few up to 100 per resolution element (a few arcsec^2). A recent study based on N V 1238 Å line spectra of a large prominence observed with the SOHO/SUMER instrument gives 15–20 unresolved threads.

It is common practice in solar physics to specify the fraction of the overall volume filled with emitting matter, i.e. emitting and/or absorbing threads, as the filling factor f. Values of f between 0.01 and 0.1 are commonly quoted for prominences.

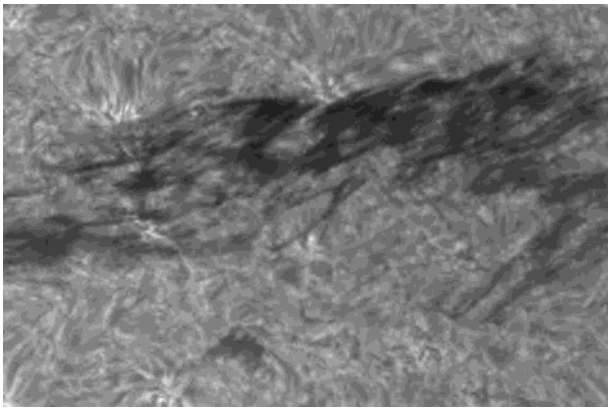

Figure 2. A large polar crown prominences observed with the Swedish Vacuum Solar Telescope on La Palma on 19 June 1998. The Hα filtergram shows that the prominence consists of numerous fine threads which are oriented at an angle of 20°–30° relative to the long axis of the filament.

Lifetimes

In hedgerow prominences (Tandberg-Hanssen 1995) the lifetime of vertical threads is $\leq$10 min. High-resolution Hα filtergrams obtained with the SVST, La Palma (see figure 2), show individual thin filament threads appearing and disappearing in the course of 1 min. This suggests that prominence plasma may be undergoing rapid variations in temperature and/or density. Such short lifetimes might imply that the prominence plasma is not in a stationary radiative state.

Dynamics

The term quiescent is somewhat misleading in describing stable, large prominences, since their small-scale structure is strikingly dynamic. One sees small-scale line-of-sight velocities of a few km s^{-1}, both in horizontal and vertical directions. Limb observations show an apparent random motion of the threads at velocities up to about 8 km s^{-1}. Doppler measurements in disk filaments show both upwards and downwards mass motion (cf Schmieder 1988). The dominant vertical motion in the main body of filaments appears to be oscillatory. SOLAR PROMINENCE OSCILLATIONS in velocity and intensity have periods ranging from less than 1 min to hours; the shorter periods are presumably associated with the small-scale structure.

Time series of Hα filtergrams of large quiescent prominences show bidirectional motions lasting for up to 7 h. Such motions, which are noticed throughout the full body of prominences, in the spine as well as in the more vertical bundles of threads in barbs, suggest that the prominence plasma is flowing along the magnetic field lines.

Interpretation of observations

The magnetic nature of prominence threads

It is generally assumed that prominence threads outline a fine-scale structure of the magnetic fields of solar prominences. This view is supported by the fact that threads typically are inclined by 20°–30° relative to the prominence long axis, which is similar to the general orientation of the magnetic field.

Since the PLASMA β $<$ 1 in solar prominences, i.e. the ratio of gas pressure to magnetic pressure, it is somewhat surprising that their magnetic fields are so highly structured. Therefore, could the fine threads seen in Hα rather be 'veins' of denser and 'cooler' plasma in a relatively uniform magnetic field, instead of individual flux ropes? A uniform field would seem to be at variance with the observed fluctuation in line-of-sight velocity of individual neighboring threads, which seems to imply that the threads represent separate flux tubes. A possible weak interaction between neighboring threads is indicated from observations showing that the *velocity* threads seem to be slightly thicker than the *density–intensity* threads.

Table 1. Characteristic values of prominence threads.

	Value
Width	200–2000 km
Length	5000–35 000 km
Lifetime	1–10 min
Velocity along spine	5–15 km s^{-1}
Velocity variation	
$\perp$ threads	$\pm$5–12 km s^{-1}
$\parallel$ threads	$\pm$1–5 km s^{-1}
Magnetic flux density	4–20 G

Temperatures

The strong EUV line emissions (see SOLAR SPECTROSCOPY: ULTRAVIOLET AND EXTREME ULTRAVIOLET EMISSION) show that solar prominences contain gas at all temperatures between 10^4 K and 10^6 K. Recent observations with the SUMER instrument on board SOHO show that the thread-structure prevails up to temperature $\sim 10^5$ K. Emission measure studies of EUV line emission from quiescent prominences show that the emitting structures have subresolution geometries. The nature of these geometries is still unknown, but the following two scenarios are being considered:

1. Being situated in a hot coronal cavity with cold cores, the threads are 'wrapped' in a thin transition region in a direction perpendicular to the magnetic field.
2. The individual threads are essentially isothermal, but a given thread may attain various temperatures between 10^4 K and 10^6 K.

The tenuous interthread medium could be either hotter or cooler than the threads themselves. It is generally assumed, however, that prominences and their substructures are embedded in hot CORONAL CAVITIES.

Relation to photosphere below

Assuming that single fibrils or threads form on individual thin magnetic flux tubes, these must evidently tie back

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

down onto the chromosphere and photosphere on both sides of the prominence. This tying is most conspicuous where several threads cluster and form barbs. Recent observational results suggest that the magnetic fields of many barbs do *not* connect to the well-known magnetic network that is located at the boundaries of the supergranulation cells below (see SOLAR PHOTOSPHERE: SUPERGRANULATION), but rather to the weaker intra-cell field. Additionally, the lack of merging or embedding of the barb footpoint into the network implies that many barb ends are rooted in the half of the bipolar intra-cell fields that are opposite in polarity to the network magnetic fields. This would be consistent with the few examples of barbs whose rooting is associated with the relatively strong magnetic fields of ephemeral ACTIVE REGIONS or very small active regions. In these cases, the rooting has been identified with the polarity opposite to the network instead of to the polarity that is the same as the network (Martin, 1998).

It is likely that an exchange of mass between the prominence and the photosphere below takes place via these magnetic anchor points.

Modeling of threads

The physical cause of threads or fibrils and their effects on the MAGNETOHYDRODYNAMICS of prominences are not well understood.

Various static models have been put forward to explain the thread-like substructure of prominences. These models all assume a basically horizontal magnetic field to support the plasma.

It is likely that the thermal instability which might be triggering the formation of a prominence as a whole does so preferentially in a filamentary manner. Equilibrium solutions are found that seem to reproduce well the horizontal threads of prominence spines.

On the other hand, modeling of vertical threads that are perpendicular to a horizontal magnetic field meets severe difficulties. At a temperature of 8000 K the hydrostatic scale height in the lower solar corona would be about 200 km. Observations show, on the other hand, that vertical threads are much longer by at least two orders of magnitude. The length-scale associated with normal thermal conductivity perpendicular to the magnetic field becomes very short compared with the length of a typical thread. It has therefore been suggested that anomalous perpendicular thermal conduction, possibly due to turbulence, might produce length scales similar to observed thread lengths. Another idea is that vertical threads could be the result of gravitational Rayleigh–Taylor instability, but such a mechanism would require an extremely high viscosity in order to produce the observed width of a thread.

Other studies of stationary prominence thread models include ambipolar diffusion perpendicular to a horizontal magnetic field. Furthermore, from magnetostatic theory one may derive equilibrium solutions that give long vertical fibrils whose weight may be supported by locally bowed magnetic fields (Lorentz force), which implies strong localized electric currents.

However, none of the static models seems able to explain the dynamic character of prominence threads. The inferred field-aligned flows would suggest that the magnetic fields in prominences barbs are nearly vertical, in which case one would expect to see the cool prominence plasma in the threads sliding down towards the photosphere at 'free fall' velocities. Neither Doppler shifts in prominences seen against the solar disk nor movies of prominences at the solar limb show evidence for 'free fall' velocities at locations where vertical thread structure is clearly developed. The propelling force exerted by weakly damped, high-frequency Alfvén waves is currently being investigated in a search for mechanisms that may counteract gravity in nearly vertical magnetic flux tubes.

Future prospects

Today's solar physicists do not yet fully understand how solar prominences are formed, supported and finally destroyed. More high-angular-resolution, high-cadence studies of the enigmatic fine structure will provide better insight in the basic physics of prominences. Lifetimes of only a few minutes and flow velocities of some km s^{-1} along horizontal and vertical prominence threads, as determined from the best observations of today, could imply that the mass contained in an individual fine thread is continuously being drained and replenished. The notable dynamical and small-scale character of the substructure is an important feature and consideration in modeling of prominence support in the field of gravity. Likewise, the mechanism by which mass is supplied to prominences, through either condensation or inflow from the photosphere below, awaits further observational and theoretical investigations.

Solar Prominence Formation

Most aspects of PROMINENCE formation are only observable against the solar disk where prominences are called 'FILAMENTS'. The formation of filaments can be described as a two-stage process: (1) the development of an environment necessary for filaments and (2) the formation of the filament. After the filament environment is established, the physics of formation of the filament involves two interrelated processes: the formation of the filament magnetic field and the filling of a volume of space within or around that magnetic field with the mass of the filament. Although prominences have been frequently modeled as if they were static structures, there is both old and recent evidence that the formation is a continuous process. Mass is continuously entering and exiting the filament magnetic field throughout its lifetime. It is likely, but not proven, that the magnetic field is also continuously increasing, decreasing or changing. If so, it is necessary to know the properties of the filament environment in order to understand the source of the magnetic field and mass flows in filaments.

The features of a filament environment

The photospheric and chromospheric filament channel

Characteristic features of the filament environment are revealed in the photosphere, the chromosphere and corona. Filaments only form in close association with photospheric magnetic field boundaries where there is a sharp reversal in the direction of the photospheric magnetic field from outward to inward or vice versa. While filaments are not found along all such boundaries, the presence of an apparent 'polarity reversal boundary' is a necessary condition for prominence formation (reviewed in Martin 1990, 1998).

Vector magnetograms have been successfully used to further identify the photospheric magnetic field environment of filaments in active regions. Filaments selectively form only at those boundaries where the magnetic field is both along the polarity reversal boundary and nearly parallel to the photospheric solar surface. When this condition exists, the magnetic field at the polarity reversal boundary does not have a loop configuration across this boundary at either the photosphere or the chromosphere or within the volume of the filament. Instead, in the dimension across the boundary, the magnetic field has a rotational component; precisely at the polarity reversal boundary, the magnetic field, at the photosphere, chromosphere and within the filament above, is parallel or nearly parallel to the boundary (Martin *et al* 1994). This field configuration across the polarity reversal boundary is also described as 'magnetic shear'.

In magnetograms at the photosphere, the polarity reversal boundary is identified by a series of sites where positive and negative network or active region magnetic fields come into contact. Thus, at any given time, the polarity reversal boundary has a precise location; the change in direction of the field at the photosphere occurs in a volume smaller than the spatial resolution of current-day magnetograms. However, this polarity inversion is also a flexible boundary; its exact location at any time is dependent on the slow migration of active region and network magnetic fields of either polarity toward or away from the opposite polarity.

In and around active regions, the chromosphere is largely composed of ubiquitous fine structure called 'fibrils'. They are aligned with the magnetic field. When the fibrils are aligned along a polarity reversal boundary, one of the conditions of filament formation has been satisfied; a chromospheric 'filament channel' has formed and its magnetic field pattern is like the photospheric field pattern (see SOLAR FILAMENT CHANNELS). The channel is more clearly seen when not occupied by a filament. An example of an empty filament channel near an active region with sunspots is shown in figure 1.

In active regions the channel is often extremely narrow, sometimes only 1000 km wide. The length is typically a few to many tens of thousands of kilometers. As the magnetic fields of active regions disperse with age, the magnetic flux density decreases and the scale of the filament channel increases proportionately. In intermediate cases, filament channels are more typically 10 000–30 000 km wide and several hundred thousand kilometers long.

Filament channels also exist along polarity reversal boundaries where the magnetic flux density of the network is very low such as in the polar areas. In these cases, the polarity reversal boundary is identified in magnetograms only by a series of discrete points at the boundaries of the supergranule solar convection cells where opposite-polarity network magnetic fields have become abutted. In these circumstances of low magnetic flux density, the fibril orientations are nearly random. However, the channel (excluding the filament) is characterized nevertheless by an absence of vertical coronal structures and a dominance of horizontal fields. The horizontal fibril structure simply lacks the organization found in filament channels of higher magnetic flux density.

The overlying arcade

Every filament forms beneath a coronal loop system which resembles a tunnel. This system of CORONAL LOOPS is also known as the 'overlying arcade' as it arches over the filament and connects opposite-polarity magnetic fields in the photosphere on the two sides of the filament. These loops and photospheric magnetic fields are the fields of active regions or decaying active regions, fields between adjacent active regions (as in figure 1) or those between merged remnant fields of many active regions. More filaments form beneath coronal arcades joining adjacent active regions than between the loops within an original bipolar active region. There is a relatively large separation between the overlying arcade and the filament both in height and laterally.

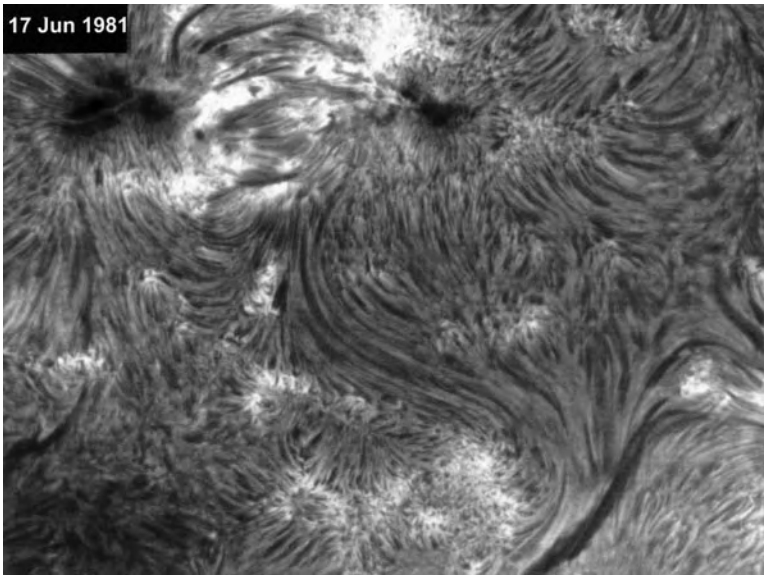

Figure 1. The S-shaped trail of fibrils in the middle of this image is a filament channel. A filament channel typically lies between opposite-polarity magnetic fields at the sides of the channel. Its ends connect to other opposite-polarity magnetic fields. In this case, the channel joins the active region with sunspots in the upper part of the image and another filament channel containing a filament in the lower right. When a filament forms, its axis is aligned with the channel. This H alpha image was recorded at the Big Bear Solar Observatory on 17 June 1981.

The cavity around prominences

Another key feature of the filament environment is the 'filament cavity'. It is a volume of space above and to the sides of prominences where the coronal density is very low at all wavelengths. The physical nature of the cavity has been a mystery. On the quiet Sun, the magnetic flux density at the photosphere beneath the cavity is much less than at the base of the overlying arcade; additionally, the aligned fibrils indicate that the network field becomes mostly horizontal at the base of the cavity. This means that there is very little photospheric magnetic field threading through this part of the corona between the filament and the coronal arcade which defines the outer boundary of the cavity. For pressure balance, the low plasma density implies a slightly higher magnetic field in the cavity rather than a lower magnetic field. This apparent discrepancy of implied higher magnetic field without any associated source of observable photospheric magnetic flux might be resolved by further consideration of new information on the opposing chiralities of the filament channel and the filament (see SOLAR PROMINENCE CHIRALITY). Currently, there is no consensus on the physics of the cavity.

Chirality of filaments and their environment

The chromospheric and photospheric filament channel and the overlying coronal arcade have a property known as 'chirality' which means 'handedness'. The chirality of the pre-filament environment is a new key to filament formation. A filament only forms with the same sign of chirality as its channel. For active-region and intermediate filaments, this leads to the partial alignment of some of the filament structure with the chromospheric fibrils as seen in figure 2 (see also CHROMOSPHERE: FIBRILS). The sinistral (left-handed) filament and channel are on the left in figure 2 and the dextral (right-handed) filament and channel are on the right. The handedness is defined for each solar feature by the orientation of its fine structure relative to the polarity reversal boundary or to the axis of the filament. Looking along the long axis of the filaments in figure 2, the filament fine structures form acute angles to the right of the long axis on the dextral filament but to the left on the sinistral filament.

The coronal arcade is the first condition to be established before a filament can form. The coronal loops within the arcade are either left skewed or right skewed relative to the polarity reversal boundary which it straddles (Martin and McAllister 1995). Again, looking along the polarity boundary, if a coronal loop makes an acute angle to the right, it is defined as right skewed and similarly, if it makes an acute angle to the left, it is left skewed.

The filament channel begins its existence with the reorientation of the chromospheric fibrils; the direction of reorientation determines the chirality of the channel. The fibrils become skewed relative to the polarity reversal boundary in the opposite sense to the overlying arcade. Hence the channel develops the opposite chirality relative to the arcade. When the fibrils above the polarity reversal boundary are completely aligned with the boundary, the channel is fully formed. At this stage, the environmental conditions are suitable for the formation of a filament of the same chirality as the filament channel and opposite

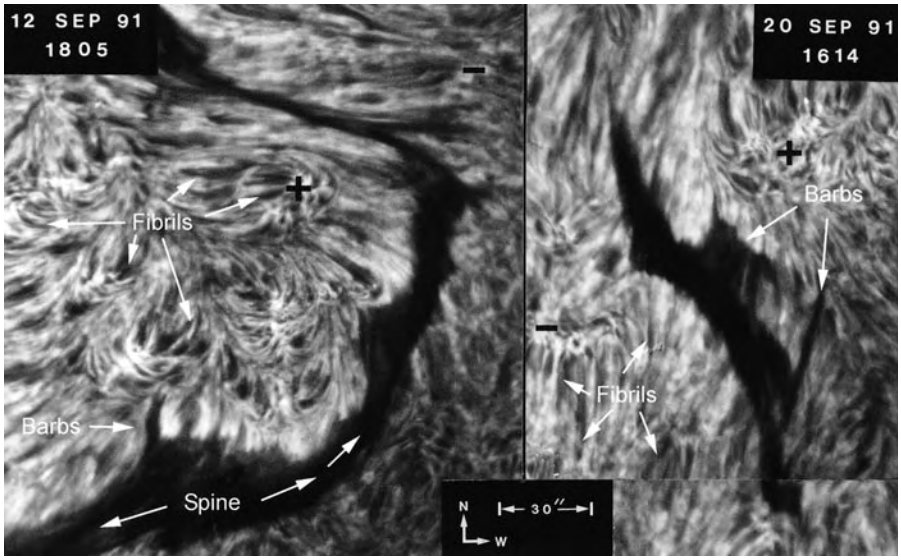

Figure 2. Example of a sinistral filament (left) and a dextral filament (right). This perspective, mostly looking at the filament from above, reveals the approximate alignment of the fine structure of the filament barbs with the chromospheric fibrils. From photographs recorded though an H alpha filter at the Big Bear Solar Observatory.

in chirality to the overlying arcade. The seminal example of channel formation followed by filament formation is illustrated by Gaizauskas *et al* (1997).

Features of the same chirality merge with one another. Examples are the merging of filaments and filament channels on the Sun to make much longer channels and filaments. Filaments and other solar features of opposite chirality remain separate and do not merge (Martin *et al* 1994). Because filaments and their overlying arcades are of opposite chirality, they too should be expected to remain isolated from each other; indeed, they are observed to be separated by the filament cavity. For this reason, it now appears that filaments cannot be formed from the magnetic fields of their overlying arcades. This is a significant new constraint not previously imposed on filament models.

Chirality can be directly interpreted as helicity of the same sign. The significance of helicity in the development of filament channels and filaments and their overlying arcades is not yet fully understood. Filaments and filament channels might develop the opposite sign of helicity from their overlying coronal arcades as a requirement of the conservation of helicity. Another idea is that the eruption of filaments (Rust 1994; see also SOLAR PROMINENCE ERUPTION) and their overlying arcades is a means by which the build-up of excess helicity is removed from the Sun. It has been shown that the chirality of filaments (Rust 1994) and coronal arcades (Martin and McAllister 1997) is directly related to the helicity of interplanetary clouds. Interplanetary magnetic clouds are the expelled parts of coronal arcades and their embedded filament magnetic fields.

Filament formation

Definition of terms

The formation of the magnetic field of a filament can be considered as two stages. The first is the formation of the axial magnetic field along the spine. The spine is the highest horizontal part of the filament. It is thought to be common to all filaments. The mass which forms the spine of filaments only accumulates precisely along and above the boundary between the opposite polarity magnetic fields at the photosphere. The spine lies beneath a coronal loop system but is separated from the loop system by the volume of space called the prominence cavity.

Barbs are appendages along the sides of filaments which extend from the spine to the chromosphere (see figure 2). The pattern of deviation of the barbs from the spine is related to their chirality while the average angle of deviation appears to be inversely related to the magnetic flux density of the surrounding active region or network magnetic fields.

Formation of the spine

There are many alternative models for the structure and formation of the magnetic field of filaments (see SOLAR PROMINENCE MODELS). Until recently, most models have only attempted to explain the spine. There is no consensus on a model for magnetic field structure or mode of formation of spines or barbs. However, there are specific observed properties and dynamics which are relevant to the formation.

The dynamics of filaments, as well as their location along polarity reversal boundaries, indicates that changes in the magnetic field precisely at the polarity inversion are important to the formation of the spine. Filaments

only form when opposite polarity network magnetic fields converge and encounter one another. On encounter, the opposite polarity patches of magnetic field disappear or 'cancel'. Cancellation is defined as the mutual disappearance of magnetic flux of both polarities at a common boundary. The convergence and cancellation of active region or network magnetic fields is a necessary condition for the formation of a filament spine (Martin 1990) but the cancelling magnetic fields can be interpreted in a number of different ways. There is yet no consensus on a single interpretation. Hence prominence models differ widely.

After the specific environment is established, and convergence and cancellation are occurring, pre-filament mass begins to accumulate along the polarity inversion within the cavity of the coronal arcade. The mass can appear as condensations along the polarity inversion above the chromospheric fibrils. It can also appear to be injected along the polarity inversion by surges associated with small flares. In other cases, as in figure 3, the filament appears to grow as an extension of the spine of an initial small filament. The initial development by apparent injection is common in active regions while apparent condensations are more characteristic of filaments forming on the quiet Sun. However, even when apparent condensation is observed, the filament mass is thought to come from the chromosphere. It was previously assumed that the injection was usually not seen because the temperature is too high or the density too low for the mass to be visible. However, high-resolution observations of filaments at diverse wavelengths now reveal some mass inflows from the chromosphere.

The example of filament formation in figure 3 shows a continuity between the classic active region filament and a quiescent filament; the upper end is characteristic of active region filaments and the lower end is characteristic of quiescent filaments. Such examples demonstrate that separate models are not required for filament formation in active regions and on the quiet Sun.

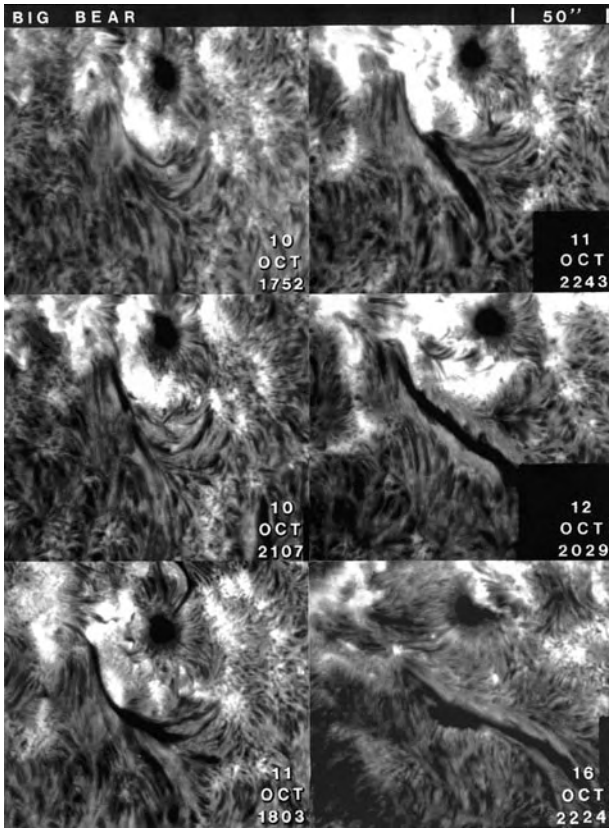

Figure 3. The formation and growth are seen over a 3 day interval from 10 to 12 October. The growth appears as an extension of an initial small filament in the active region. As the filament extends away from the active region, it begins to form conspicuous barbs characteristic of intermediate and quiescent filaments. From a photographic series recorded in H alpha at the Big Bear Solar Observatory.

Formation of barbs

If barbs are seen on active-region filaments within bright plage, they are nearly aligned with the spine. Such filaments are low and narrow and are bounded by regions of high magnetic flux density. They do not necessarily have barbs. Therefore, the barbs are regarded as secondary to the formation of the spine. Barb formation is prevalent at the stage when the active-region fields are dispersed by the large convection cells known as supergranules.

The complete nature of barbs is not known but a number of properties have been identified. There is an anticorrelation of barb ends with network magnetic fields (Engvold 1998). Many chromospheric barb ends are associated with extremely weak magnetic fields. However, recent observations of the formation of some barbs, in concert with the evolution of ephemeral active regions, confirm that some barbs are also associated with strong magnetic fields (Martin 1998). In these cases the barb ends appear to be only linked to the polarity that is opposite to the dominant network magnetic polarity on each side of the filament. This observed linkage implies that the magnetic fields in these barbs has a component opposite in direction to the magnetic component in the overlying arcade that is perpendicular to the filament axis.

The formation of some barbs in conjunction with the small, short-lived, bipolar fields of ephemeral active regions is additional evidence that the filament barbs are secondary to the spine. That is, without the spine, barbs would not form. However, mass is not necessarily visible along the entire magnetic field of the spine in observations of filaments in the light of H alpha. The mass of filaments tends to vary with the magnetic flux density in the adjacent photosphere and with the age of the filament. Among magnetic fields of low flux density, filaments can consist only of a series of tufts of mass along a polarity reversal boundary. These tufts are not necessarily perpendicular to the chromosphere but most have large vertical components and semiregular spacing. They can erupt in unison, which implies that there is a magnetic

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

field composing the spine of the filament which links the tufts together even though the density of mass along the spine can be too low to be visible.

In regions of high to intermediate magnetic flux density, the barbs also maintain a specific pattern in relation to the fibril pattern in the filament channel. While the barbs, except for their endpoints, are above the chromosphere, they have an axis with a horizontal component that is nearly aligned with the fibril structure below. This relationship is readily seen when intermediate filaments are observed from above (as in figure 2). This pattern of the barbs is related to the local magnetic field and identifies their chirality or handedness. The pattern is such that the barb magnetic fields on both sides of a filament always have a component in common with the direction of the magnetic field along the spine of the filament and a component perpendicular to the spine.

Maintenance of a filament

With the discovery of bi-directional streaming in the spines and barbs of filaments (Zirker *et al* 1998), the formation process is more clearly recognized as a continuous process of mass transport into and out of the filament magnetic field. The relative rates of mass inflow and outflow into a prominence magnetic field are important to filament visibility. A filament cannot form unless the rate of plasma inflow exceeds the rate of outflow. To be sustained, the inflow must be equal to or greater than the outflow. The time that mass resides or is recycled along the filament magnetic field is still unknown owing to the difficulty of tracking discrete packets of mass observed in filaments. The duration of any mass in filaments could be only minutes to a few hours. This would mean that a continuous recycling of mass from the chromosphere into the filament magnetic structure and back to the chromosphere is always a normal part of their formation and existence.

The extent to which the magnetic field changes in filaments, along with mass input, is not known. However, many factors indicate the filament magnetic fields are continuously changing by small amounts. These are intermittent cancellation of opposite-polarity magnetic fields along the polarity reversal boundary, the continuous formation and dissolution of barbs, the migration of the barb endpoints, the merging of two filaments to create a single longer one and the formation of a new filament at the location where one has erupted. New filaments commonly develop immediately after the eruption of a filament in an active region. On the quiet Sun, new filaments sometimes form within a few days after the eruption of a quiescent filament. However, reconfiguring of the magnetic field environment, in either case, can also eliminate the conditions necessary for filament reformation.

High-resolution velocity data and magnetic field observations are still needed to answer many remaining questions about filament formation. One of the outstanding questions is how mass is continuously guided into and out of filament magnetic fields

Solar Prominence Models

SOLAR PROMINENCES are ribbons of cool dense gas embedded in the hot tenuous corona, which forms the outer atmosphere of the Sun. Prominence models aim to describe the physical conditions in and near prominences and the physical processes involved in their formation, maintenance and disappearance.

PROMINENCES are located tens of thousands of kilometers above the visible 'surface' of the Sun (the photosphere) and have temperatures $\sim 10^4$ K, a hundred times lower than the temperature of the surrounding corona. The particle densities in prominences range from 10^{16} to 10^{17} m^{-3}, a hundred times greater than coronal values. When viewed above the solar limb, prominences appear as bright features against the dark background. They can also be observed on the solar disk by taking images of the Sun in certain narrow wavelength bands corresponding to strong Fraunhofer lines in the solar spectrum. The higher opacity of the solar atmosphere in a spectral line allows observers to see structures higher up in the atmosphere which are not visible in broad-band 'white' light. One spectral line often used for such studies is the hydrogen Hα line at a wavelength of 6563 Å, which is formed in the solar chromosphere. When observing in Hα on the disk, prominences show up as dark filaments overlying the chromosphere. In the following we refer to these filaments as 'prominences' since they really are one and the same phenomenon.

Prominences are always located at the polarity inversion lines separating regions with opposite magnetic polarity in the photosphere (i.e. lines where the radial component of the photospheric field changes sign). They form in so-called filament channels, regions where the chromospheric fibrils (thread-like fine structures in the chromosphere) are aligned parallel to the inversion line (see SOLAR FILAMENT CHANNELS and SOLAR PROMINENCE FORMATION). The magnetic field in a filament channel is mainly horizontal and directed *along* the polarity inversion line. Filament channels can be classified as *dextral* or *sinistral*, depending on the direction of the axial field as seen by an observer standing on the positive-polarity side. Quiescent prominences in the northern hemisphere are predominantly dextral, while those in the south are predominantly sinistral (see SOLAR PROMINENCE CHIRALITY).

Prominences are large, long-lived structures which can persist for many days, but they usually contain thread-like fine structures which last only a few minutes (see SOLAR PROMINENCE FINE STRUCTURE). Some of these threads are clearly aligned with the local magnetic field, but this is not so obvious for the vertical threads frequently seen in quiescent prominences above the limb. It is unclear, for example, whether the magnetic field in these vertical threads is vertical or horizontal.

Magnetic fields play a key role in many aspects of prominence physics, including their support against gravity and thermal insulation from the surrounding corona. It the following we discuss some of these aspects in more detail.

Prominence support

The outer atmosphere of the Sun is permeated by magnetic field, and this field is also present within prominences, where it provides the magnetic force necessary to support the dense prominence gas against gravity. This magnetic force is made possible by the fact that prominences (and the surrounding corona) consist of partially ionized gas, or *plasma*, in which there is a high concentration of unbound electrons. The electrical conductivity of this plasma is very high, and electric currents can easily flow through the plasma. In such a highly conducting medium the plasma is forced to move *along* magnetic field lines and cannot easily cross from one field line to another. Therefore, a parcel of dense prominence plasma will stay on the field line on which it was originally located. Under the influence of gravity, the parcel will slide down along the field line until it reaches the chromosphere or encounters a 'dip' in the field line where the field is locally horizontal and curved upward. Various models of magnetic configurations with dipped field lines have been proposed (see figure 1). Prominences are thought to be cool plasmas which have come to rest in such dipped (or nearly horizontal) field lines.

Kippenhahn and Schlüter (1957) were the first to develop a model of the equilibrium and stability of prominence plasma in a magnetic configuration with dipped field lines. They assumed a so-called *normal polarity* configuration in which the field lines pass through the prominence from the region of positive polarity (radially outward magnetic field in the neighboring photosphere) to the region of negative polarity (figure 1(*a*)). Kuperus and Raadu (1974) later proposed a different model in which the prominence has *inverse polarity* compared with the neighboring fields (figure 1(*b*)). These figures show vertical cross-sections of a prominence in a plane perpendicular to the long axis of the prominence. It should be kept in mind that in general there is also a component of magnetic field *along* the prominence (into or out of the plane), which often is stronger than the component within the plane. However, as we will see below, this axial component of the field is not essential for prominence support.

The magnetic force in a plasma is given by the Lorentz force, $\boldsymbol{j} \times \boldsymbol{B}$, where $\boldsymbol{B}(\boldsymbol{r})$ is the *magnetic induction* and $\boldsymbol{j}(\boldsymbol{r})$ is the *electric current density*, i.e. the electric current per unit area perpendicular to the current. Hence, to support the weight of the prominence in the dips of field lines, there must exist an electric current which flows through the prominence in a horizontal direction which crosses the magnetic field lines. An important difference between the Kippenhahn–Schlüter and Kuperus–Raadu models is the direction of this electric current: in figure 1(*a*) the current flows out of the plane of the figure (toward the observer), whereas in figure 1(*b*) the current flows into the figure (away from the observer). Moreover, in the Kuperus–Raadu model the current is present not only inside the prominence, but also in the 'magnetic island' just above the prominence, as indicated by the cross in figure 1(*b*).

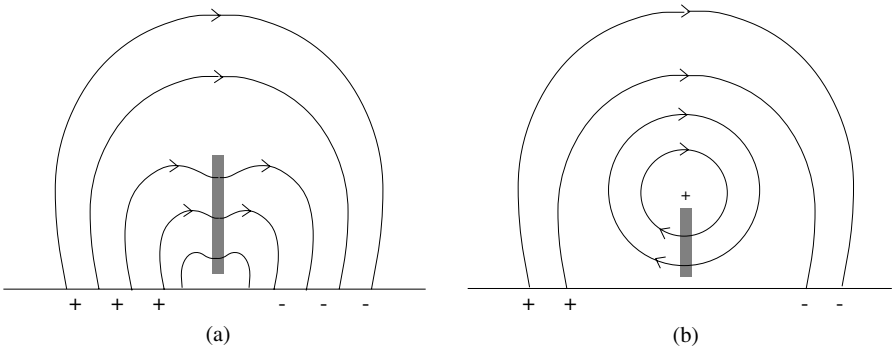

Figure 1. Two models of the magnetic field supporting a solar prominence: (*a*) Kippenhahn–Schlüter model; (*b*) Kuperus–Raadu model. These figures show the projection of the field lines onto the plane perpendicular to the long axis of the prominence (shaded region). The horizontal line at the base indicates the solar photosphere.

The plasma within the prominence is subject to three forces: (1) the Lorentz force, $\boldsymbol{j} \times \boldsymbol{B}$; (2) the gravitational force, $-\rho g \hat{\boldsymbol{z}}$, where $\rho(\boldsymbol{r})$ is the mass density, g is the acceleration of gravity and $\hat{\boldsymbol{z}}$ is the radially outward direction on the Sun; (3) the force due to the gradient of gas pressure, $p(\boldsymbol{r})$. In equilibrium these forces must balance each other:

$$-\boldsymbol{\nabla} p - \rho g \hat{\boldsymbol{z}} + \boldsymbol{j} \times \mathbf{B} = \mathbf{0}. \tag{1}$$

Using Ampère's law, the electric current density can be written as $\boldsymbol{j} = \mu^{-1} \nabla \times \boldsymbol{B}$, where μ is the magnetic permeability. The mass density can be written as

$$\rho = \frac{mp}{kT} \tag{2}$$

where $T(\boldsymbol{r})$ is the temperature, k is the Boltzmann constant and m is the mean mass per particle (m lies between 0.6 and 1.3 times the proton mass, depending on composition and ionization state of the plasma). Kippenhahn and Schlüter (1957) modeled the prominence as a thin vertical sheet in which the pressure $p(x)$, density $\rho(x)$ and vertical magnetic field $B_z(x)$ depend only on the horizontal coordinate x perpendicular to the sheet. The temperature T and horizontal field components B_x and B_y are assumed to be constant. Then the x- and z-components of equation (1) reduce to

$$-\frac{\mathrm{d}}{\mathrm{d}x}\left(p + \frac{B_z^2}{2\mu}\right) = 0 \tag{3}$$

$$-\rho g + \frac{B_x}{\mu}\frac{\mathrm{d}B_z}{\mathrm{d}x} = 0. \tag{4}$$

The boundary conditions far away from the sheet ($x \to \pm\infty$) are $p \to 0$ and $B_z \to \pm B_{z\infty}$. Integrating equation (3) yields

$$p = \frac{B_{z\infty}^2 - B_z^2}{2\mu} \tag{5}$$

and, using equations (2) and (5), equation (4) yields a differential equation for B_z which has the following solution:

$$B_z(x) = B_{z\infty} \tanh \frac{B_{z\infty} x}{2 B_x H_p}$$

$$p(x) = \frac{B_{z\infty}^2}{2\mu}\left(\cosh \frac{B_{z\infty} x}{2 B_x H_p}\right)^{-2}.$$

Here $H_p \equiv kT/mg$ is the so-called *pressure scale height* which describes how rapidly the pressure and density fall off with height along the field lines ($H_p \sim 200$ km within the prominence). Note that the plasma pressure at the center of the prominence sheet is equal to the external magnetic pressure associated with the *vertical* component of the magnetic field and that the width of the sheet is of order $4(B_x/B_{z\infty})H_p$. The observed widths of quiescent prominences (~8000 km) can be reproduced with $B_{z\infty} \sim 0.1 B_x$, in other words, the support of the prominence requires only a minor perturbation of the surrounding magnetic field.

In general there is also a component of magnetic field along the prominence (B_y), so the normal polarity field shown in figure 1(*a*) is actually a sheared arcade (with dips at the loop tops), and the circular field lines in figure 1(*b*) are actually helical windings which are wound around a horizontal axis that runs parallel to and above the prominence. Therefore, to obtain a more accurate picture of the prominence magnetic field we must consider its full three-dimensional structure.

Prominence magnetic structure

There exist a variety of methods for measuring the magnetic fields in and around prominences, most of which are based on the *Zeeman effect* (the splitting of atomic energy levels in the presence of a magnetic field). The Zeeman effect causes the light emitted in a spectral line to become circularly polarized. By measuring the degree of circular polarization it is possible to deduce the component of magnetic field along the line of sight in a prominence. Another method is based on the fact that much of the light emitted by a prominence above the solar limb is actually scattered light which originates from the chromosphere

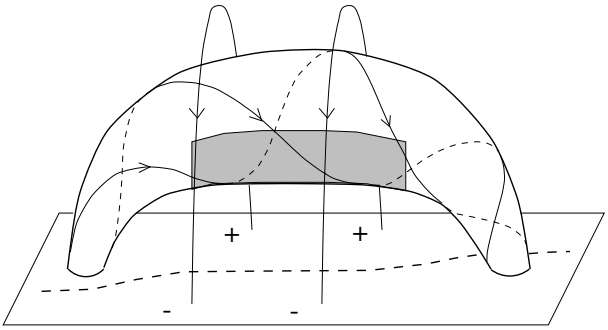

Figure 2. Twisted flux tube model for solar prominences. The prominence sheet is indicated by the shaded region.

below. The magnetic field affects the scattering properties of the atoms, and manifests itself as a change in the state of linear polarization of the scattered light in certain spectral lines. This so-called *Hanle effect* allows observers to deduce both the strength and direction of magnetic fields in prominences. Observational studies have shown that the magnetic fields in quiescent prominences are in the range (3–30) $\times 10^{-4}$ T and that the field is mainly directed along the length of the prominence: the magnetic vector is inclined to the prominence axis at an average angle of about 25° (Leroy 1989). Most quiescent prominences have *inverse* polarity, i.e. the magnetic field traverses the prominence from the region of negative polarity to the region of positive polarity, opposite to what would be expected for a coronal arcade. The field strength increases with height in the prominence.

These observations are consistent with the idea that a quiescent prominence is located within a large, twisted flux tube or flux rope (see figure 2). A number of authors have developed prominence models based on this idea (e.g. Priest *et al* 1989). According to these models, an arched flux tube is anchored in the photosphere at two ends, and the field lines in the coronal portion of the tube make one or two revolutions about the tube axis, forming a helical field. Overlying this helical field is a coronal arcade, which probably plays an important role in the equilibrium and stability of the field. Cool prominence plasma is supported at the troughs of the helical windings where the field lines are curved concave-upward. This twisted flux tube model has many features which agree with observations, including the inverse polarity of the magnetic field in the prominence and the fact that when a prominence erupts it sometimes looks like a twisted tube (see SOLAR PROMINENCE ERUPTION).

How does the Sun produce such helical fields? One possibility is that the twist is produced by vortical motions of the photospheric footpoints of the tube, but this would require persistent twisting over several revolutions, which is not observed. Another possibility is that the twisted flux rope is created in the convection zone below the photosphere and emerges through the photosphere with its twisted structure already formed (e.g. Rust and Kumar 1995). A third possibility is that the helical field is produced by magnetic reconnection, i.e. the reconfiguration of magnetic field lines due to plasma resistivity effects (see MAGNETIC RECONNECTION). For example, Pneuman (1983) proposed that the radial outward distension of a bipolar region by gas pressure gradients could lead to an inward collapse of the region, causing the field lines to reconnect. If the initial field is significantly sheared along the polarity inversion line, reconnection produces helical field lines in the region above the reconnection site.

Observations indicate that prominences tend to form in regions where opposite-polarity flux is being cancelled at the polarity inversion line. In a sheared coronal arcade magnetic flux cancellation can proceed only if reconnection occurs in the region just above the inversion line (van Ballegooijen and Martens 1989). The process is illustrated in figure 3, which shows the evolution of a sheared arcade in response to converging motions of the photospheric footpoints. The initial field is assumed to be sheared (figure 3(*a*)), which may have been caused by flows along the inversion line or by some other effect. When the footpoints of the coronal loops are pushed to the inversion line, the loops become more and more aligned with the inversion line, eventually causing different loop systems to reconnect (figure 3(*b*)). The model assumes that the short, highly curved loops produced by such reconnection are pulled below the photosphere by magnetic curvature forces, causing magnetic flux to disappear from the photosphere (flux cancellation). However, the reconnection also produces longer loops which remain in the corona because their curvature radii are too large to overcome the buoyancy forces at and below the photosphere. As overlying loops are pushed to the inversion line, further reconnection produces helical loops in which a prominence can form (figures 3(*c*) and 3(*d*)). As more and more flux is forced to reconnect at the inversion line, the width of the helical flux tube gradually increases and the axis of the tube slowly rises. Eventually the magnetic structure becomes unstable, causing the helical field to erupt.

Origin of prominence plasma

How do prominences acquire their mass? One viewpoint is that prominences are formed by the cooling and 'condensation' of plasmas from the surrounding corona (see Priest 1982, chapter 11). To understand how this happens, we must consider the energetics of the coronal plasma. A hot gas such as the corona is subject to radiative cooling, i.e. the loss of thermal energy due to collisional excitation of ions by electrons and the subsequent emission of radiation at extreme ultraviolet and x-ray wavelengths (the corona is optically thin, so this radiation can freely escape into space). The rate of energy loss per unit volume is approximately given by $n_e^2 \Lambda(T)$, where n_e is the electron density, T is the temperature and $\Lambda(T)$ is the so-called radiative loss function, which depends on atomic parameters and the chemical composition of the plasma. In a coronal loop

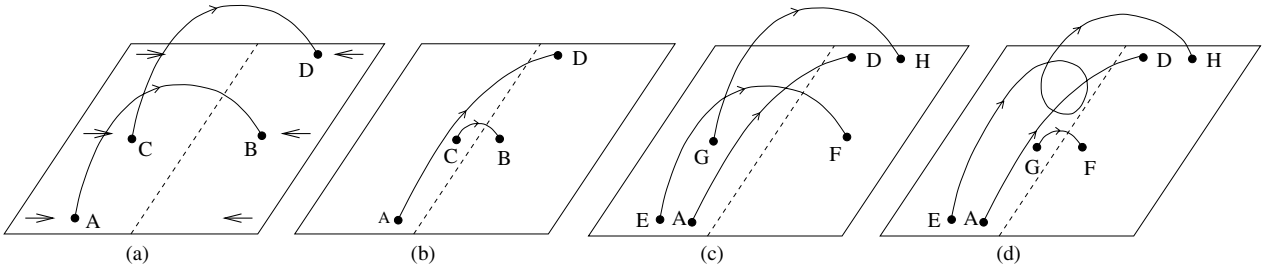

Figure 3. Flux cancellation in a sheared coronal arcade. The rectangle represents the solar photosphere, and the broken line is the polarity inversion line. (*a*) Initial sheared field subject to converging flows. (*b*) Reconnection produces a long loop AD and a shorter loop CB, which subsequently disappears below the photosphere. (*c*) Overlying loops EF and GH are pushed to the inversion line. (*d*) Reconnection produces the helical loop EH and a short loop GF, which again submerges.

these radiative losses are balanced by heating due to dissipation of magnetohydrodynamic (MHD) waves or other disturbances. Electron thermal conduction plays an important role in redistributing this heat along the coronal loop. However, as coronal conditions change, the density and/or loop length may slowly increase with time, causing radiative losses to become more important relative to conduction. Eventually, the coronal loop may reach a point where a stable equilibrium between energy gains and losses is no longer possible. The plasma then rapidly cools and settles into a new equilibrium with much lower temperature but higher density. This condensation process occurs for a wide range of forms of the heating function.

A difficulty with the above scenario is that the mass of a quiescent prominence ($\sim 10^{12}$ kg) typically exceeds the mass available in the surrounding corona before the prominence is formed. Therefore, additional mass must somehow be supplied to the prominence. One possibility is that the mass is injected along the field lines that connect the prominence with the chromosphere below. This could be in the form of a *siphon flow* driven by a possible pressure difference between the chromosphere and the prominence. Another possibility is that cool plasma is lifted up by magnetic fields as they rise through the chromosphere. For example, in the flux rope model of Rust and Kumar (1995), the twisted flux rope emerges from the convection zone and sheds most of its mass on it way up into the corona (the density in the corona is much less than that in the convection zone). However, a small fraction of the initial mass remains trapped in the troughs of the helical windings. This remnant is believed to form the prominence.

Observations suggest that prominences are very dynamical structures, with plasma continually draining downward and new material being injected into the prominence. Priest *et al* (1996) propose a model in which the prominence is maintained by a continual input of mass and magnetic flux from below. In this model the correct dextral and sinistral patterns for high-latitude, east–west prominences are produced by the combined effects of differential rotation acting on subphotospheric flux, its subsequent emergence by magnetic buoyancy and its rearrangement by reconnection to form a filament channel with magnetic flux oriented along its axis. Continual emergence and reconnection creates a prominence as a flux tube along the filament channel and filled with cool plasma which is lifted up from the photosphere and chromosphere by the reconnection process. According to this model, reconnection occurring in the chromosphere yields prominence densities in rough agreement with observations.

Thermodynamic modeling

The temperature within a prominence is determined by the balance between heating and cooling of the prominence plasma. There are several possible contributions to the heating: (1) energy may be transported into the prominence by thermal conduction from the hot corona, but this is not very effective in the low-temperature prominence material; (2) the plasma can be heated by dissipation of MHD waves or other disturbances which propagate into the prominence from the sides; (3) the prominence may be heated by absorption of ultraviolet radiation from the chromosphere. The energy losses occur mostly in the form of radiation in hydrogen spectral lines and continua (Lyman and Balmer series). The radiation transport is complicated by the fact that prominences are optically thick at these wavelengths, which means that the ultraviolet radiation is reabsorbed and reemitted many times before it finally escapes. Another complication is that prominences have a filamentary structure, with thin (sometimes vertical) threads of dense plasma embedded in a much more tenuous medium. This allows the ultraviolet radiation to penetrate deep into the prominence, greatly enhancing the excitation rate compared with models without such fine-scale structures (Heasley and Mihalas 1976). The cause of these fine structures is not yet understood.

Solar Prominence Oscillations

SOLAR PROMINENCES are continuously subject to oscillations in response to ambient atmospheric perturbations. These vibrations can be of global nature, for example when a large-scale disturbance, carrying considerable energy, impinges on the broad side of the prominence body and shakes its whole structure, or of local nature, when the prominence material is perturbed by motions in the SOLAR PHOTOSPHERE, CHROMOSPHERE or CORONA. In any case, the response of the PLASMA is directly related to its physical parameters, so the investigation of this type of phenomenon can provide information on the physics of prominences.

The research of prominence oscillations, also known as prominence seismology, seeks to achieve a success similar to that of HELIOSEISMOLOGY from the comparison between observations and the theoretical analysis of prominence vibrations. This task is not an easy one because of the complicated three-dimensional structuring of these objects, whose theoretical modelling is extremely complex (see SOLAR PROMINENCE MODELS). With the investigation of prominence oscillations we expect to improve our knowledge on the nature of these exotic objects.

Flare-initiated filament oscillations

Observations of solar FILAMENTS through a narrow Hα FILTER made during the first half of the 20th century revealed that prominences can be activated by FLARES as far away as 500 000 km, a considerable distance compared with the 4.4×10^6 km length of the solar circumference. This activation often leads to the disappearance of the filament, or the appearance of a previously undetected filament, in the Hα image. The associated optical effect gave rise to the term 'winking filament' for this kind of filament behavior.

The first reports on prominence oscillations came from the detection of 'winking filaments' that disappear and reappear at regular intervals after being disturbed by a wave emanating from a distant flare. In 1966 H Ramsey and S Smith made an in-depth study of this type of filament activation by using three narrow filters, one centered in the Hα line and the other two in the red and blue wings of the line, ± 0.5 Å from the centre. An unperturbed prominence is only visible in Hα, but invisible at the other two wavelengths; however, Ramsey and Smith discovered that, on the passage of the flare-induced wave, the absorption wavelength of the prominence material oscillates about the Hα line center, with an amplitude of at least 0.5 Å, for a few periods before the oscillations are damped. They also found that this process is more or less periodic, with periods between 6 and 40 min for different filaments. In addition, they were able to study the perturbations induced by four flares on a particular filament in three consecutive days and found that its frequency of oscillation remained almost unchanged.

A few years later, J Kleczek and M Kuperus gave a theoretical explanation of these flare-induced oscillations. The complicated prominence magnetic field was represented by an 'effective' uniform magnetic field in the direction of the prominence main axis and with its endpoints tied at a fixed position (simulating the photospheric line-tying effect). The magnetic tension in this kind of configuration provides the force required to counteract the pull of gravity and also a restoring force that tends to bring the prominence to its equilibrium state after suffering a disturbance. Then, the passage of a large-amplitude wave induces horizontal prominence motions which result in a periodic variation of the line-of-sight velocity component (of course, this is not true when the filament is near the center of the solar disk and the line of sight is almost perpendicular to the oscillatory motions, but this was not the case with Ramsey and Smith's observations). The consequence of these periodic mass motions is a periodic Doppler shift of the filament absorption wavelength about the Hα line centre, alternatively towards the red and blue wings, in agreement with observations. The Doppler displacements detected by Ramsey and Smith, of at least 0.5 Å, point to an oscillatory amplitude in excess of 20 km s^{-1}, a rather large value.

Kleczek and Kuperus also gave an expression for the oscillatory period in terms of the prominence's mean magnetic field and density. The fact that in this model different filaments have different effective magnetic fields and densities implies that a given prominence will oscillate at its own characteristic frequency as long as its overall properties do not change in time (as is the case with Quiescent prominences over a few days). Using values of density and magnetic field typically found in these objects, these authors obtained periods and damping times around 20 min, also in reasonable agreement with the observations.

Small-amplitude oscillations: observations

In contrast with the previous large-amplitude, global oscillations triggered by a flare, quiescent prominences are also subject to small-amplitude, small-scale periodic vibrations not related to flare activity. In 1969 J Harvey examined in his PhD thesis the Doppler velocities of a sample of 68 non-ACTIVE REGION prominence oscillations. He concluded that 31% of the objects presented no significant velocity change along the line of sight, 28% showed apparently random line-of-sight velocity variations and 41% displayed an oscillatory behavior. The measured periods were distributed between 1 and 13 min, with a tendency of periods between 3 and 7 min to occur more frequently. In addition, the line-of-sight velocity amplitude in most cases ranged from 0.1 km s^{-1} (the signal noise level) to 2 km s^{-1}.

Following this preliminary investigation the subject received little attention in the next decade, after which systematic observations were undertaken. The analyses made at the beginning of the 1980s served to confirm Harvey's results, with regard to periods and amplitudes, but they also indicated the presence of an apparently new kind of small-amplitude prominence vibrations. Velocity

oscillations with periods between 40 and 80 min and amplitudes around 1–2 km s^{-1} were abundantly reported. The large values of these periods led to the classification of prominence vibrations into short- and long-period oscillations and to the belief that they are of different nature. Nevertheless, according to theoretical models (see below), long and short periods are the consequence of the same physical processes and intermediate values do also exist, in agreement with later observations.

The instrumental setup normally used to study prominence oscillations involves placing a SPECTROGRAPH slit on a quiescent prominence or filament so that the emission or absorption spectrum of the plasma along the slit can be investigated. A selected spectral line, such as Hα or Ca II K, can then be used to deduce the temporal dependence of the line-of-sight velocity for the points of the prominence along the slit (see figure 1). Some instruments, such as the MSDP spectrograph, allow observers to gain spectral information of a two-dimensional field of view, thus making feasible a better understanding of the spatial distribution of oscillations. Subsequent analysis of the data, e.g. using the FFT, yields information on the presence of periodic vibrations at each of the prominence locations. Sometimes more than one period will be present in a given Doppler signal at a given spatial point. On the other hand, just as Harvey found, it is common to obtain velocity signals which do not change periodically in time. The reason for this is either that the velocity amplitude or its projection along the line of sight is too small to be detected or that the prominence material does not actually oscillate, which must be understood as an indication that prominence oscillations are episodic phenomena that are continuously excited by external agents and last for a moderate time before being damped by some dissipative processes.

Regarding the sizes of regions where oscillations with a given period are detected, they range from the telescope resolution limit (i.e. a few hundred km) to as much as 20 000 km, a considerable length compared with typical quiescent prominence dimensions. Therefore, periodic vibrations seem to be excited both at local and global scales. Some authors have even been able to associate the oscillating portions of prominences with the fibril structure of these objects (see SOLAR PROMINENCE FINE STRUCTURE). This is not surprising since, after motions are excited in a fibril, its enhanced magnetic field can act as a waveguide (see MAGNETOHYDRODYNAMIC WAVES) and the perturbations will spread over the whole fibril.

Approximate or limiting values for other parameters have also been determined from the study of the vibrating areas. Wavelengths are typically found to lie between 10 000 and 100 000 km, while phase speeds lie between 25 and 100 km s^{-1}, although values outside this range have also been reported.

Researchers face a number of problems when trying to detect periodic changes in quiescent prominences. First of all, there are the inevitable consequences of the Earth's atmosphere, mostly by means of SEEING conditions,

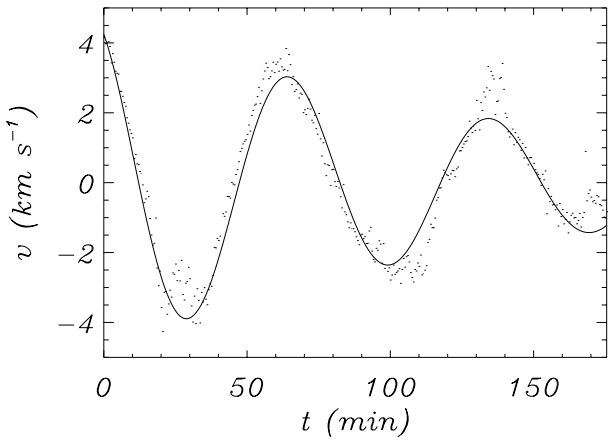

Figure 1. Time variation of the Doppler velocity observed in a quiescent solar prominence. The data can be fitted by a function of the form $v_0 \cos(2\pi t/T + \phi)\ \exp(-t/\tau)$, with amplitude $v_0 = 4.8$ km s^{-1}, period $T = 70$ min and damping time $\tau = 140$ min (solid curve). The well-defined periodic variation readily recognizable in this figure provides good support for the existence of prominence oscillations, although in most data sets they are usually harder to detect visually because of their smaller amplitude and/or higher noise level. Courtesy R Molowny-Horas.

imperfect telescope guiding and limited spatial resolution, which generally result in a slight degradation of the data. A more fundamental source of data corruption, however, may arise from the fact that light emitted or absorbed by various plasma elements along the line of sight is collected together by the detector, so the observed spectral line contains contributions from all the elements and incorrect Doppler velocities follow. This is probably the reason why oscillations seem easier to identify where the prominence looks fainter.

Small-amplitude oscillations: theory

Theoretical investigations of prominence oscillations are based on the assumption that an external perturbation excites eigenmodes of the prominence structure. At present very little is known about the mechanism responsible for generating small-amplitude waves in prominences, although it has often been claimed that some short-period oscillations can be the response of the prominence to a forcing produced by the chromospheric 3 min oscillations and photospheric 5 min oscillations (see SOLAR CHROMOSPHERIC OSCILLATIONS), whose influence could propagate along magnetic field lines and induce motions of the prominence plasma. Nevertheless, this explanation leaves out most of the detected periods, whose origin could be in small-scale, impulsive disturbances coming from the surrounding corona that would shake the prominence and would excite its normal modes of vibration.

To illustrate the kind of theoretical progress accomplished so far let us consider a basic prominence equilibrium made of a cold and dense plasma slab embedded in a

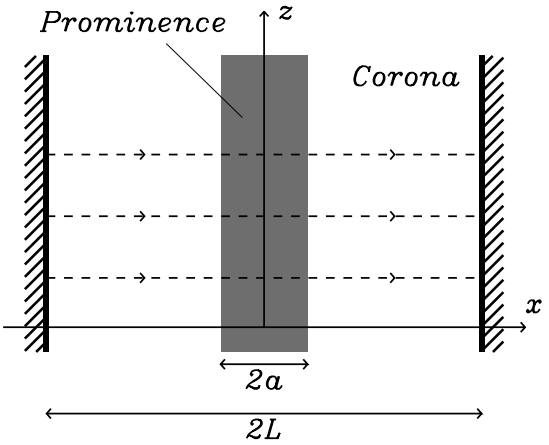

Figure 2. Sketch of an elementary equilibrium used in modelling prominence oscillations. The drawing represents a cut across the prominence, devised as an infinitely high and long plasma slab of width $2a$ embedded in the solar corona. Dashed lines represent the horizontal magnetic field threading the system and anchored at $x = \pm L$.

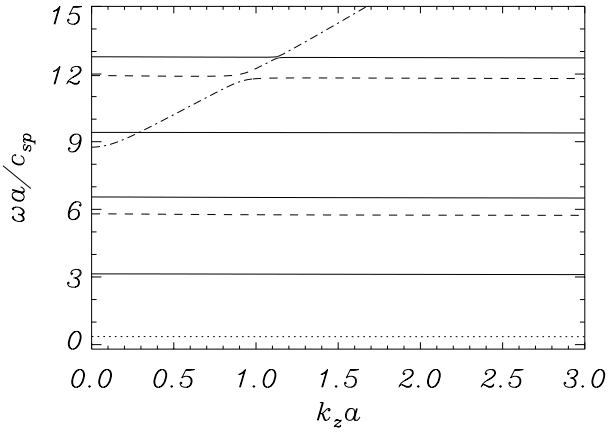

Figure 3. Frequency versus vertical wavenumber for slow and fast magnetoacoustic modes with v_x even about $x = 0$. The quantity $c_{\rm sp}$, coming into the dimensionless frequency, is the adiabatic sound speed in the isothermal prominence. Solid lines, internal slow modes; dashed lines, external slow modes; dotted line, hybrid slow mode; dot-dashed line, internal fast mode. A similar dispersion diagram is obtained for slow and fast odd modes, the central difference being that the hybrid slow mode is replaced by the hybrid fast mode. For a description of the properties of MHD modes see MAGNETOHYDRODYNAMIC WAVES.

hotter and rarer corona (figure 2). The system is threaded by a uniform, horizontal magnetic field and the photospheric line-tying is simulated by placing two vertical boundaries symmetrically with respect to the prominence center ($x = 0$). A Cartesian coordinate system is used in which the prominence long axis lies in the y-direction, the vertical lies in the z-direction and the x-axis is transverse to the prominence body. Gravity is neglected in this simple equilibrium and, to ensure total pressure (magnetic pressure plus gas pressure) balance at the prominence-corona interface, the product of density and temperature must be equal in the two uniform regions. This equilibrium model is very idealistic since the physical parameters are assumed uniform, although it is well known that quiescent prominences are highly structured. Nevertheless, this model will be helpful to introduce the basic concepts in theoretical studies of prominence oscillations.

To fully understand the dynamics of this structure one must first investigate its normal modes, which in our particular case have a velocity of the form $\boldsymbol{v}(x)\exp(-\mathrm{i}k_y y)\exp(-\mathrm{i}k_z z)\exp(\mathrm{i}\omega t)$. This expression represents a standing wave in the x direction, with frequency ω and wavenumbers k_y and k_z in the prominence long direction and in the vertical direction, respectively. After making the simplifying assumption $k_y = 0$, one is left with the task of solving a pair of ordinary differential equations for v_x and v_z decoupled from a third equation for v_y only. The large photospheric density prevents coronal motions from displacing magnetic field lines or perturbing the photosphere, so the velocity vector must vanish at $x = \pm L$. With these boundary conditions, the velocity $\boldsymbol{v}(x)$ and frequency of normal modes can be calculated. Owing to the symmetry of the equilibrium configuration and the boundary conditions, solutions to the first two equations are called even or odd depending on whether v_x is even or odd about $x = 0$. The dispersion diagrams of even and odd modes are thus drawn separately (figure 3). The two types of curves in this diagram (straight and parabolic lines) betray the different physical nature of slow magnetohydrodynamic modes and fast magnetohydrodynamic modes (magnetohydrodynamic waves). The first one is essentially non-dispersive (i.e. ω independent of k_z) and gives rise to motions practically parallel to magnetic field lines (that is, $v_x \gg v_z$) which are driven by the pressure gradient force. On the other hand, fast modes present a wavelength-dependent frequency, have basically vertical motions ($v_z \gg v_x$) and are driven by the magnetic Lorentz force.

A more detailed inspection of figure 3 and of the velocity perturbations associated to each of the modes reveals they can belong to an internal, external or hybrid class. The main features of internal (external) modes are determined from the characteristics of the prominence (corona) but are little influenced by the existence of the other region. According to this classification scheme, hybrid modes are internal and external at the same time. Thus, for example, modifying the width $2L$ of the system results in a variation of the frequency of external and hybrid modes, while internal modes remain unscathed. The eigenfunctions (v_x for slow modes and v_z for fast modes) are also useful in determining the character of modes: hybrid modes are the ones with the simplest possible structure in the x-direction, showing two nodes at $x = \pm L$ and a single maximum (at $x = 0$), external modes achieve a much larger amplitude inside the corona than in the prominence and, finally, the velocity amplitude

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

of internal modes is as large in the prominence as in the corona.

The third possible orientation of gas motions, in the y-direction, corresponds to solutions driven by the magnetic tension in which the density remains unperturbed. These are basic features of the Alfvén mode, for which the subdivision into internal, external and hybrid is also pertinent in the present case.

At this point the obvious question is how well the periods of the three magnetohydrodynamic modes compare with the observed ones. Using reasonable values of the equilibrium parameters one recovers long periods (accounted for by the hybrid slow mode), intermediate periods (hybrid fast and Alfvén modes) and short periods (slow, fast and Alfvén internal modes). External modes are of no interest because of their presumed minute velocity inside the prominence.

Apart from reproducing the values of periods, this naive theoretical work has important implications for the detectability of periodic Doppler variations caused by the three magnetohydrodynamic modes. For example, the chances of observing the vertical motions generated by the fast mode are largest for a filament at the solar disk center, whereas they are practically null for a limb prominence. The velocity polarization associated with each mode is then an essential result of theoretical investigations. This study was later extended to include other basic ingredients of quiescent prominences, such as the curvature of magnetic field lines, the magnetic field shear with respect to the prominence long axis (see SOLAR PROMINENCE CHIRALITY), the prominence–corona TRANSITION REGION and the internal fibril structure. The addition of these complexities is fundamental for progress in this area as they substantially modify the picture given here with respect to the frequency and velocity polarization of the magnetohydrodynamic modes.

Solar Prominences

Prominences are clouds of relatively cool and dense gas in the solar atmosphere. These clouds change shape and come and go, but they do not drift like terrestrial clouds. Prominences are suspended above magnetic channels (see SOLAR FILAMENT CHANNELS) that change little from day to day. They are trapped in magnetic fields in the solar atmosphere, but they churn slowly, at heights of up to 100 000 km above the photosphere (see SOLAR PHOTOSPHERE). They peek brilliantly over the Moon's limb during eclipses. The magnetic fields thread them through and balance the force of gravity, and some prominences live, thus suspended, for months. The magnetic fields also inhibit heat flow from the surrounding corona (see CORONA), where the temperature is 200 times higher than their 6000 K. Thus, prominences emit the visible radiation of hydrogen and helium.

Prominences take on many forms and their frequency of appearance generally parallels the sunspot cycle. Also, while they have long been distinguished for their comeliness (e.g. figure 1) and for the challenges they pose to theorists, they have recently been the focus of heightened interest because they appear to play a fundamental role in the 11 yr solar cycle of magnetic field generation and dispersal (see SOLAR CYCLE).

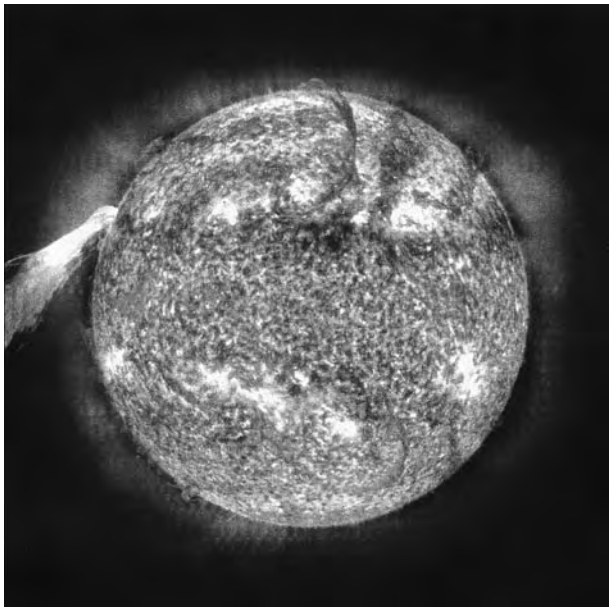

Figure 2. An eruptive prominence (left) and a quiescent filament (upper center) photographed on 15 June 1998 with a SOHO telescope.

History of prominence research

Prominences, or *protuberances*, were recorded during eclipses as early as 1239, but their true character was not understood until the solar eclipse of 1868. It was then that spectroscopy revealed the distinctive emissions of hydrogen and calcium, which had earlier been detected in the solar spectrum. At the same eclipse, the great French astronomer, Pierre-Jules-César Janssen, first obtained evidence from prominence spectra for an unknown element. The element was later named helium for its solar origins, after it was identified in terrestrial minerals in 1895.

The hydrogen spectral lines in prominences are so bright that they can be seen without an eclipse and, at the turn of the century, G Hale in the United States and H Deslandres in France independently invented the spectroheliograph to study them. In the spectroheliograph, the entrance slit of a spectrograph moves across a solar image formed with a telescope. In unison, an exit slit passing only a single spectral line moves over a photographic plate which records a monochromatic image of the Sun. Spectroheliograms of hydrogen and calcium emission revealed that prominences are almost always present at the sun's limb (edge). They also revealed dark threads, *filaments*, on the disk. L d'Azambuja at the Meudon Observatory outside Paris and Hale in California showed that filaments are just prominences seen with the chromosphere (see CHROMOSPHERE) instead of the dark sky as background.

In the first half of the 19th century, E Petit, D Menzel and others classified prominences according to their shapes and motions. The names convey the variety of forms seen—tornado, spray, surge, loop, coronal rain, hedgerow—but little physical insight was achieved until the spectroscopic analyses of the 1950's and 1960's. H Zirin and E Tandberg-Hanssen and others established that prominences can have a range of temperatures and densities with some parts as cool as 6000 K and other parts above 50 000 K.

Two advances in instrumentation by B Lyot greatly aided the study of prominences: the CORONAGRAPH in which a disk inside the telescope serves the function of the moon and allows viewing of prominences and the surrounding corona as in an eclipse, and the Lyot filter, which replaced the spectroheliograph and gives monochromatic images of the whole sun with exposure times as short as 0.2 s. These instruments allowed films of prominences and filaments to be made. The most interesting motions are the sudden eruptions or *disparitions brusques* by which prominences leap from the Sun. Many eruptive prominences have been recorded since the International Geophysical Year (1958–1959) by a worldwide network of telescopes with Lyot filters. Eruptive prominences (figure 2) leave the Sun at 300–1000 km s^{-1} and are associated with SOLAR FLARES.

Shortly after H Babcock developed the solar magnetograph in 1953, H Zirin and A Severny made the first prominence magnetic field measurements. D Rust established that the magnetic field strength in quiescent prominences averages about 10 G and that there is a global pattern to their fields (see SOLAR PROMINENCE CHIRALITY). J Harvey found fields up to 100 G in active prominences (see SOLAR PROMINENCES: ACTIVE), and J–L Leroy and his coworkers at Pic-du-Midi in France established that the fields are predomi-

nantly horizontal, a result that confirmed that prominence gases are supported by the magnetic fields against the pull of gravity.

With the advent of observations from space, R Munro and others established a statistical link between prominence eruptions and coronal mass ejections (CMEs) (see SOLAR CORONAL MASS EJECTION: OBSERVATIONS). L Burlaga detected cool gas clouds in the solar wind near Earth.

Typically, one of his magnetic clouds will arrive at Earth about 4 days after a prominence eruption from the center of the visible solar disk. Many such clouds have elevated levels of helium and this may be a sign that they originated in an eruptive prominence. Furthermore, they are embedded in the hot interplanetary magnetic clouds that fly past the Earth and which are associated with CMEs. As solar telescopes in space improve and as more interplanetary plasma detectors are distributed about the heliosphere, it should be possible to sample eruptive prominences systematically and link the sampled plasmas to their precise origins on the Sun.

Figure 4. Loop prominences photographed in the emission of atomic hydrogen with a Lyot filter at the Sacrament Peak Observatory.

Morphology and dynamics

Solar prominences take on a bewildering variety of shapes because of their complex fine structure and their large size. The best observations show structure down to a few hundred kilometers, and prominences (or filaments; the terms are used interchangeably) may stretch to nearly a solar radius (700 000 km) in length across the face of the Sun. Eruptive prominences are frequently 500 000 km long or longer because they expand radially as they stream outward (figure 2).

Prominences that appear in regions well removed from SOLAR ACTIVE REGIONS are called quiescent. They belie their name because films and spectra frequently show motions of 10–20 km s^{-1} at their edges, especially at the top. Nevertheless, quiescent prominences usually maintain their overall shape for days. They often resemble leafy trees or hedgerows on the limb and long (10 000–500 000 km), thin (500–10 000 km) threads on the disk. Quiescent filaments invariably overlie the borders between oppositely directed magnetic fields in the underlying photosphere and chromosphere. They seem confined to 10 000 km wide zones where magnetic fields of opposite polarities mingle in a sort of no man's land between large patches of positive and negative fields. The stability of these large field patterns on the Sun no doubt accounts for the stability of the quiescent filaments. However, the mingling magnetic fields underneath may be just as important for their maintenance as for their stability. The underlying fields are thought to be magnetic flux ropes which merge in the filament channel and expand upward, possibly carrying mass and twisted magnetic fields upward from the chromosphere. Maintaining the 10^{15} g of mass in a typical filament may therefore be a matter of dynamic balance between updrafts in expanding magnetic fields and downdrafts where the horizontal fields are too weak or disordered and material falls into the chromosphere.

Active prominences (figure 3) are those that occur near active regions, of course. They are thinner, darker and more changeable than quiescent prominences and have names that convey it (surges, sprays, loops). Quiescent and active prominences can be distinguished not only by their morphology and motions but also by their spectra. The neutral hydrogen spectral lines and the so-called H and K lines of ionized calcium dominate quiescent prominence spectra, but there are many cool spectral lines, such as those of neutral and singly ionized iron, titanium and chromium. These are also characteristic of the photospheric spectrum, which is emitted by a 5800 K gas. The spectra of active prominences have much brighter and wider hydrogen and helium lines and fainter photospheric lines. Sometimes very highly ionized lines such as the yellow line of Ca XV appear. The latter occurs only in loop prominences (figure 4), which are really a component of solar flares. The presence of Ca XV reveals temperatures above 2 million kelvins. Active prominence spectra also frequently reveal highly broadened lines that vary in brightness, possibly indicative of ion beam heating. Quiescent prominences have remarkably repeatable and stable spectra, which suggests that one of the explanations for their stability may be that the radiation rate is well balanced with the heat input.

Flares, flare waves, and filaments appear in monochromatic images obtained at the wavelength, 6563 Å, of the hydrogen Balmer line, which is commonly called Hα by astronomers. The hydrogen line sometimes shows red and blue Doppler shifts starting when a flare wave reaches a filament. Vertical oscillations can be induced. Some observers suggest that a particularly strong flare wave can cause a filament to erupt from the Sun, but definitive observations are lacking. Whether a filament erupts or not appears to depend mostly on the magnetic fields in and around it.

Quiescent prominences oscillate even in the absence of flares. The oscillations are horizontal and have periods anywhere from less than 5 min up to 90 min, with 7.5 min being most frequently reported. They last only a few cycles and are not well understood theoretically. Considering, however, that prominences are held in place by magnetic tension and that the underlying atmosphere is always oscillating (see SOLAR INTERIOR: LOCAL HELIOSEISMOLOGY), oscillations are practically inevitable.

Prominence plasma and environment

While most quiescent prominences have very similar spectra, monochromatic images obtained in 'hot' and 'cold' emission lines of the same prominence may differ

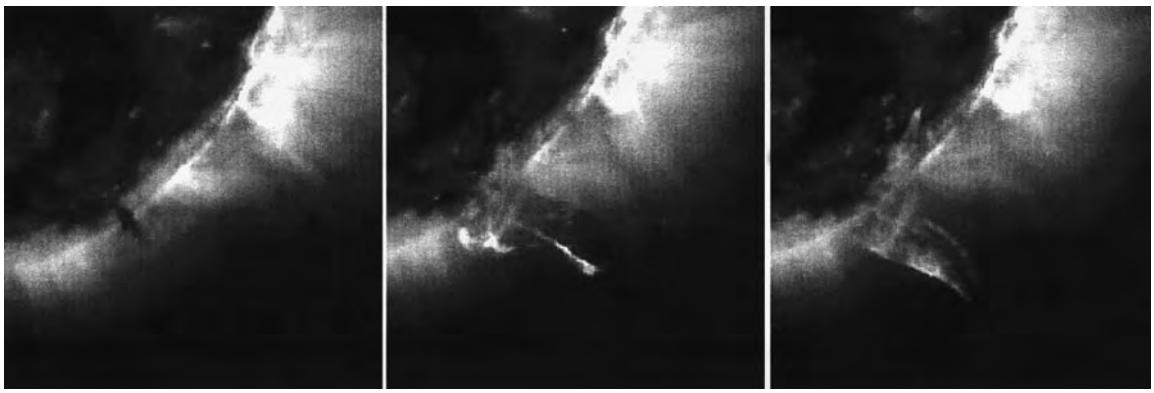

Figure 5. An eruptive prominence showing the transformation of cool, absorbing material (dark feature, left center, left image) into a bright spray (center and right images) emitting the radiation of Fe XII, which exists only at temperatures above one million kelvins.

considerably in appearance. For example, an image formed from the emissions of ionized helium ('hot') may show a high, diaphanous cloud, while an Hα ('cold') image would show a low, dense hedgerow. This means that, although the average properties of prominences are fairly stable, the temperature may vary considerably from 6000 K to 50 000 K from point to point within a single entity. There is some evidence that the local heating rate may change and a prominence may then just 'evaporate' when the delicate normal balance among heat input, radiation rate, density and gravity is lost.

Prominences literally reflect their environment because most of the radiation they emit originated in photons absorbed from the underlying chromosphere. Filaments appear darker against the chromosphere because they absorb most of the upward-directed photons and reemit them in all directions. They appear bright against the dark sky for the same reason. Prominences also radiate from their interfaces with the million kelvin corona, showing that some of the intense heat there is penetrating the magnetic barriers. These radiations are in the ultraviolet region of the spectrum and are indicative of a 100 000 K gas.

Images from the Solar and Heliosphere Observatory (see SOLAR TELESCOPES AND INSTRUMENTS: SPACE) provide dramatic evidence of how efficient the hydrogen and helium of prominences are at absorbing radiation (figure 5). The first image (left) of figure 5 shows a quiescent prominence as a *dark* feature in the corona. This is because the helium atoms in it are absorbing the extreme UV emission at 195 Å from the corona behind it. However, in the other two images, we see the prominence erupt and begin to emit strongly the same high-temperature radiation that comes from the million kelvin corona. Thus, this sequence of images traces the dramatic heating of prominence material at the same time as it is ejected from the coronal cavity in which it rested. Theory suggests that turbulence and reorganization of the magnetic fields heat the material. The heating is too rapid and localized to be explained by thermal conduction.

Figure 6. The S-shaped feature on the right is the signature of an eruptive prominence in this image of the Sun in x-rays, from the Yohkoh satellite.

Magnetic fields

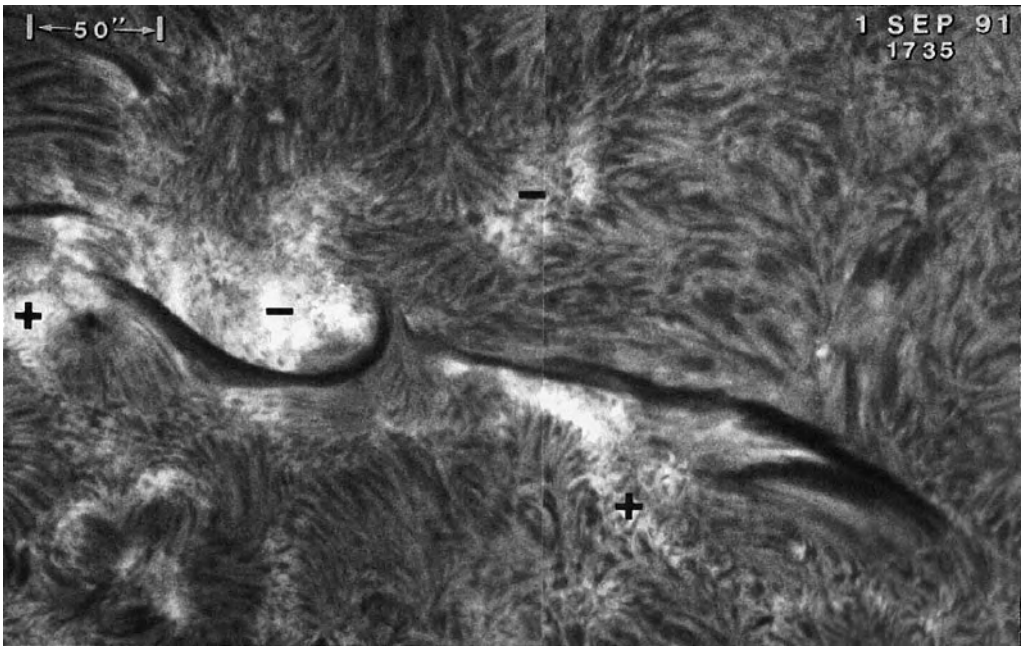

Figure 7. The two filaments shown here have opposite chiralities (sinistral and dextral), yet they spring from nearly the same point (center) in the chromosphere. The sinistral filament on the right clearly resembles a left-hand screw.

polarimeter attached to a telescope will reveal much about the magnetic fields inside prominences. The Zeeman effect, for example, causes circular polarization when the magnetic field is parallel to the line of sight. It produces linear polarization when the field is perpendicular. The sense of polarization changes with increasing wavelength through the spectral line, so a magnetograph measures the rate of change of polarization with wavelength. There is no net polarization in prominence lines because of the Zeeman effect.

The light emitted by prominences is scattered incident light that comes only from the solar disk (i.e. the light is anisotropic). This scattering of anisotropic light causes weak linear polarization parallel to the limb. In the presence of a magnetic field, the plane of polarization will rotate. This is called the Hanle effect (see SOLAR MAGNETIC FIELD: ZEEMAN AND HANLE EFFECTS). It depends in a complicated way on the direction and strength of the field and the height of the prominence, but it has been carefully calculated and measured by J–L Leroy and his colleagues, and it is the most useful diagnostic of the magnetic fields in prominences.

The Zeeman and Hanle effects reveal that a prominence's magnetic field vector will be generally within 25° of its long-axis direction. The fields are predominantly horizontal and actually strengthen slightly with height. Theory shows that these characteristics are required for prominence stability and support against gravity. The fields in quiescent prominences most likely resemble twisted ropes called magnetic flux tubes (see SOLAR INTERIOR: EMERGING MAGNETIC FLUX TUBES). However, the resolving power of present-day magnetographs is considerably less than the smallest features in prominences, so there is some uncertainty about the field's fine structure.

Magnetic fields in active prominences are much less well understood than in quiescent prominences, of which hundreds were measured over three solar cycles. Active prominences are much more difficult to catch. One measurement of fields in a loop prominence gave 60 G fields, which is about 10 times the field in quiescent prominences. However, the morphology of the fields in loop prominences is possibly one of the least controversial issues, because loops (see SOLAR PROMINENCES: ACTIVE, figure 5) look so much like the loops of magnetic field lines seen in textbooks. The smooth slippage of plasma down the legs of a loop prominence and the ease with which the loops' shapes can be matched by elementary models suggests that the magnetic fields in loop prominences have been drained of most of their energy. This is not surprising considering that loop prominences appear only after solar flares. Presumably most of the available energy, in the form of electric currents, has been drained from the fields to produce the flare.

The magnetic fields in eruptive prominences are of great interest because they may be a vital clue to the instability that causes eruptions. However, from its onset to its disappearance from the field of view of most telescopes, an eruptive prominence is visible for only about 20 min. This is hardly enough time to obtain a good measurement of its magnetic fields, so solar physicists have to rely on theoretical models. The models are helped

along by a curious feature of eruptives, however. The first stage of many eruptions is an apparent simplification of its structure. What had looked like a hedgerow for a week may, in the course of a few hours, turn into a well-defined dark thread. As it rises off the Sun's limb, an eruptive prominence may resemble a coiled spring. The pitch of the coil is sometimes easy to measure and it decreases as the prominence lengthens. The total number of turns from end to end remains the same even as the length increases.

How can we explain the observations of magnetic fields in prominences? See the article on SOLAR PROMINENCE MODELS for details, but from observations we are drawn to eruptive prominences which often have a characteristic twist. They become unstable and expand outward, and they still have enough internal energy to overcome solar gravity and accelerate 10^{15} g of plasma up to speeds as high as 1000 km s^{-1}. Many theorists have pointed out that fields twisted beyond a certain point, usually about one full turn from end to end, will become unstable. The best evidence that prominences erupt as the result of MAGNETOHYDRODYNAMIC INSTABILITIES was obtained with the x-ray telescope aboard the Yohkoh satellite. As shown in figure 6, a sigmoid (S-shaped) brightening appears at the onset of filament eruption. The ratio of sigmoid length to width in a large sample of eruptives peaks at a value of 5, and this is exactly the shape of the most likely helical kink instability of a twisted magnetic field.

Birth and death

The origin of the cool plasmas of prominences is a controversial subject. It is almost impossible to discover from limb observations how a prominence forms. Observations usually show that a small bright feature grows upward from the Sun's limb. However, this could sometimes be explained simply as a filament rotating onto view, because the Sun rotates completely every 27 days. Other possible explanations are condensation from the surrounding corona or injection of chromospheric material from below. There do not seem to be any convincing observations of clouds condensing from the corona, except in the special case of loop prominences. On the disk, filaments appear to form from the coalescence of thin chromospheric threads that lie parallel to the border separating positive and negative magnetic fields. This may indicate operation of a kind of siphon, or it may suggest that magnetic fields are emerging from beneath the surface parallel to the boundary and carrying material with them as they expand into the corona. Doppler observations of filaments usually show blueshifts, indicative of rising material.

Prominences nestle inside so-called coronal cavities which are so dark that none of the usual emissions from the corona is detected there. This suggests an explanation for the origin of prominence material. Maybe material could somehow be squeezed or condensed from the surrounding corona, in some way that has so far eluded detection. There are many theories for condensation, and a key element of them all is that the million kelvin coronal gases must cool to 10 000 K and even less. The process seems to occur in loop prominences where a great quantity of hot, dense gas is created in the corona and conditions are right for condensation by thermal instability. A hot gas radiates energy, which cools it. It then becomes more dense and then radiates more, because the radiation rate is proportional to the square of the density. This instability nicely explains loop prominences where stages of ionization indicative of temperatures from 10 million kelvins down to 10 000 K are present. In normal prominence formation, however, there are no high-temperature emissions. Another problem is that the mass deficiency of a typical coronal cavity is much smaller than the mass of a typical prominence.

Global patterns

Filaments form along the magnetic polarity borders in active regions, between adjacent active region remnants and between active region remnants and the polar fields. These three families of filaments occupy three tiers of latitude in each hemisphere. The active ones lie between the equator and 30°, the next between 30° and 50°, and, finally, the polar crown filaments between 50° and 80°.

The orientation of the axial magnetic fields in active region filaments follows Hale's law of sunspot polarities. A filament's axial field will have its western end in or near the leader spots. The eastern end will be near the follower spots. The axial fields flow from near the leader polarity spots to near the follower polarity spots. Of course, the direction changes each 11 yr, and it is opposite in the opposite hemispheres, consistent with Hale's law.

As active regions age and spread out, new filaments form along their high-latitude borders. In these filaments the axial fields flow from the *follower* fields of one active region remnant eastward to the *leader* fields of the next remnant. The average latitude of these filaments increases as the active region remnants expand toward the poles. Shortly after the beginning of a new cycle, the filaments of this 'first tier' begin to appear. By the beginning of the next cycle, these filaments form two crowns around the Sun at about 50° north and south latitude. Individual filaments will come and go, but the loci of active region, first tier and polar crown filaments are stable features on synoptic maps of the chromosphere.

The polar crowns persist until about 1 yr before the maximum of the sunspot cycle. Then, in the course of 1 yr, they shrink toward the poles. The average latitude increases quickly from 50° to 80° and at about sunspot maximum all the polar crown filaments disappear as the sign of the polar fields changes. To summarize, the axial fields of filaments in the low-latitude sunspot zones point to the west when negative spots follow (are westward of) positive spots. At the same time, the axial fields in the first tier of filaments point eastward, and those in the polar crown point westward. It is as though sections of the global toroidal fields of three sunspot cycles were manifested piecemeal in the corona by solar filaments.

Until 1992 no one suspected that filaments in the north were any different from those in the south. Then, S Martin noticed that barbs along the sides of polar crown filaments and those in the first tier are consistently slanted one way in the north and another way in the south. Northern hemisphere filaments somewhat resemble right-handed screws. Martin called them dextral filaments. Those in the south resemble left-handed screws and are called sinistral filaments. The pattern is less evident in active region filaments, but even they seem to differ statistically between north and south. Sometimes a dextral filament and a sinistral filament each have one end in a common point in the chromosphere (see figure 7), but, otherwise, the two filament types are never connected.

It now appears, although there is still some controversy, that most magnetic fields in the northern hemisphere are composed of flux ropes with a left-handed twist. Those in the south have a right-handed twist. Why filaments threaded by fields with a right-handed twist should resemble left-handed screws is not clear.

The importance of the chirality segregation by hemisphere rests on theories of the solar cycle, which predict that the magnetic helicity (tendency to twist) of northern and southern fields should be opposite. This is just what has been inferred from solar filament observations, and it has been confirmed by measurements of the fields in space plasmas and in active regions.

Eruptive prominences preserve their sense of twist. Recent studies indicate that those erupting from the north become left-handed magnetic clouds in space. Similarly, measurements of the magnetic fields in the eruptive prominences from the southern hemisphere, as they pass by Earth, reveal magnetic flux ropes with a right-handed twist. Quite a lot of magnetic flux and helicity leave the Sun each solar cycle in eruptive prominences and coronal mass ejections. The total flux and helicity measured in space during each 11 yr solar cycle is equal to the total flux and helicity of the eruptives and CMEs. Also, these values agree with the total flux and helicity that the solar cycle generates, according to theoretical calculations. It appears, then, that eruptive prominences and CMEs carry off very nearly all of the magnetic fields generated in each solar cycle.

Future research

Solar prominences are much better understood today than a century ago, of course, but many fundamental questions remain. There is no consensus on how prominences form. Dark threads develop in filament channels, but it has been impossible from the images at hand to determine where the material comes from. Observations eventually will show whether it comes up from the chromosphere or condenses from the surrounding corona.

Although some puzzling details remain unresolved, the stability of prominences and their resistance to heat conduction from the corona are generally understood. Magnetic tension supports the material, and the extremely low rate of thermal conduction across magnetic field lines prevents temperature changes. When prominences do become unstable, it is probably because of the helical kink instability. With sufficient magnetic helicity, any prominence will become unstable. However, we do not know how the magnetic helicity accumulates.

No theory explains the fine vertical and horizontal threads of a hedgerow prominence. Perhaps three-dimensional images will reveal them to be part of a simple pattern of concentric coiled fields. Future observations of prominences will be carried out with matched telescopes operating from two or more widely separated points in the heliosphere. The arrival of stereoscopy will add a new dimension to prominence research.

Solar Prominences: Active

Solar prominences may be divided into two classes, quiescent and active objects (see SOLAR PROMINENCES). While quiescent prominences form a fairly homogeneous group, active prominences comprise a bewildering array of objects, from filament-like prominences in active regions to surges, sprays and loop structures associated with solar flares (see SOLAR FLARES and flare SURGES). The many morphological classifications published in the 1920s–1960s that tried to describe the many aspects of active prominences now mainly have historical interest. Nevertheless, several of these classifications invoked crucial physical parameters, e.g. velocity, association with active regions or flares, and helped to establish the nature of these active objects.

In the following we shall discuss in some detail some common and fairly easily discernable classes of active prominences, i.e. active region filaments and associated sprays as well as surges and loops. Quiescent prominences often ascend in a spectacular eruption called a disparition brusque. These eruptive, quiescent prominences are treated separately (see SOLAR PROMINENCE ERUPTION) and are not to be considered active prominences *per se*. Note that when both quiescent and active region prominences are seen in absorption, e.g. in the H-alpha line, against the solar disk, they are often referred to as filaments.

Both surges and loops occur in conjunction with flare activity and may be considered part of an overall flare phenomenon. However, they are also *bona fide* prominences, i.e. contain 'cool plasma' in the hot corona, and as such will be discussed below. A number of descriptive names are given to other active prominences, e.g. coronal clouds, caps and fast ejections, but we shall concentrate on the classes mentioned above that constitute the large majority of active objects. Figure 1 illustrates the activity that can be seen in the solar atmosphere when the Sun's prominences put on their impressive show.

As a general rule, the magnetic field in active prominences is considerably stronger than the roughly 1D G field that characterizes quiescent prominences. In surges and loops the field may search values of 100–200 G.

Notice eruption of prominence on south-east limb, appearance of surge at east limb, and major change in prominence near north pole. (Courtesy Observatoire du Pic-du-Midi and J-C Noens.)

Active region filaments

These prominences always occur in, or very close to, active regions, normally with sunspots, and are also referred to as sunspot filaments. Figure 2 shows, in addition to several large, quiescent prominences, a number of small active region filaments.

Filaments, both quiescent and active, are found in regions between opposite magnetic polarities. These regions form narrow lanes between the extended plages of magnetic field, and are referred to as the polarity-inversion zone where we find the filament channel (see SOLAR FILAMENT CHANNELS). The occurrence on filament-type prominences seems to be intimately linked to the concept of chromospheric fibrils (see CHROMOSPHERE: FIBRILS). These are one of the most conspicuous features seen in the H-alpha line in and around active regions. In the central part of active regions the fibrils are arranged in patterns connecting spots and plages of opposite magnetic polarity. However, before a filament will form, the fibrils will no longer connect these areas of opposite polarities, but will curve into the polarity- inversion zone. In the middle of this channel the fibrils will thereby be more or less aligned along the direction that will become the long axis of the forming filament.

The long, thin fibrils typically have lengths of 11 000 km, a width of from 700 to 2200 km and a lifetime of 10–20 min. Active filaments come in nearly all sizes, from small structures barely larger than fibrils, to long—always low-lying—filaments measuring 100 000 km or more. While the two ends of the filament dip down into chromospheric plages of opposite magnetic polarities, the main body of the filament forms a long, nearly horizontal, magnetic flux tube.

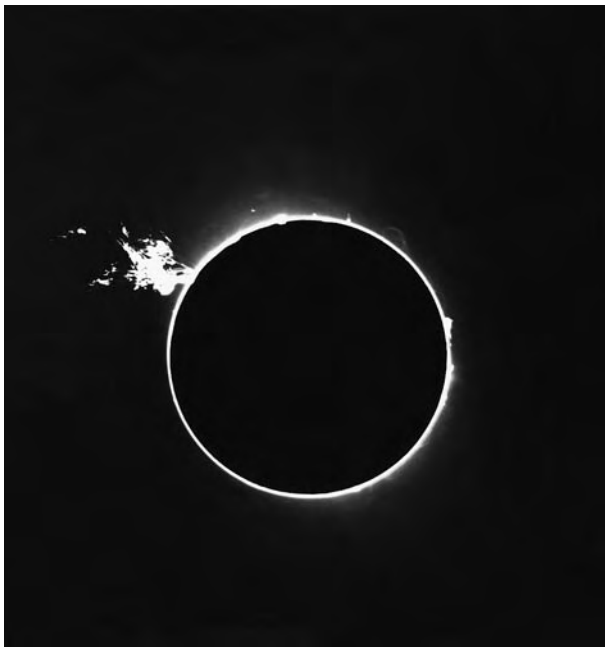

Figure 3. Spray prominence observed in H-alpha, 28 October 1972. Climax Station of the High Altitude Observatory, Boulder, CO.

No generally accepted theory exists for the formation of these prominences. Models range from invoking a coalescence of fibrils, pre-existing in the filament channel, to picturing the emergence from subphotospheric layers of the already complete magnetic flux tube anchored in plages of opposite polarity.

Since the magnetic field is oriented along the long axis of the filament, material motion along this axis will not be impeded, and under favorable conditions a continuous mass flow is seen in most active filaments. This flow is one of the strongest descriptive differences between active and quiescent filaments, and it demands a completely dynamic model for the former.

Active region filaments may last from hours to several days. Their disappearance is preceded by an activation that may manifest itself either by increased internal motion, up to 30 km s^{-1}, along the axis of the filament, or—in spectacular cases—by a genuine disparition brusque. These activities normally precede flares and hence furnish a good flare precursor (see SOLAR FLARE FORECASTING). Particularly violent expulsions of active filaments may result in sprays.

Sprays

Sprays are violent, flare-associated ejections of plasma which are frequently disrupted into clumps. They reach velocities of 500–1200 km s^{-1} in a few minutes owing to an initial very high acceleration of a few km s^{-2}. Figure 3 shows an example of a spray prominence.

When sprays originate on the visible disk one sees that the ejected material comes from a pre-existing active region filament which undergoes increased absorption some tens of minutes prior to the abrupt chromospheric brightening at the start of the spray. Often most of the spray material from the filament is confined within a steadily expanding loop-shaped envelope with parts of the material draining down both legs of the loop. In other instances the material is sprayed out in a seemingly chaotic fashion. Some material may escape the Sun as its velocity exceeds the velocity of escape. The nature of the expelling force is not known, but energy freed in magnetic reconnection seems a likely candidate.

Surges

Surges are prominences that seem to be shot out of active regions as long straight or curved columns and return along the same trajectory; see figure 4. As the material falls back, it often triggers a new surge. Surges may reach to great heights (several hundreds of thousands of km), and their velocity may exceed several hundred km s^{-1}. Some active regions produce nearly identical surges during part of their life (homologous surges). As the material is ejected, it often performs a spiraling motion on its way out. A flare is often seen at the foot point of a surge, and the phenomenon may be considered as part of the flare complex.

The trajectory of the moving plasma and its collimation indicate that surges are confined by more or less radial magnetic fields. From combined H-alpha, UV and x-ray data one can study both the cool and the hotter

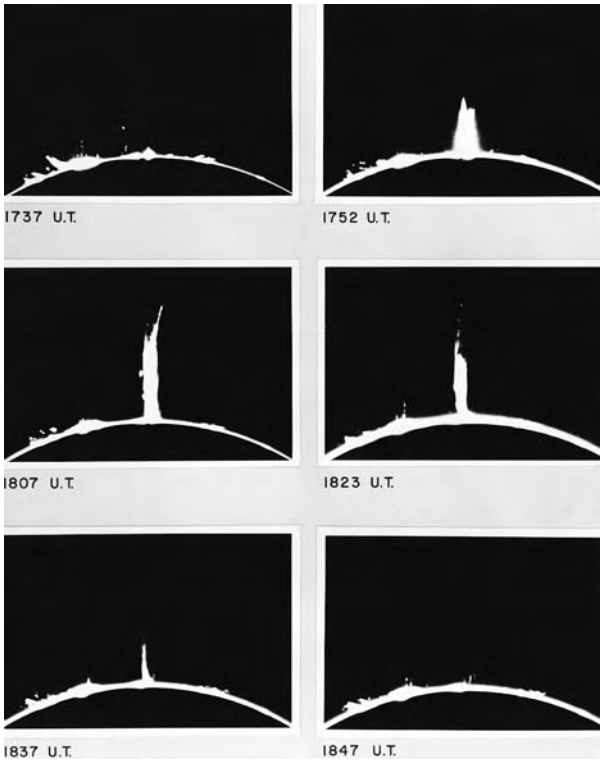

Figure 4. Development of surge prominence, 12 June 1946. Climax Station of the High Altitude Observatory, Boulder, CO.

components of the surge plasma, and one finds that cool and hot material follow parallel but separate paths. It seems that different parts of the surge may be ejected into adjacent, but separate, flux tubes. The nature of the explosive force that propels material into a surge is not known, but magnetic reconnection in the active region field again has been suggested.

Loops

Some of the most beautiful examples of gracious motion of material in the corona are provided by loop prominences and coronal rain; see figure 5. In these objects matter is observed to flow down along curved trajectories into active regions, seemingly after condensing out of the corona, often at great heights. These prominences are intimately connected with the late phase of the flare phenomenon and are, therefore, referred to as post-flare loops. They occur after the disparition brusque of a filament (quiescent or active), forming an arcade of loops connecting the two strands of emission appearing as a two-ribbon flare. The systematic motion in these loops reveals material streaming down the two legs of the loops from their apexes. The streaming motion follows a single arc; one does not observe the spiraling motion often seen in surges and in erupting quiescent prominences. During the next several hours the loop system expands and reaches, typically, a height of 50 000 km. It is important to note that

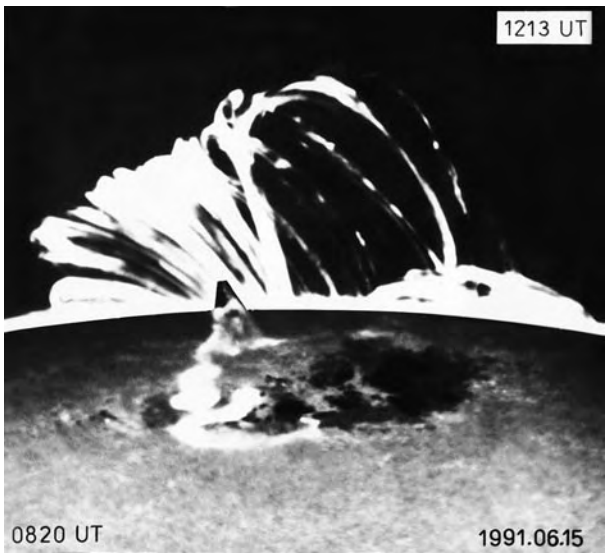

Figure 5. Composite H-alpha picture showing loop–prominence system in the corona above the solar limb (at 1213 UT) and the flares near the loops' feet in active with sunspots (at 0820 UT), 14 June 1991. (Courtesy Astronomical Observatory, Wrocław, Poland, and B Rompolt.)

the individual loops do not grow or expand much; rather, the system expands by generating higher and higher loops, while the lower ones fade away. The resulting apparent velocity of expansion is quite small, $\sim$5 km s^{-1}. The real downward flow motion in the two legs of the loop is considerably faster. (Free fall of 8–10 min. would give 130–160 km s^{-1}, but much lower values have been observed.) The density and the magnetic field in the loops strongly influence the velocity of the downward flow.

Oscillations of loop-type prominences have been reported and may be associated with the flaring activity. These post-flare loops should not be confused with the loop-like structures that at times are seen during a flare display or other plage activity, when material is ejected into radial flux tubes, giving surges, or into loop-shaped flux tubes that bend over toward the surface. In the latter case the motion is along the loop, moving up one leg and down the other. In particularly large loop structures that reach high into the corona, the ejected material may form so-called flaring arches.

In coronal rain material is often seen to rain down into active regions from coronal clouds suspended in the corona. The trajectories followed by the streaming material generally are strongly curved, apparently following the lines of force of coronal magnetic fields. The velocities along these paths are comparable with the flow velocities observed in loop prominences.

Models for post-flare loops have been worked out (see SOLAR PROMINENCE MODELS and SOLAR FLARE MODELS) and imply magnetic reconnection in the arcade field that surrounds the pre-existing quiescent prominence involved.

Solar Spectroscopy and Diagnostics

Solar spectroscopy and diagnostics provide the opportunity for determining the physical parameters in different parts of the solar atmosphere.

The story of solar spectroscopy really began in 1666, when Isaac NEWTON studied the *phenomenon of colors* using a triangular glass prism which he bought in a local market. In his early experiments, he split sunlight into the colors of the rainbow. The radiation from the photosphere is similar to that of a black body with a characteristic temperature of 6000 K, which peaks in the visible wavelength range. It was only much later, in 1814, when FRAUNHOFER determined that the hundreds of dark lines in the solar visible spectrum were actually a property of the sunlight, rather than any earthly phenomenon (see FRAUNHOFER LINES). During a total eclipse of the Sun, the Fraunhofer spectrum, normally seen as absorption lines, is briefly replaced by an emission-line or flash spectrum from the chromosphere, the thin layer just above the photosphere.

QUANTUM THEORY, developed in the 1920s and 1930s, provided an explanation for spectral emission and absorption lines in terms of changes of energy state of atoms by discrete amounts—*quanta*, related to the wavelength of the radiation. Each atom has characteristic *fingerprints* of spectral lines which enable us to dissect the spectrum and determine the nature of the solar plasma where it originated. A plasma is a gas in which the atoms have been ionized.

At the time of totality, the CORONA is visible in all its glory—the *crown* around the Sun. Normally, the visible emission from the corona cannot be seen, since it is very weak, only a millionth of the intensity of the SOLAR PHOTOSPHERE or surface of the Sun. During an eclipse, the Moon blocks out exactly the photosphere and allows us a brief glance at the corona. Skilled work by a gifted French astronomer called LYOT, provided in 1930 an instrument, a coronagraph, which could simulate a total eclipse, allowing the visible coronal spectrum to be continuously observed. The coronal visible spectrum comprises emission lines (the brightest are the coronal green, red and yellow lines). These lines provided an intriguing puzzle for many years, indeed, a new element called *coronium* was invented to explain them. Although Lyot noted that the width of the green line indicated a characteristic temperature much higher than the photosphere, it was the painstaking scientific investigations by Grotian and Edlen around 1940 which eventually led to the identification of these lines from ions which only exist at very high temperatures (above 10^6 K). The green line comes from Fe XIV (iron with 13 electrons stripped off), the red line from Fe X and the hottest line, the yellow line, is from Ca XV. Thus it was established that the corona is very much hotter than the photosphere—a fascinating phenomenon, which solar physicists are still seeking to explain.

Modern technology has enabled us to move far beyond the visible wavelength range into the ultraviolet, x-rays, infrared and radio wavelength ranges. From space observatories, we are able to monitor the corona continuously in the UV and x-rays. At these wavelengths we see hundreds of emission lines, covering a wide range of temperatures. Spectroscopic diagnostics encompasses the study of techniques which have been developed to deduce plasma parameters, such as electron density and temperature, elemental abundances and mass motions from spectral lines. A comprehensive review of spectroscopic diagnostics for solar and stellar plasmas in the VUV (100–2000 Å) was published by Mason and Monsignori Fossi (1994). To use these techniques it is necessary to build accurate atomic models, including all the important processes and using the best available atomic data.

Electron temperature

As the temperature increases in a gas, the particles become very energetic, so more and more electrons get stripped off the ions. For example, neutral oxygen has eight electrons, but at a temperature of 10^5 K, four electrons have been removed. The ion formed is O V (or O^{4+} in notation used by atomic physicists). So, if we make images of the solar atmosphere in different spectral lines, we are in fact able to take 'slices' at different temperatures. For example, the Coronal Diagnostic Spectrometer (CDS) on the Solar and Heliospheric Observatory (SOHO) was designed to do just that. Simultaneous rasters, up to $4' \times 4'$ in size, can be obtained at different wavelengths, with a high spatial resolution (approximately $3''$) (see figure 1). The SOHO-CDS instrument covers lines from ions formed over a wide temperature range (2×10^4–6×10^6 K), including the low-temperature emission from He I at 584 Å (2×10^4 K), transition region emission from O V 630 Å (2.5×10^5 K); the Mg IX 368 Å line at coronal temperatures (10^6 K) and the Fe XVI 335 and 361 Å lines observed in active regions (2×10^6 K). From the CDS rasters it is evident how different the solar atmosphere looks at various temperatures.

During solar flares, the temperature can exceed 10^7 K, and many lines from highly ionized iron ions can be observed in the x-ray wavelength range. Figure 2 is an observation made with the Bent Crystal Spectrometer (BCS) instrument on the YOHKOH satellite (ISAS, Japan). The presence of the Fe XXVI lines indicates a very high temperature of around 30×10^6 K.

In the simplest coronal model approximation, we find that the emission line intensity from a volume of plasma V can be expressed as

$$I(\lambda_{ij}) = \frac{1}{4\pi} Ab(X) \int_V G(T) N_e^2 \, \mathrm{d}V \, (\text{photons}\,\text{s}^{-1}\,\text{sr}^{-1})$$

where λ_{ij} is the wavelength for the transition between energy level j and i in the ion, $Ab(X)$ is the element abundance and N_e is the electron number density (cm^{-3}). The *contribution function*, $G(T)$, contains all of the relevant atomic physics parameters—it is strongly peaked in temperature (see figure 3).

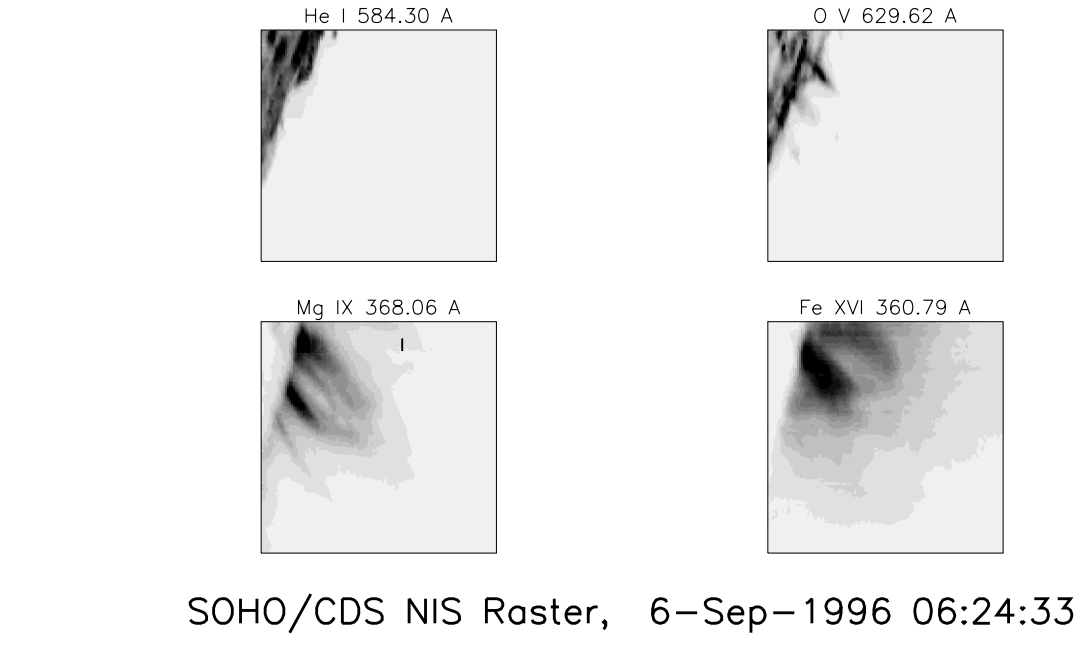

Figure 1. SOHO-CDS rasters of an active region, showing emission from He I, O V, Mg IX and Fe XVI.

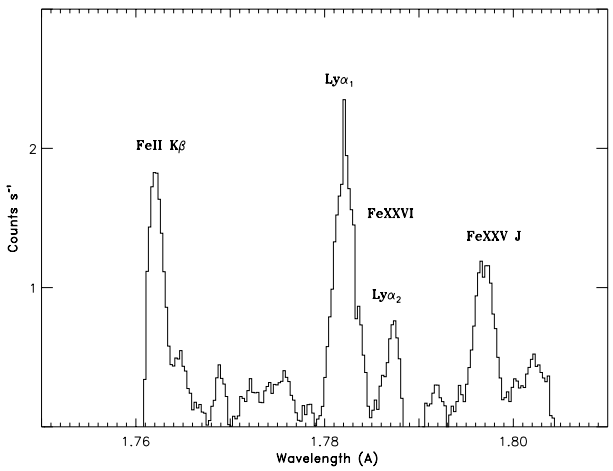

Figure 2. Fe XXVI lines observed with the YOHKOH BCS instrument. (Courtesy of Pike.)

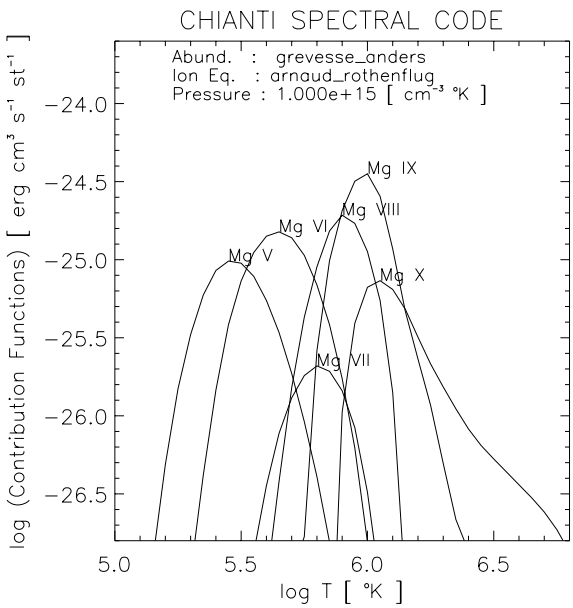

Figure 3. The contribution functions $(G(T)Ab(X)/4\pi)$ for various ionization stages of Mg: Mg V (353.09 Å), Mg VI (349.17 Å multiplet), Mg VII (363.77 Å), Mg VIII (315.04 Å), Mg IX (368.07 Å), Mg X (624.94 Å).

From a study of the intensity of spectral lines formed at different temperatures, it is possible to deduce the amount of material in each temperature range, which is called the *emission measure distribution*. With further assumptions about the geometry of the region, one can directly compare the observations with theoretical models.

Vast quantities of atomic data are required to simulate the observed spectra. For example, the CHIANTI atomic database and analysis software (Dere *et al* 1997), has been developed as a collaboration between the USA, Italy and the UK to provide a comprehensive dataset for ions of astrophysical interest. A comparison of the simulated and observed CDS spectrum is given in figure 4. Several other atomic databases and packages are available such as the Atomic Data and Analysis Structure (ADAS) developed at Strathclyde University.

Electron density

The electron pressure is an important parameter in any theoretical model for the plasma. This is proportional to the product of the electron density and temperature. Experience from solar observations is that the plasma often exists in the form of unresolved filamentary structures, even down to the best spatial resolution which has yet been obtained. At one extreme is the solar transition region, where only a very small fraction of the observed emitting volume is actually filled with plasma.

An estimate for the electron density can be deduced from the absolute intensity of one emission line, if the relevant atomic parameters are known. However, this method depends on several assumptions and breaks down if any filamentary structure exists.

Techniques have been developed to determine electron density from spectral line intensity ratios for the same ion. These methods make no assumption about the size of the emitting volume or the element abundance value. They therefore provide a powerful and important diagnostic for the solar plasma. Spectral lines may be grouped into different categories according to the way in which they are produced. In the coronal model approximation the spectral line intensity is a function of N_e^2; however, for some transitions, the dependency on N_e is different. The atomic processes within each ion determine the way in which the spectral line intensities vary with N_e.

For example, Si X, formed at around 1.3×10^6 K, provides a useful electron density diagnostic with lines at 347.4 Å and 356.0 Å. The intensity ratio (356.0/347.4) varies with electron density as shown in figure 5.

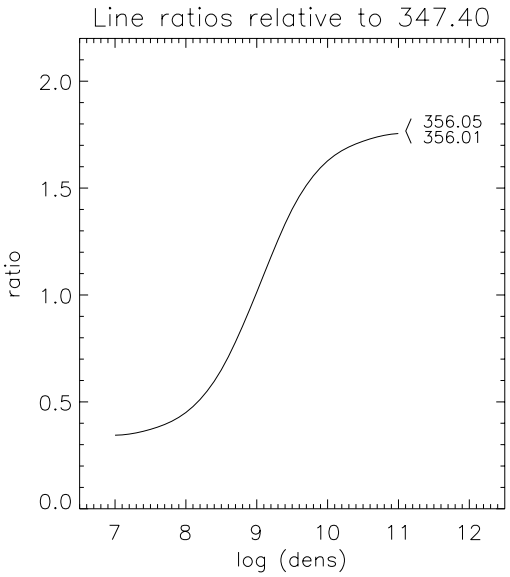

Figure 5. The Si X density sensitive 356.03/347.40 ratio (the observed 356.03 Å line is a blend of two Si X lines).

In the hottest parts of active regions the 356.0 Å line can be found to be around twice as intense as the 347.4 Å

line, implying a high electron density $>10^{10}$ cm^{-3}. In contrast the characteristic electron density for the quiet Sun is around 10^8 cm^{-3} and in coronal holes it is even less.

Elemental composition

There has been a great deal of discussion and controversy about variations in the elemental abundances in the solar atmosphere (see SOLAR ABUNDANCES). The element abundances measured in the solar wind differ from those in the photosphere. The coronal abundances also differ from those in the photosphere, in fact they seem to vary in different solar features. This behavior depends on the value for the first ionization potential (FIP)—which is the energy required to ionize the neutral atom. The ions with FIP greater than 10 eV appear to behave differently from those with FIPs less than 10 eV. It is believed that this could reflect the ionization and acceleration processes for the solar corona, low down in the solar atmosphere.

The intensity of a spectral line is directly dependent on the elemental abundance. One approach to determining element abundances is to use the detailed shape of the emission measure distribution for ions from the same element and apply an iterative procedure to normalizing the curves for different elements. Another procedure is to use the intensity ratios for individual spectral lines which have very similar $G(T)$ functions, but different FIPs. For example, neutral neon, with an FIP of 21.6 eV, has a closed shell structure which is difficult to ionize, whereas it is much easier to ionize magnesium, with an FIP of 7.6 eV. Studies of the Mg/Ne relative abundances indicate that some low-lying dense structures in active regions have photospheric abundances, whilst other larger more open-loop structures have coronal abundances. This could indicate the emergence and heating of dense flux tubes from beneath the solar suface.

Elemental abundance determinations in a CORONAL STREAMER have recently been made with the Ultraviolet Coronagraph Spectrometer (UVSP) on SOHO. The UVSP team find a depletion of the high-FIP elements in the center of a quiescent streamer and suggest that gravitational settling may be partly responsible. It is important to attempt to relate the elemental abundances determined in the solar atmosphere with those measured further out in the solar wind.

Spectral line profiles

Line shifts and broadenings give information about the dynamic nature of the solar atmosphere. The transition region lines, formed at around 10^5 K, are characterized by broadened and irregular line profiles, which put constraints on possible heating processes. These profiles show evidence for small explosive events which occur around the edges of the magnetic network. They could be linked to coronal heating processes in the quiet Sun. Transient brightenings in transition region lines, called *blinkers*, have been observed by SOHO-CDS.

Many detailed studies have been carried out for a variety of solar features. For example, figure 6 shows a macrospicule-like feature at the limb, which was recorded by SOHO-CDS (Pike and Mason 1998). The left-hand side shows the OV intensity raster and the right-hand side shows an OV velocity map. If an axis is defined through the center of the OV feature and extended above the limb from the footpoint region, the emission is apparently blueshifted (black) on one side of the axis and redshifted (white) on the other. It is likely that a combination of both rotating and accelerating plasma would explain these observations.

Outflows of coronal material have been correlated with CORONAL HOLES, the source of the fast SOLAR WIND. The excess broadening of the transition region and coronal lines could be due to macroturbulence and provides valuable information on the heating of the solar atmosphere and the SOLAR WIND ACCELERATION.

The SOHO-UVCS instrument is designed to carry out diagnostic studies of the extended corona, in particular to measure coronal line intensities and profiles. For the O VI lines, a process called Doppler dimming enables a determination to be made of the solar wind outflow velocity. In the equatorial streamers, the outflow velocity reaches a value of around 100 km s^{-1} at four solar radii. Bright ray-like structures have been observed in coronal holes which could be related to POLAR PLUMES. The SOHO-LASCO (Large Angle Spectroscopic Coronagraph) instrument comprises three coronagraphs which cover different distances out into the extended corona. The inner coronagraph has the capability of observing in the green, red and yellow lines as well as in white light. Dynamic features can be tracked from close to the solar surface right out to 30 solar radii. In particular LASCO has observed many CMEs (coronal mass ejections), streamers, polar plumes and comets.

Conclusion

Spectroscopy provides a powerful opportunity for probing the nature of the solar atmosphere. This is illustrated by recent advances in UV observations of the transition region and corona by SOHO. In particular, examples have been given for diagnostic techniques involving optically thin emission lines. Lower down in the solar atmosphere (photosphere and chromosphere), it is necessary to solve the radiative transfer equations to study emission or absorption features.

The x-ray spectrum has only briefly been mentioned. The SOLAR MAXIMUM MISSION (SMM) satellite flown in the 1970s and the more recent YOHKOH satellite have provided extensive observations of active regions and solar flares in the x-ray wavelength range. A multitude of diagnostic possibilities exist and have been explored with these data.

From diagnostic studies of the solar atmosphere, we now know that the transition region is dynamic and filamentary in nature. MAGNETIC RECONNECTION at the network boundaries is correlated with enhanced transition region emission, indicative of heating. The corona is confined by small- and large-scale magnetic features. In active regions, the temperature is high and the measured

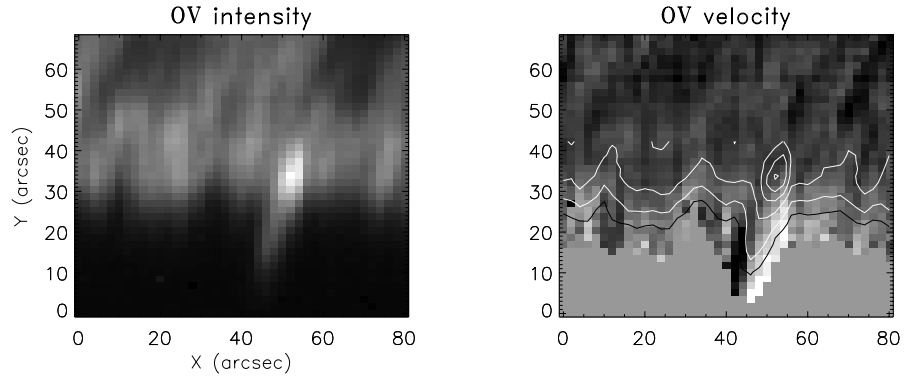

Figure 6. OV intensity (lhs) and velocity (rhs) maps for a solar tornado. The contours on the rhs velocity map are OV intensity. (From Pike and Mason 1998.)

electron densities are at least an order of magnitude higher than the quiet Sun. However, the densest, hottest parts of active regions are often low down, close to the regions of greatest magnetic shear. Large, cool (around 10^5 K) loops are a common feature of active regions. These are not stable and large velocities (around 100 km s^{-1}) have been recorded. In coronal holes, diagnostic studies give a low electron density and a characteristic temperature below 10^6 K. A heated debate is in progress about whether it is the polar plume or inter-plume regions which are the source of the high-speed solar wind. Initial velocity measurements from SUMER indicate that it is the latter, but further studies are in progress.

One has to stop and ponder what Newton would have thought about the advances which have been made in spectroscopy. Space technology has provided the opportunity to go far beyond the colors of the rainbow. Would he have shared our enthusiasm and excitement for studying the intricate features of the Sun?

Solar Spectroscopy and Diagnostics: X-ray Emission

X-ray emission from the Sun arises primarily from the solar outer atmosphere, particularly the hot corona. During transient events, such as flares and coronal mass ejections, there is also enhanced emission of both soft and hard x-rays from plasma above ten million kelvins (see SOLAR FLARES: RELATION TO CORONAL MASS EJECTIONS). Outside of flares, the bulk of the coronal plasma is at temperatures in the range 1–10 MK, leading to radiation primarily in spectral lines from ions of heavy elements in the atmosphere formed at these temperatures. Above 10 MK, the atoms of the coronal plasma are stripped of most of their outer electrons and continuum emission gains in importance.

Figure 1 shows a calculation of the soft x-ray emission (to 100 Å) of the coronal plasma at a temperature of 3 MK, which is typical of SOLAR ACTIVE REGIONS. The quantity plotted is the spectral emissivity $P(T, \lambda)$, which is the plasma emission summed over all spectral lines and continuum processes, but kept as a function of wavelength. $P(T, \lambda)$ is therefore the spectrum emitted by a unit volume of the coronal plasma; it has units erg cm^3 s^{-1} Å^{-1}.

The emission spectrum is seen to be dominated by individual strong emission lines, especially at wavelengths 10–20 Å; there are also some strong emission lines in the extreme ultraviolet (EUV) between 170 and 600 Å, not discussed in this article (see SOLAR SPECTROSCOPY: ULTRAVIOLET AND EXTREME ULTRAVIOLET EMISSION). At lower temperatures the spectrum shifts to longer wavelengths, while at higher temperatures it is dominated by shorter-wavelength lines. This is determined by the ionization stages attained by the ions in the coronal gas at each temperature, as described in the main article for this section. In the following we discuss the mechanics of emission specifically with reference to x-ray emission from the solar atmosphere.

Abundances and ionization balance

If we assume local thermodynamic equilibrium, then the x-ray emission from a given region of the solar atmosphere is determined by the composition of the plasma and its temperature. The abundances of all elements heavier than helium in the solar atmosphere are very small relative to hydrogen, in the range 10^{-4}–10^{-6} as a proportion by number. Table 1 gives estimates of abundances for the most important elements (see also SOLAR ABUNDANCES).

Coronal abundances differ from photospheric values for some elements. Known as the first ionization potential (FIP) effect, elements such as C, N and O having FIP $>$ 10 eV are underabundant compared with elements such as Mg, Si and Fe. The difference can amount to nearly an order of magnitude in some cases, and the size of the effect also varies from one place to another in the corona. A discussion of this effect and references to literature on the subject are found in Golub and Pasachoff (1997, ch 3.3).

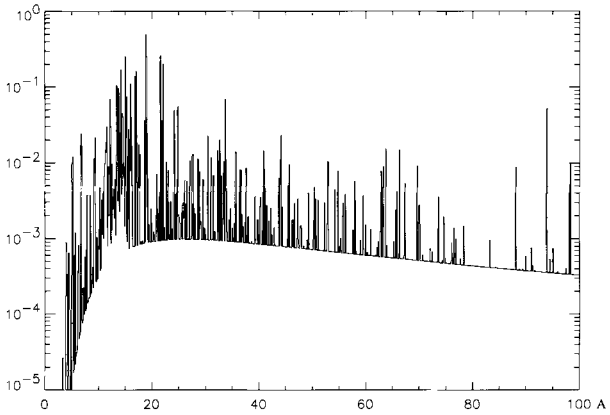

Figure 1. The spectral emissivity of the solar corona for a unit of plasma at $T = 3$ MK. The vertical scale is in units of 10^{-23} erg cm^3 s^{-1} Å^{-1}. Courtesy E DeLuca, SAO.

Table 1. Coronal abundances, normalized to hydrogen.

Element	Coronal abundance
H	1
He	0.10
C	2.3×10^{-4}
N	3.9×10^{-5}
O	2.4×10^{-4}
Ne	3.5×10^{-5}
Na	2.7×10^{-6}
Mg	3.7×10^{-5}
Al	2.7×10^{-6}
Si	3.9×10^{-5}
S	8.6×10^{-6}
Ar	2.1×10^{-6}
Ca	2.9×10^{-6}
Fe	3.9×10^{-5}
Ni	2.2×10^{-6}

The most abundant element, hydrogen, has no strong emission lines in the x-ray region; the strongest line of helium arises from the Lyman-α transition of He^+ at 304 A, in the EUV. At temperatures between 100 000 K and 1 MK the most important contributors to the total power emitted by the solar atmosphere, taking into account the combined emission from all of the relevant ionization stages of each element, are C and O; above 1 MK, the most important contributor is Fe. The fraction, f, of an element that is in a given ionization stage is a function of temperature, determined by the balance between the formation and removal processes: ionization from a lower stage, ionization to a higher stage, recombination from a higher stage and recombination to a lower stage; see main article for further details. A list of the most prominent emission lines in the corona and the temperatures at which they are maximally present is given in table 2.

If the energy balance at a given location in the corona is variable, the abundance of a given ionization stage will change. Timescales for such changes show considerable

Ion	$\log(T_{max})$	$-\log(f)$[a]	τ (s)
Ne^{6+}	5.7	0.5	1.6
Fe^{8+}	5.9	0.5	0.4
Mg^{9+}	6.1	0.7	14
O^{6+}	6.3	0.3	0.4
O^{7+}	6.4	0.3	103
Fe^{16+}	6.4	0.1	10
Fe^{23+}	7.2	0.5	206

[a] f is the fraction of the element in the given ionization stage at the stated temperature.

differences among the various elements and ionization species. Table 3 gives some examples of the timescale for the appearance of a given ion from the next lower ionization stage, at pressure $N_eT = 3 \times 10^{15}$ cm^{-3} K, in response to a sudden increase in temperature. These values are calculated at the temperature of maximum formation for the listed species. This subject is discussed in Golub and Pasachoff (1997, pp 232–3).

Emitted power

The power emitted by a unit volume of coronal plasma at a given wavelength is $N_eN_pP(T,\lambda)$, where $N_{e,p}$ are the electron and proton number densities, respectively.

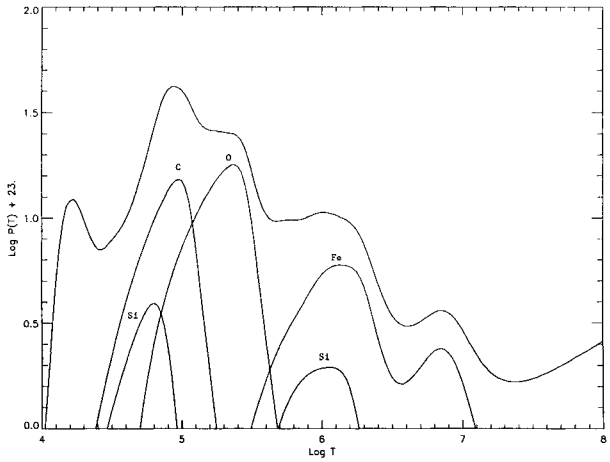

Figure 2. The radiative loss function $P(T)$ for the coronal plasma. Top curve is the total, bottom curves are individual sums for O, C, Fe and Si. Courtesy J Raymond, SAO.

The total radiative loss rate is found by integrating over all wavelengths, $E_R = N_eN_pP(T)$. The quantity $P(T)$ is known as the radiative loss function; it has units erg cm^3 s^{-1}, so that the radiative loss rate E_R has units erg cm^{-3} s^{-1}. At typical coronal temperatures $P(T)$ is of the order of 10^{-23}; a calculation of $P(T)$ from $T = 10^4$ K to $T = 10^8$ K is shown in figure 2.

Solar Spectroscopy: Atomic Processes

A Greek philosopher called DEMOCRITUS (*c*. 460–370 BC) first introduced the concept of atoms (which means indivisible). His atoms do not precisely correspond to our atoms of today, which are not indivisible, but made up of a nucleus (protons with positive charge and neutrons which have no charge) and orbiting electrons (with negative charge). Indeed, in the solar atmosphere, the temperature is such that atoms are often ionized (to form ions), that is they have lost one electron or two or more. It is the interaction of the atoms and ions with electrons, protons and the radiation field which we refer to as atomic processes. These atomic processes in a PLASMA (ionized gas) determine the intensity or brightness of the radiation which we observe at all wavelengths from the SOLAR ATMOSPHERE. In particular, the transitions give rise to emission and absorption spectral lines.

The birth of quantum mechanics

In 1900, MAX PLANCK presented a derivation of the black-body law in Germany, and the theory of quantum physics was born. In his derivation for the intensity of radiation as a function of wavelength and temperature, Planck set aside classical physics and made an *ad hoc* assumption that light energy, E, was emitted and absorbed in packets (photons) ($E = h\nu$) by oscillators with a natural frequency, ν, where h is a fundamental constant of nature, now known as Planck's constant. Planck himself was not at all happy with his own idea, and he tried for many years to disprove it and understand black-body radiation with classical physics. The radiation from the SOLAR PHOTOSPHERE can be approximated to a black body of temperature just below 6000 K.

ALBERT EINSTEIN, in 1905, went on to explain the photoelectric effect. When light is incident on a metal surface, electrons are ejected. He proposed that the energy in the beam of monochromatic light comes in parcels, $h\nu$. This quantum of energy, a photon, could be transferred completely to the electron. This explanation of the photoelectric effect added substance to Planck's earlier supposition. QUANTUM MECHANICS was born.

Solar and stellar spectral lines

The first SPECTROSCOPE, created by JOSEPH VON FRAUNHOFER in 1814, combined a prism with a small viewing telescope focused on a narrow slit. He used this instrument to view the Sun's spectrum and saw not a continuous spectrum of light, but many, many dark lines. It was later found that any chemical compound, gas or vapor, which emitted light produces its own unique spectrum.

The pattern in emission lines was established by BALMER in 1885, from studies of the hydrogen lines in the spectrum of stars. It was the theory put forward by Bohr in 1913, using Planck's ideas, which accounted for the Balmer analysis of the hydrogen spectrum. Bohr's model for the atom was based on Rutherford's model comprising a positive core, nucleus, surrounded by negatively charged electrons. However, Bohr proposed that electrons could only exist in discrete orbits. In these orbits, they did not radiate energy, but when they jumped from one orbit to another, they emitted a quantum of light. With this hypothesis, everything fell into place.

The FRAUNHOFER LINES are absorption lines from many different elements. The radiation passing through the layers in the solar atmosphere is absorbed by the atoms and ions to excite electrons to higher orbits.

Bright emission lines from PROMINENCES were recorded by Sir JOSEPH NORMAN LOCKYER in 1868. Laboratory experiments were carried out to try and reproduce these lines, but without success. He suggested that the lines were due to an element named *helium* after the Greek Sun god *Helios*. It was 25 years before the existence of helium was confirmed on Earth.

We now know that the Sun is composed mainly of hydrogen, with some helium and traces of many other elements. The spectral line patterns from these atoms and ions can be very complex, reflecting the intricacy of their atomic structure.

Atomic processes

There has been a close association between the study of the Sun and developments in atomic collision physics. The formulation of the so-called *coronal equilibrium* equations over fifty years ago pointed to the importance of excitation, ionization and recombination collisions in determining the state of the plasma and the nature of the spectral emission lines. In earlier *local thermodynamic equilibrium* models, the plasma state was determined by its temperature and the laws of statistical physics.

In the solar atmosphere, the ionization and recombination processes can usually be solved separately from the statistical equilibrium equations for the atomic processes amongst the low lying levels in the ion.

In a hot ($T > 2 \times 10^4$ K) and low electron density ($N_e < 10^{12}$ cm^{-3}) plasma, such as the outer atmosphere of the Sun and stars, it can be assumed that the spectral lines are optically thin. Low down in the atmosphere, it is necessary to solve the RADIATIVE TRANSFER equations.

The notation used is such that Fe XIV (or Fe^{13+}) is the element iron with thirteen electrons stripped off. Taking Fe XIV as an example, the ground configuration $3s^23p$ has two levels—$^2P_{1/2}$ and $^2P_{3/2}$—the transition between these two levels gives rise to the coronal green line at 5303 Å. The transitions between the excited configurations $3s3p^2$ and $3s^23p$ are at around 300–400 Å and those between $3s^23d$ and $3s^23p$ are at shorter wavelengths around 200 Å.

Spectral emission line

An ion in an excited state can spontaneously emit radiation:

$$X_j^{m+} \Longrightarrow X_i^{m+} + h\nu_{i,j} \qquad (1)$$

where an atom X of charge state m, in a bound state (orbit) j emits a photon of energy $\Delta E_{i,j}$ ($= h\nu_{i,j} = hc/\lambda_{i,j}$) to arrive at a lower energy state i.

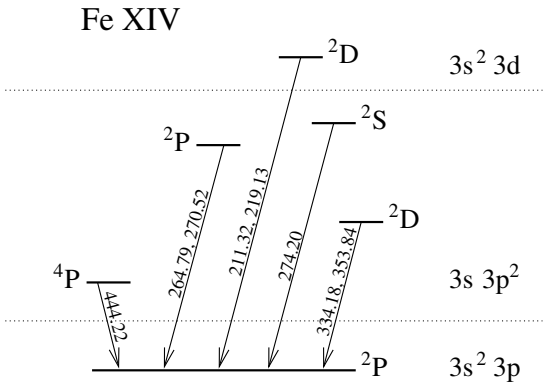

Figure 1. A diagram illustrating the strongest EUV transitions. Wavelengths are given in ångströms.

Ionization and recombination

The degree of ionization of an element is obtained by equating the ionization and recombination rates that relate successive stages of ionization.

$$N^{m+}(q_{\rm col} + q_{\rm au}) = N^{(m+1)+}(\alpha_{\rm r} + \alpha_{\rm d}). \tag{2}$$

The dominant processes in optically thin plasmas are *direct electron impact ionization* ($q_{\rm col}$)and excitation followed by *autoionization*($q_{\rm au}$); *radiative recombination* ($\alpha_{\rm r}$) and *dielectronic recombination*($\alpha_{\rm d}$). The fractional ionization ratio for each ion

$$R_m = N(X^{m+})/N(X) \tag{3}$$

is significant over a small range of temperatures and peaks at a different $T_{\rm max}$ for each ion stage. As the temperature increases, so does the ionization stage, as more and more electrons are stripped off (Arnaud and Raymond, 1992).

Direct electron impact ionization from the inner and outer shells of the ground configuration can be expressed as:

$$X_n^{m+} + {\rm e} \Rightarrow X_{n'}^{(m+1)+} + {\rm e}' + {\rm e}'' \tag{4}$$

with n and n' being the quantum state of the ions.

The process of *radiative recombination* is:

$$X_n^{(m+1)+} + {\rm e} \Rightarrow X_{n'}^{m+} + h\nu. \tag{5}$$

The inverse process is *photoionization*, which is a dominant process for many low-density astrophysical plasmas, but not for the outer atmospheres of the Sun and stars.

For the solar CORONA, the main ionization and recombination processes were originally thought to be direct electron impact ionization and radiative recombination. However, early calculations gave values of $T_{\rm max}$ for the coronal forbidden lines (due to Fe X and Fe XIV) much lower than the temperatures deduced from their spectral line profiles. This discrepancy was eventually resolved by Burgess, who showed the importance of dielectronic recombination, a process which can proceed via doubly excited autoionizing states. The process of *dielectronic recombination* is:

$$X_n^{(m+1)+} + {\rm e} \Rightarrow (X_{n'}^{m+})^{**} \Rightarrow X_{n''}^{m+} + h\nu \tag{6}$$

where an electron is captured by an ion with charge $(m + 1)+$ to form a doubly excited state $(\ )^{**}$ of an ion X with charge $m+$. This ion can then either *autoionize* back again or undergo a spontaneous radiative transition of the inner excited electron to a state below the first ionization limit. Dielectronic recombination is now known to be the dominant recombination mechanism at high temperatures, for example in the solar corona. It is at least a factor of twenty higher than radiative recombination.

The inverse process to dielectronic recombination is *autoionization*:

$$(X_n^{m+})^{**} \Rightarrow X_{n'}^{(m+1)+} + {\rm e}'. \tag{7}$$

The coronal model approximation

The atomic processes which determine the populations of the low-lying levels in an atom or ion in the solar corona are *excitation by electron (e) or proton (H^+) impact*:

$$X_i^{m+} + {\rm e}\ ({\rm H}^+) \Rightarrow X_j^{m+} + {\rm e}'\ ({\rm H}^+) \tag{8}$$

and radiative processes, spontaneous ratiative decay and photoexcitation (the excitation by absorption of photospheric radiation)

For optically allowed (electric dipole transitions) which give rise to spectral lines in the UV, EUV and x-ray wavelength ranges, the *coronal model* approximation is usually valid. The population, $N_j(X^{m+})$, of the upper level, j, is determined by electron collisional excitation from the ground state i and radiative decay from j back down to i.

$$N_i(X^{m+})N_{\rm e}C_{i,j}^{\rm e} = N_j(X^{m+})A_{j,i} \tag{9}$$

where the spontaneous radiative decay rate is $A_{j,i}$ and the electron number density is $N_{\rm e}$. The electron collisional excitation rate coefficient, $C_{i,j}^{\rm e}$, is obtained by integrating the electron impact collision cross section over a Maxwellian electron velocity distribution with a temperature $T_{\rm e}$(K).

For a typical EUV transition, for example from Fe XIV, at coronal densities and temperatures, we find that $A_{j,i}$ is approximately 10^{10} s^{-1}, whereas $N_{\rm e}C_{i,j}^{\rm e}$ is around unity. The population of the upper level j is negligible in comparison with that of the ground level i.

The solution of the electron–ion scattering problem is complex and takes a great deal of computing resources. The accuracy of a particular calculation depends on two main factors. The first is the representation which is used for the target, the atom or ion, and the second is the type of scattering approximation chosen. The main approximations used for electron–ion scattering are *distorted wave* (DW), *Coulomb–Bethe* (CBe) and the more elaborate *close-coupling* (CC) approximation. The

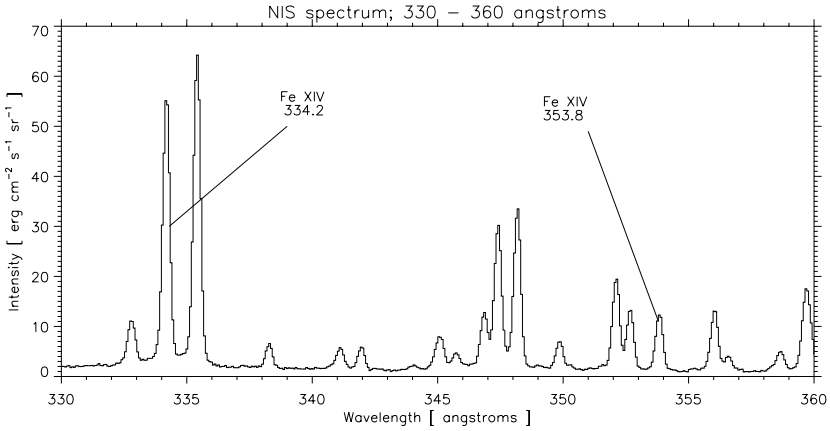

Figure 2. NIS spectrum in the range 330–360 Å taken above an active region on the solar limb. The Fe XIV 334.2 and 353.8 Å lines are clearly seen.

DW approximation neglects the coupling of the channels (target + scattering electron). Since the scattering electron sees a central field potential, the DW approximation is only valid for systems which are a few times ionized. For high partial wave values of the incoming electron, the CBe approximation is valid, when it is assumed that the scattering electron does not penetrate the target. In the CC approximation, the scattering electron sees individual target electrons, the channels are coupled and a set of integro-differential equations are solved. The CC approximation is the most accurate (better than 5%) but it is also the most expensive in terms of computing resources.

The proton collisional excitation and de-excitation rates become comparable with electron collisional processes for transitions where $\Delta E_{i,j} \ll kT_e$, where k is the Boltzmann constant. This happens for transitions between fine structure levels at high temperatures, for example the Fe XIV transition in the ground configuration: $3s^23p$ ($^2P_{1/2}$ - $^2P_{3/2}$).

Solar EUV spectral emission lines

The EUV wavelength range provides a wealth of spectral emission lines from many different elements and ion stages (see SOLAR SPECTROSCOPY: ULTRAVIOLET AND EXTREME ULTRAVIOLET EMISSION). Fe XIV is one of the most important diagnostic ions in the solar corona. It is abundant at a temperature of about 2×10^6 K. Transitions within Fe XIV give rise to spectral lines in the visible (green line, 5303 Å) and extreme ultraviolet (EUV) wavelength ranges. The transitions between the ground configuration ($3s^23p$) and excited configurations ($3s3p^2$, $3s^23d$) give rise to strong lines in the EUV wavelength range. These have been extensively observed with the Coronal Diagnostic Spectrometer on SOHO and can be used to determine electron density in the solar atmosphere. The transitions and observations are illustrated in figures 1 and 2.

New CC atomic calculations have recently been carried out as part of the IRON project for Fe XIV and many other coronal ions. The results provide a significant advance over previous work. In particular, many of the persistent discrepancies between observed and theoretical intensity ratios now seem to have been resolved.

Summary

The story of solar spectroscopy and the corresponding study of atomic processes has been fascinating to follow. The requirement for high accuracy atomic data to interpret astrophysical spectra has provided the stimulus for the development of new techniques in atomic physics. These new atomic data have provided the means to probe and define the physical parameters in the solar atmosphere. The two fields of study have been closely interwoven, with a very fruitful return for each. From recent solar observations, we know that the solar atmosphere is dynamic, constantly changing on all spatial scales. This poses an exciting challenge for atomic physics, to interface the theoretical solar models with atomic processes. The strong possibility exists that the solar plasma is not in equilibrium, that assumptions such as Maxwellian velocity distributions and ionization equilibrium may no longer be tenable.

Solar Spectroscopy: Coherent Plasma Emission

Radio emission from the Sun is highly variable, and often much brighter than can be explained in terms of thermal radiation from the solar CORONA. The various kinds of non-thermal radio emission are called solar radio bursts.

Frequency ranges

Solar radio bursts are classified first according to the (cyclic) frequency of observation, ν, or wavelength, $\lambda = c/\nu$. The bursts discussed in this section are at decimeter-λ ($\nu \sim 0.3$–3 GHz) and meter-λ ($\nu \lesssim 300$ MHz) or longer. Decimeter-λ bursts are generated low in the corona, meter-λ bursts at heights $\sim 1 R_\odot$ and kilometer-λ bursts (observed from spacecraft) originate in the interplanetary medium (IPM). Emission at higher frequencies in the radio range (mm-λ and microwaves at $\gtrsim 3$ GHz) is discussed in SOLAR FLARES: RADIO BURSTS.

Dynamic spectra

The classification of a radio burst is based primarily on its appearance on a dynamic spectrum, which shows ν versus time t with the intensity of emission represented by a gray scale, cf figure 1. Important characteristics of bursts are their drift rate, $\dot{\nu} = \mathrm{d}\nu/\mathrm{d}t$, their bandwidth $\Delta\nu$ (at fixed t), their duration Δt (at fixed ν), harmonic structure and other fine structures.

Polarization

Solar radio bursts are usually partially circularly polarized. This is interpreted in terms of the birefringence of the coronal plasma, whose ordinary mode (o-mode) and extraordinary mode (x-mode) have their electric vectors rotating in the opposite and same senses, respectively, as electrons gyrate in the magnetic field.

Brightness temperature

The brightness temperature, T_b, is related to the specific intensity, $I(\nu)$ (the power per unit area, per unit solid angle per unit frequency), by $I(\nu) = 2\nu^2 k T_\mathrm{b}/c^2$, where k is Boltzmann's constant. A RADIOTELESCOPE measures the flux density, and this is divided by the relevant solid angle to find $I(\nu)$. A radioheliograph uses interferometry to measure the angular size of sources directly. Emission is non-thermal if T_b exceeds the temperature of the plasma in the source region. For incoherent emission kT_b cannot exceed the energy of the emitting particles. A coherent emission mechanism is required when this limit is exceeded.

Emission mechanisms

Most meter-λ and decimeter-λ solar radio bursts require a coherent emission mechanism and most are interpreted in terms of *plasma emission*, which results in either fundamental (F) emission near the plasma frequency, $\nu_\mathrm{p} = 90(n_\mathrm{e}/10^8\ \mathrm{cm}^{-3})^{1/2}$ MHz, or second harmonic (H) emission at $\nu \approx 2\nu_\mathrm{p}$. Theory predicts that the F component should be highly polarized in the sense of the o-mode, and the H component weakly polarized in the same sense. This contrasts with the x-mode polarization typical of *gyromagnetic emission*, which is due to electrons gyrating in a magnetic field, B. Incoherent gyromagnetic emission by mildly relativistic electrons, called *gyrosynchrotron emission*, is the emission mechanism in solar microwave bursts. Gyromagnetic emission can lead to coherent emission through *electron cyclotron maser emission* (ECME), which occurs when gyromagnetic absorption by non-relativistic particles is negative. ECME causes x-mode radiation to grow at just above the cyclotron frequency, $\nu_B = 2.8 \times 10^{10} B$ Hz, where B is in gauss. Plasma emission is effective in weakly magnetized plasmas ($\nu_B \lesssim \nu_\mathrm{p}$), and ECME requires $\nu_\mathrm{p} \lesssim 0.3\nu_B$. The coherent emission mechanisms are discussed in more detail below.

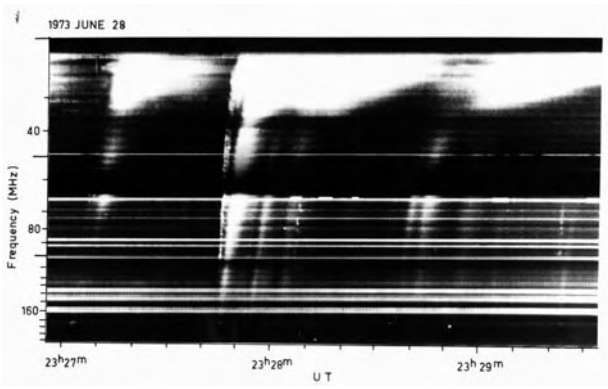

Figure 1. Example of a dynamic spectrum showing type III bursts drifting rapidly from higher to lower frequencies. The horizontal lines are interference.

Meter-λ and decimeter-λ bursts

Meter-λ bursts were originally classified (in 1950) into three types, denoted type I, type II and type III, according to their appearance on a dynamic spectrum. Later (*circa* 1960) this classification was extended to include types IV and V bursts. Detailed investigation of bursts at decimeter-λ started in the late 1970s.

Type III bursts and related bursts

Type III bursts were originally identified due to their rapid drift ($\dot{\nu} \sim -0.01\nu^{1.84}$, with ν in MHz), short duration ($\Delta t \sim 220/\nu$, with ν in MHz) and a relatively broad bandwidth ($\Delta\nu \sim \Delta t\,|\dot{\nu}|$) at a given time due to their high drift rate. A significant fraction of type III bursts exhibit harmonic structure: the F and H components are seen simultaneously with their frequency ratio, ~1:1.8. There is a broad range of T_b for type III bursts in the corona, from the lowest detectable value $\sim 10^6$ K to a maximum value that increases with decreasing frequency from $\sim 10^{11}$ K at ~100 MHz to $\sim 10^{16}$ K at ~30 kHz. Proportionally higher values of T_b are implied if the apparent sizes are scatter images of much smaller actual sources; a strong indication that they are scatter images is that the height

in the corona of an apparent source is determined by its frequency, rather than by whether it is an F or a H component. The bursts at ∼100 MHz are usually weakly circularly polarized (<0.15) in the sense of the o-mode, and occasionally the polarization is moderately high (∼0.5) for the F component. The H component is more weakly polarized in the same sense.

There are various subclasses of type III bursts. Inverted-U bursts turn over at some minimum frequency and then drift back from lower to higher frequency (interpreted as an electron beam propagating along a magnetic loop that closes very high in the corona). J bursts are similar to U bursts without the return stroke. In type V bursts the turnover in frequency is replaced by a long-duration continuum. About 10% of F components of type III bursts are type IIIB bursts, which consist of *stria bursts* (fine structures with double or triple splitting drifting more slowly than a type III burst), with an envelope similar to the profile of a type III burst.

Type III bursts are characteristic of the impulsive phase of solar flares: groups of several to several tens of type III bursts are associated with small to moderate-sized flares. There are also non-flare associated storm type III bursts. The exciting agency for a type III burst is a beam of energetic electrons propagating outward through the corona. These beams often continue through the IPM past the orbit of the Earth ($\nu_p \sim 30$ kHz), and to beyond the orbits of the GIANT PLANETS. The properties of the electron beams can be measured *in situ* at the orbit of the Earth, where a typical electron beam contains $\sim 10^{33}$ electrons over an area ~ 1 AU^2. The fastest electrons ($v \approx 0.6c$) arrive first, after which a power-law spectrum builds up and joins on smoothly to the ambient thermal distribution when the slower electrons arrive. A single interplanetary event, which lasts for ∼1 h, corresponds to many overlapping groups of type III bursts at ∼100 MHz. The mean energy of the electrons in storm type III events is significantly lower, ∼2 keV, than in flare-associated type III events, ∼10 keV.

Type II bursts

Type II bursts are slowly drifting (∼MHz s^{-1}) and narrow-band (a few MHz at ∼100 MHz). They are excited by flare-generated shock waves propagating outward through the corona. Both F and H components may be present, and they have polarization similar to type III bursts. The bursts sometimes exhibit *band splitting* in which the F and/or H component splits in two ($\Delta\nu/\nu \sim 0.1$) or *multiple-lane structures* in which multiple splitting occurs. Some bursts exhibit *herringbone structure* in which type-III-like bursts emanate from a 'backbone' of emission, and propagate either to lower or to higher frequencies. Type II bursts are sometimes seen in the IPM, although most fade from view at $\lesssim 1$ MHz, and most shocks in the IPM are not associated with type II bursts. Type II bursts are statistically associated with coronal transients, but the relation is not one-to-one.

Storms: type I emission

Type I emission is not associated with flares, but occurs in storms that can last for hours to days. Storms can include type I bursts, a type I continuum and type III bursts (type I–III storm). Type I emission is restricted to $\gtrsim 100$ MHz, and storm type III bursts to $\lesssim 100$ MHz; it appears that these originate from, respectively, closed and open magnetic structures in the solar corona, with the type I–III transition indicating the boundary between the closed and open regions. Type I emission is restricted to a few tens of megahertz, suggesting that the source is high in the corona, just below this transition.

Type I emission differs from types II and III emission in that it is strongly (∼100%) circularly polarized, and in that there is only F emission with no H component. Type I bursts have $\Delta\nu \sim 5$ MHz, $\Delta t \sim 0.3$ s at 200 MHz and $T_b \lesssim 10^9$ K. The bursts can drift to either higher or lower frequencies, with most bursts having negligible drift. Sometimes bursts line up on a dynamic spectrum to form a chain which drifts to either higher or lower frequencies at ∼0.3 MHz s^{-1}. Type I sources are directional, and are rarely visible near the solar limb. The type I continuum, which may occur with or without type I bursts, appears to be a distinct phenomenon rather than many unresolved bursts.

Continuum emission: type IV bursts

There are several different classes of radio continuum, that is, broad emission in frequency and time with little structure on a dynamic spectrum (see SOLAR SPECTROSCOPY: CONTINUUM RADIO EMISSION AND DIAGNOSTICS). The name type IV bursts was originally defined to describe continuum emission, but it is appropriate to use more specific descriptive names, such as flare continuum which is directly associated with flares, type I continuum which occurs in storms, and moving type IV bursts which drift to lower frequencies and are interpreted as gyrosynchrotron emission from plasmoids drifting out through the corona.

Decimeter-λ bursts

Type IIIDM bursts are type-III-like bursts at decimeter-λ. They are related to flare-associated meter-λ type III bursts.

Spike bursts are short-duration ($\lesssim 0.1$ s) narrow-band ($\Delta\nu/\nu \lesssim 0.03$), highly polarized bursts which may have very short (∼10 ms) rise or decay times. They can occur in the range ∼300 MHz–8 GHz, and at the highest frequencies can occur in clusters of up to 10^4 bursts. They are strongly correlated with flares, but are observed in only a few per cent of flares. The favored (but still uncertain) interpretation is: (a) that they are due to ECME generated by beams of electrons, and (b) that they represent the basic fragmentation of the energy release in flares.

Theory of solar radio emission

The basic concepts in the theory of the coherent emission mechanisms for solar radio bursts are well established but uncertainties remain in the details of the applications.

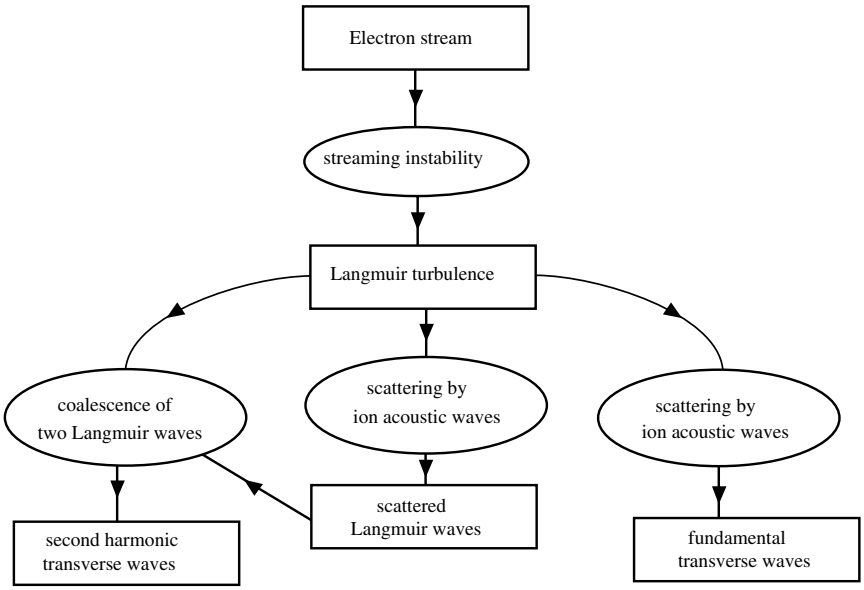

Figure 2. Flow diagram for the generation of plasma emission. In this variant of the theory the nonlinear processes involve ion acoustic waves.

Plasma emission

The first detailed theory for plasma emission was due to Ginzburg and Zheleznyakov in 1958, and although the details of the plasma physics have since been updated, the basic ideas are unchanged, cf figure 2. The first stage involves generation of Langmuir waves, which are longitudinal electron plasma oscillations just above the plasma frequency. These waves grow in a plasma instability, which in the simplest case is the bump-in-tail instability due to a beam of suprathermal electrons with distribution function, $f(v)$, with a bump, $\mathrm{d}f(v)/\mathrm{d}v > 0$, at the beaming speed, v_b. Growth of Langmuir waves is a maximum for waves propagating along the beam direction ($\theta = 0$) with phase speed, $v_\phi \lesssim v_\mathrm{b}$, and growth is effective only for small ranges of θ and v_ϕ. The evolution of the waves and of the particles is described by a pair of quasilinear equations. The back reaction on the distribution of particles, referred to as quasilinear relaxation, involves a smoothing out of the bump to form a plateau, $\mathrm{d}f(v)/\mathrm{d}v \approx 0$. In an inhomogeneous beam model, faster electrons outpace slower electrons tending to increase $\mathrm{d}f(v)/\mathrm{d}v$ near the front of the beam, and quasilinear relaxation drives the distribution function back toward marginal stability where the growth rate ($\propto \mathrm{d}f(v)/\mathrm{d}v$ at $v_\phi = v$) is just large enough to overcome any damping or losses of the waves.

The other stages involve nonlinear processes that result in partial conversion of the energy in Langmuir waves into either F or H transverse waves. The nonlinear processes can be either weak turbulence effects, involving three-wave interactions, or strong turbulence effects. The weak turbulence effects indicated in figure 2 require that low-frequency (e.g. ion-acoustic) waves be present, and these must be generated independently of the Langmuir waves. The three-wave processes saturate when the T_b of the F or H emission reaches approximately the effective temperature of the Langmuir waves, which can be estimated from the theory of the bump-in-tail instability. The required low-frequency waves have wavenumbers approximately equal to those of the Langmuir waves generated in the instability, and the three-wave interactions favor producing either transverse waves, resulting in F emission, or backward Langmuir waves, which can coalesce with the initial Langmuir waves to produce H emission. The evolution of the spectrum of Langmuir waves due to these three-wave interactions is toward higher phase speeds until they collect in a condensate at very high v_ϕ. Three-wave interactions involving even lower frequency waves, which are a common feature in the IPM, tend to scatter the Langmuir waves with little change in v_ϕ, so that they diffuse in θ. A Langmuir wave spends only a small fraction of its time in the small cone of angles about the beam direction where it grows, and a much larger fraction of its time in other directions where it damps. As a consequence, the growth rate has to be quite large to result in net wave growth.

Strong turbulence effects include parametric instabilities that are counterparts of weak-turbulence effects. One example is a decay instability in which the beam-generated Langmuir waves act as a pump that produce daughter ion-acoustic waves and either (backward) Langmuir waves or (F) transverse waves. Another example is a modulational instability which involves a four-wave interaction that tends to drive Langmuir waves to lower v_ϕ until they approach the thermal speed of electrons when Landau

damping by thermal electrons acts as an energy sink. An intrinsically strong turbulence effect is Langmuir collapse, in which the Langmuir wave energy collects in localized regions called *cavitons*. A caviton grows due to refraction of Langmuir waves into the underdense region increasing the local energy density in the waves, and the ponderomotive force due to the gradient in this energy density drives plasma out of the caviton, further decreasing its density.

Interpretation of in situ data

Direct confirmation of the theory of plasma emission comes from *in situ* data on type III events in the IPM and from analogous emission from planetary bow shocks. The Langmuir waves observed in association with the type III electrons are highly spatially inhomogeneous, in the form of localized clumps. The data have not proved definitive in deciding between weak and strong turbulence effects, with evidence supporting both. The shape of the distribution function is consistent with the inhomogeneous beam model, and the observed values of T_b are of the same order as those expected for the saturation model. There is direct evidence for the decay instability: ion-acoustic waves with the expected properties are observed, especially in planetary bow shocks. However, there is no compelling evidence for Langmuir collapse: the clumps of Langmuir waves are too large to be cavitons. A statistical distribution of the electric fields in the clumps is consistent with a stochastic growth theory in which an individual burst of growth increases the energy density from W_0 to $W = e^G W_0$, with G a random variable.

Electron cyclotron maser emission (ECME)

ECME results when gyromagnetic absorption by nonrelativistic particles is negative. The most favored case is for a loss-cone instability, in which there is a deficiency of electrons with small pitch angles. A loss cone is present in the reflected electrons when precipitation preferentially removes the electrons with small pitch angles at a footpoint of a magnetic loop. ECME causes x-mode radiation to grow at just above ν_B. A serious problem with application of ECME to solar radio emissions is that it should be reabsorbed by thermal electrons at the second ($\nu = 2\nu_B$) harmonic layer. Suggestions as to how this difficulty might be overcome or avoided include (a) emission at higher harmonics above the second harmonic absorption layer, (b) tunneling through this layer and (c) escape through windows in θ. However, each of these introduces other difficulties, and interpretation of any solar emissions in terms of ECME should be regarded as tentative until it can be shown how the radiation can escape. An interpretation in terms of plasma emission should not be excluded.

Propagation through the solar corona

Local inhomogeneities in the coronal plasma cause local variations in the refractive index $n(\nu) = (1 - \nu_p^2/\nu^2)^{1/2}$ of transverse waves, and hence lead to coronal scattering. This scattering tends to increase the angular size of the source, which opposes the systematic refraction into the radial direction due to the average coronal density gradient. In addition to scattering, there is strong evidence for ducting for some bursts, in which the radiation is guided from its actual source to a much greater height where it is scattered to produce an apparent source. Observations suggest that the observed meter-λ sources are scatter images, that are much higher and larger than the actual sources. Propagation effects also modify the polarization. In particular, although the ~100% o-mode POLARIZATION of many type I bursts confirms the prediction of the theory of plasma emission for plausible values of B in the source region, the much weaker polarization in type III and type II emission, and for type I sources as they approach the solar limb, imply that depolarization occurs. Depolarization is probably due to reflections off overdense structures in the corona converting pure o-mode radiation into a mixture of o-mode and x-mode radiation.

Solar Spectroscopy: Continuum Radio Emission and Diagnostics

The Sun is a strong radio source (one of the first objects detected by radio telescopes) and radio observations can provide information on structures throughout the solar atmosphere. Radio techniques allow high-quality images with arcsecond resolution to be achieved, and different radio frequencies provide access to different layers of the solar atmosphere. This section discusses incoherent emission from thermal plasma in the non-flaring solar atmosphere; other relevant material may be found in SOLAR SPECTROSCOPY: COHERENT PLASMA EMISSION and in SOLAR FLARES: RADIO BURSTS.

Emission mechanisms

Three different emission mechanisms are the dominant sources of continuum radio opacity in the non-flaring solar atmosphere, and their contrasting properties allow them to be exploited in different ways. An important feature of radio emission from the solar atmosphere is that the presence of magnetized plasma breaks the degeneracy between the two electromagnetic modes and leads in general to very different opacities for them. In particular, the mode in which the electric vector rotates with the same sense as the gyration motion of an electron about a magnetic field (known as the *extraordinary* or X mode) interacts more strongly with radiating electrons than the mode with the opposite sense of rotation of the electric vector (the *ordinary* or O mode). RADIO TELESCOPES typically make images in the two oppositely circularly polarized electromagnetic modes which correspond to the natural radiation modes of the plasma: differences between the two modes result in polarized emission which reflects the conditions in the radio source and is often a valuable diagnostic.

Free–free or bremsstrahlung emission

This is the name given to the electromagnetic interaction occurring when a free electron collides with a positively charged ion. In the solar atmosphere protons and helium make up the bulk of the ions: at temperatures of 10^4 K and higher, all hydrogen atoms are ionized and the atmosphere is a plasma dominated by free electrons and protons. The opacity of this mechanism is proportional to the product of the electron and ion charge densities and inversely proportional to the square of frequency and to temperature to the power 1.5. It is therefore particularly effective at high densities, low frequencies and low temperatures. This mechanism can produce mildly polarized emission.

Thermal gyroresonance emission

An electron moving in a magnetic field gyrates about the field direction with a characteristic frequency called the electron gyrofrequency, $\nu_B = 2.8 \times 10^6 B$ Hz, where the magnetic field B is measured in gauss (G). The acceleration associated with the gyromotion provides opacity in the radio regime at frequencies which are integer multiples (*harmonics*) of ν_B for magnetic field strengths in the range 10–3000 G, which corresponds well to the range of magnetic fields seen in the solar atmosphere above active regions. Gyroresonance opacity increases strongly with temperature, and is much larger when viewed nearly orthogonal to the magnetic field direction in the source than when viewed parallel to the magnetic field. This is the dominant source of opacity in regions of strong magnetic fields in the CORONA, such as above SUNSPOTS. This mechanism can produce highly polarized emission because of the large difference in the opacities of the X and O modes. Strictly speaking this is a resonant mechanism (i.e. a given radio frequency is associated with a particular value of magnetic field strength), but may be regarded as a source of continuum opacity since B varies continuously throughout the atmosphere.

Gyroresonance opacity drops dramatically as harmonic number increases. In conditions typical of the solar corona (electron densities of order 10^9–10^{10} cm^{-3}, temperatures of order 10^6 K, length scales 10^9 cm), the third (and lower) harmonic of the gyrofrequency will be optically thick in the more strongly interacting polarization (the X mode) as long as the line of sight is not nearly parallel to the magnetic field. Since magnetic field strength generally decreases with height, emission from the first and second harmonic layers originates below the opaque third harmonic layer and is not seen, although in the O mode the third harmonic layer may be optically thin and then the second harmonic layer dominates. Thus a radio image of optically thick gyroresonance emission at a given frequency ν GHz in the polarization corresponding to the X mode can be regarded as a map of the temperature on the layer corresponding to a constant magnetic field strength of $\nu/8.4 \times 10^6$ G.

H^- opacity

As one goes deeper into the solar atmosphere the temperature drops below 10^4 K and the dominant species (H and He) become neutral. The total electron and proton densities can remain high in the chromosphere (temperatures between 5000 and 10 000 K) because the total density increases rapidly with depth while the fractional ionization decreases, but below 5000 K essentially all hydrogen is neutral. Free electrons are still present at these temperatures due to ionization of metals such as sodium, but there are insufficient free protons to provide significant free–free opacity. In this situation a mechanism involving free electrons and neutral H dominates the radio opacity: the electron polarizes an H atom and the interaction between the electron and the dipolar atom provides opacity known (somewhat confusingly) as H^- opacity. From the relevant temperature range it is clear that this mechanism is only important in the lower atmosphere near the temperature minimum, probed by very high frequencies (millimeter wavelengths). Circular polarization in the radiation from this mechanism is expected to be weak.

The appearance of the Sun at different radio frequencies

The Sun can usefully be studied at all radio frequencies, from the ionospheric cutoff of the order of 10 MHz (wavelength $\lambda = 30$ m) up to the submillimeter domain above 300 GHz ($\lambda \leq 1$ mm). Different frequencies penetrate to different depths in the solar atmosphere, depending on local conditions, so that the appearance of the Sun changes dramatically over the radio frequency range.

An important feature of solar radio emission is that every frequency becomes optically thick (i.e. opaque) at some point in the solar atmosphere. Just as we cannot see below the SOLAR PHOTOSPHERE in visible light, in a radio image at a given frequency we cannot see material below the optically thick layer. Radio wavelengths lie in the Rayleigh–Jeans limit, $h\nu \ll kT$, and therefore the radio flux is proportional to the brightness temperature. In the optically thick layer the brightness temperature is equal to the local electron temperature so that (unlike most other diagnostics of the solar atmosphere) radio images can often be interpreted directly as temperature maps. Since temperature in the solar atmosphere generally increases outwards from the temperature minimum (just above the photosphere), it is also possible for a radio image to show both the emission from the low-lying cooler optically-thick layer as well as contributions from hotter optically-thin plasma in the overlying atmosphere.

As noted above, free–free opacity increases rapidly as frequency decreases and it dominates the quiet radio Sun at low frequencies (plasma emission is also prevalent at low frequencies, and is discussed in SOLAR SPECTROSCOPY: COHERENT PLASMA EMISSION). The whole solar corona is optically thick at frequencies below 500 MHz, so that the Sun appears as a large relatively featureless source with a dimension larger than the solar radius, usually elongated in the equatorial direction due to the fact that the solar atmosphere is generally of higher density at the equator than at the poles. The fact that the low-frequency radio Sun had a brightness temperature of the order of 10^6 K was one of the important pieces of evidence which led to the discovery of the solar corona. Propagation effects can make the radio Sun appear to be larger than the actual height of the optically thick surface. Scattering off small-scale turbulence in the outer atmosphere and solar wind (see SOLAR WIND TURBULENCE) can also supply a frequency-dependent lower limit to the spatial resolution which can be achieved in an observation. Since the whole corona is at a temperature of the order of 1–2 million K, there is little contrast between quiet features on the solar disk at low frequencies. As is often the case at low frequencies, the brightest radio feature in the 0.3 GHz image shown in figure 1 (the feature at the right edge of the 0.3 GHz disk) is not due to free–free opacity at all, but rather is a noise storm (also called type I continuum, a form of broadband coherent emission commonly found over very active regions in the frequency range 200–500 MHz).

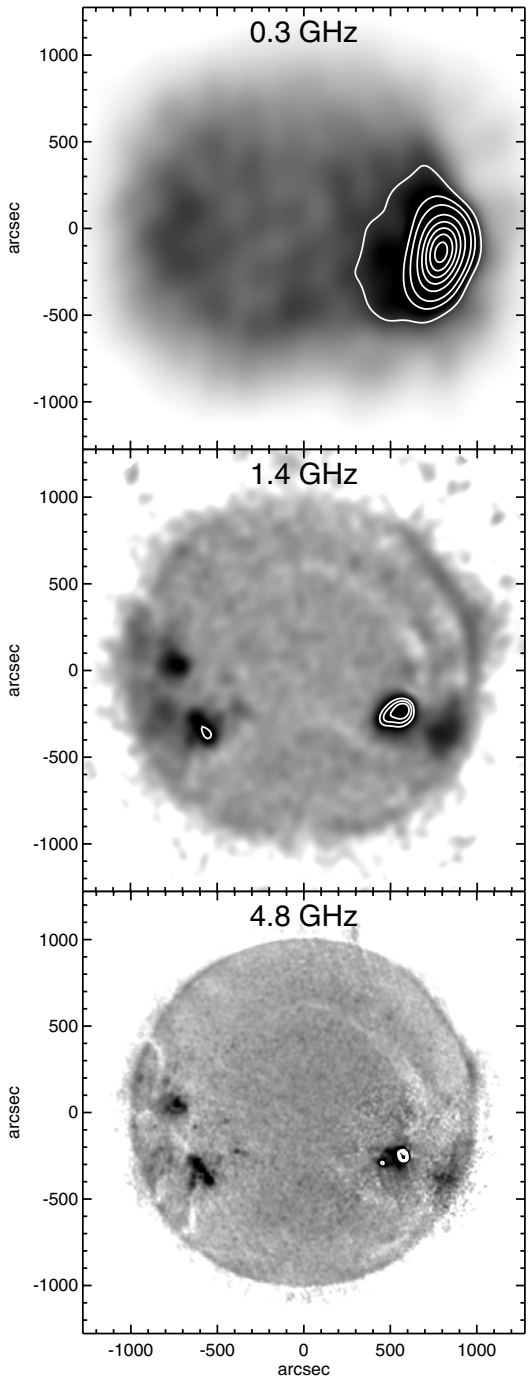

Figure 1. The appearance of the Sun at three different radio frequencies. The intrinsic resolution is different in each image: it is 220″ at 0.3 GHz (top), 50″ at 1.4 GHz (middle) and 12″ at 4.8 GHz (lower panel). These images were made with the Very Large Array radiotelescope on 7 November 1993 (courtesy S White). White contours highlighting the brightest features are plotted at brightness temperatures of 0.8, 1.2, 1.6, 2.4, 3.2, 4.0, 4.8 and 5.6×10^6 K. The color table saturates (is black) at 0.8×10^6 K at 0.3 GHz, 0.6×10^6 K at 1.4 GHz and 0.1×10^6 K at 4.8 GHz. Solar west is to the right.

As frequency increases above 500 MHz the quiet solar atmosphere starts to become optically thin and its brightness temperature drops, while the enhanced density in the corona above active regions maintains a high optical depth and hence high brightness temperatures. Thus at 1.4 GHz radio images of the Sun show much more contrast between features, depending on their density. The background disk has a temperature of the order of 10^5 K at this frequency. In CORONAL HOLES and FILAMENT channels where the density is low, the brightness temperature is below this value, while in ACTIVE REGIONS and PLAGE the brightness temperature remains above 10^6 K. Virtually all the non-flaring radio emission seen at 1.4 GHz is believed to be produced by free–free emission. Gyroresonance emission is only rarely seen at this frequency, possibly because the gyroresonance-emitting layers lie below optically thick free–free sources.

At 4.8 GHz, on the other hand, gyroresonance emission produces the brightest features observed in radio images. Optically thick free–free emission has never been clearly identified at frequencies this high, so that any feature with a brightness temperature in excess of 10^6 K at frequencies of 4 GHz or higher is almost certainly a gyroresonance source. This is true in the image shown, where two sunspots in an active region southwest of disk center show up as the only features on the disk with coronal brightness temperatures. These are the only two locations in the solar corona on this particular day where the magnetic field strength exceeded the value 600 G needed to produce gyroresonance emission at 4.8 GHz. The other bright features, such as those near the east limb, are due to optically thin free–free emission from dense structures in the corona (these also show up prominently as bright sets of loops in x-ray images), and have brightness temperatures of the order of 10^5 K, compared with 10^6 K over the sunspots. Low-density features clearly show up as regions of reduced brightness, e.g. within the active-region complex near the east limb, and in the filament channel stretching across the northwest quadrant. The disk at this frequency is at a brightness temperature of the order of 20 000 K, corresponding to the lower TRANSITION REGION/upper CHROMOSPHERE. Optically thin coronal emission from features such as active regions appears as an additional contribution to the brightness temperature, but since it is transparent the underlying optically thick chromospheric contribution can still be seen. The size of the radio disk at 4.8 GHz is of the order of 30″ larger than the optical photosphere.

The brightness temperature contribution of optically thin free–free emission scales as ν^{-2}, so that at yet higher frequencies the optically thin contributions from hot dense coronal material diminish rapidly, while the solar disk component, being due to optically thick emission from the chromosphere, diminishes less rapidly: at 17 GHz it is 10 000 K. Gyroresonance emission, on the other hand, can continue to produce features with brightness temperatures in excess of 10^6 K as long as sufficiently strong magnetic fields are present in the corona. The upper limit to coronal magnetic field strengths is not known, but may be of the order of 3000 G (the largest observed field strengths in the photosphere are of the order of 5000 G), which could produce gyroresonance emission up to 25 GHz. This results in contrasts of up to 300 between the brightest radio features and the background 'disk' brightness temperature at frequencies such as 17 GHz. Above the highest frequency at which gyroresonance emission is effective, there is no form of opacity available which can make coronal features optically thick in the quiet solar atmosphere and consequently there are no features with coronal brightness temperatures: the contrast between the disk brightness temperature and the brightest features in the radio image is greatly reduced. The height of the layer in which a given frequency becomes optically thick continues to drop through the chromosphere as frequency increases: the brightness temperature of the disk component is of the order of 6700 K at 100 GHz and 5800 K (corresponding to the vicinity of the temperature minimum) at 300 GHz, with contrasts only of the order of 10% being seen in the images. At these temperatures, free–free emission is probably still the dominant source of opacity, although H^- opacity may also be contributing.

Radio continuum diagnostics

The value of radio diagnostics lies in a number of unique characteristics which complement those available in other wavelength ranges: (i) radio data provide a direct measurement of electron temperature; (ii) again, in contrast to most other diagnostics which are optically thin above the chromosphere and thus show the emission integrated along the line of sight, radio emission is optically thick in the solar atmosphere and by using the fact that different frequencies become optically thick at different heights, multifrequency observations can be used to 'peel away' successive layers of the atmosphere; and (iii) the influence of magnetic fields on radio emission allows coronal magnetic fields to be measured directly. At present radio observations are the best technique available for studying magnetic fields in the corona.

Free–free emission can be used to study densities and temperatures in the solar corona. Radio observations of free–free emission complement x-ray and EUV observations of the corona well: both are sensitive to the dense loops found in the corona above active regions, but the radio data are often optically thick whereas the x-ray/EUV data are optically thin. The fact that the radio emission is optically thick makes it particularly sensitive to temperature gradients. The radio emission is weighted towards cooler plasma due to the $(\text{temperature})^{-1.5}$ dependence of free–free opacity. Information on abundances can be derived from a comparison of the different wavelength regimes, since x-ray fluxes depend on the number densities of ions such as Fe in specific charge states, while the radio flux depends on the number density of protons.

Observations of gyroresonance emission have wide usage in the study of coronal properties above active

regions, where magnetic fields are strong enough for gyroresonance emission to dominate. The fact that it is a resonant mechanism results in emission at a given frequency coming from a very thin layer of constant magnetic field strength: typically B varies by less than 2% across a gyroresonant layer. The optical depth may vary by a factor of 1000 from one harmonic layer to the next, which simplifies interpretation since it means that only one layer is likely to be contributing to the observed flux. Thus observations of gyroresonance emission pick out physical conditions in a highly localized region of the corona; changing the observing frequency picks out a different layer, so that in principle a three-dimensional picture of the corona may be developed. There are some complications, however, in interpreting gyroresonance emission: (i) the highest optically-thick harmonic layer is not known in advance: for typical conditions it occurs where $\nu = 3\nu_B$ in the X mode and $\nu = 2\nu_B$ in the O mode, but where the line of sight is parallel to the magnetic field the opacity is greatly reduced and one sees down to a lower harmonic layer; and (ii) the radio data do not contain any independent information on spatial scales, so that one does not know what the height of each gyroresonance layer is from the radio data alone.

Solar radio telescopes

The Sun was first identified as a radio source during World War II. In 1942 J S Hey was investigating bursty interference in meter-wavelength radar receivers in Britain when he noticed that it coincided with a solar flare. Almost simultaneously G C Southworth in the U.S. looked for and detected steady emission from the Sun at centimeter wavelengths. After the war years many veterans of the radar effort turned to RADIO ASTRONOMY. A group in Australia led by Joe Pawsey developed radio instruments for the study of the Sun and carried out pioneering work on the classification of solar radio bursts.

A number of instruments are routinely used to make radio images of the Sun at the time of writing. Solar-dedicated telescopes include the Nançay radioheliograph in France operating at frequencies in the range 150–450 MHz, the Owens Valley frequency-agile array in the USA in the range 1–18 GHz, and the Nobeyama radioheliograph in Japan at 17 and 34 GHz. In Russia the RATAN-600 telescope observes in the range 1–20 GHz and the Siberian Solar Radio Telescope at 5 GHz. Low-frequency facilities previously operated at Culgoora (40–320 MHz) in Australia and at Clark Lake (20–110 MHz) in the USA. The Very Large Array radiotelescope in the USA (0.3–22 GHz) is used for solar observing on an occasional basis, and provides a powerful combination of sensitivity, spatial resolution and frequency coverage.

Solar Spectroscopy: Infrared Emission

The solar infrared spectrum extends from 1 μm to 1 mm, nestled between the well-studied visible and radio bands. The infrared is rich in spectral proxies of temperature, velocity and magnetic field. These range from high-excitation He I 1.083 μm, to low-excitation molecules like carbon monoxide, hydroxyl, and even water vapor (in sunspots), to magnetically sensitive atomic iron absorptions near 1.5 μm, and to the curious high-Rydberg emissions of Mg I near 12 μm. Local thermodynamic equilibrium (LTE) applies to many of the line formation processes; infrared features are generally better tracers of physical conditions than the scattering lines of the visible and ultraviolet intervals. Seeing (distortions of the telescope images by turbulence in the Earth's atmosphere) also tends to improve toward longer wavelengths. However, even the world's largest optical solar telescope—the 1.5 m McMath–Pierce on Kitt Peak—is limited by diffraction in and beyond the key 5 μm region; atmospheric absorption blocks large stretches of the thermal IR; and infrared sensor technology lags behind its counterparts in the visible and ultraviolet. Nevertheless, the fast pace of discoveries makes IR solar physics one of the exciting areas of modern astronomy.

Background

The infrared generally is considered to extend from 1 μm on the short-wavelength side, to perhaps 1 mm at the longer wavelengths. The lower boundary is about where optical CCD camera technology gives way to specialized infrared sensors, and the long-wavelength side corresponds to the highest frequencies of the radio band. Both of these boundaries are somewhat vague, particularly the upper side where sub-mm radio technology is making serious inroads. Indeed, much of the region between 20 μm and 1 mm is blocked by the Earth's atmosphere, and the Sun's disk intensity distribution in that interval appears to be a featureless continuum; more akin to the radio regime than to the highly structured ABSORPTION SPECTRUM seen at shorter wavelengths.

Aside from the 1.083 μm triplet of atomic helium, there are no prominent high-excitation disk features in the spectrum longward of 1 μm. Instead, the infrared is dominated by low-excitation species: neutral atoms and molecules.

By their nature, the low-excitation species must arise in relatively quiescent gas that is not strongly heated (by the processes that cause, for example, the chromospheric temperature inversion). Such conditions are found in the outer SOLAR PHOTOSPHERE in the supergranulation cell interiors (see SOLAR PHOTOSPHERE: SUPERGRANULATION), in the interstices between the magnetic network elements (see CHROMOSPHERE: NETWORK), and in the hearts of SUNSPOT UMBRAE (cold because intense vertical magnetic fields suppress the convective heat flux). One of the key low-excitation species—carbon monoxide—has given birth to the current dominant controversy of infrared solar physics.

On the one hand, a stigmatic spectrogram of the violet Ca II K line (0.393 μm) recorded over a quiet area on the solar disk shows unmistakable core emission—classic signature of the chromospheric temperature rise—over much of the slit length. On the other hand, extreme-limb observations of the $\Delta v = 1$ fundamental vibration–rotation bands of CO near 4.7 μm reveal unexpectedly cool material ($T < 4000$ K) at high altitudes where one traditionally would place the hot chromosphere ($T \sim 7000$ K). That behavior is difficult to reconcile with the best available one-dimensional models of the solar chromosphere, and forces one to consider a highly inhomogeneous description of those 'layers'.

Infrared diagnostics

Several general characteristics of infrared diagnostics will be mentioned, followed by more detailed descriptions of specific cases. Figure 1 provides examples of some of the spectral regions that will be described later, from the quiet Sun as well as a mature sunspot umbra.

General characteristics

Low-excitation species that form close to LTE. Aside from the true 'chromospheric' tracer He I λ1.083 μm, most of the important spectral features longward of 1 μm are sensitive to *cool* gas in the stellar photosphere. Many of the infrared features form quite close to local thermodynamic equilibrium, particularly the molecules (a very desirable attribute from a diagnostic point of view: in LTE, the brightness temperature of the core of an absorption line corresponds closely to the kinetic temperature in the layers in which the line becomes optically thick).

Furthermore, between 1 μm and 1 mm the continuous opacity is dominated by H^- in the photosphere, and by $p–e^-$ collisions ('H free–free' (f–f)) at higher temperatures in the chromosphere. The negative hydrogen ion has a lone bound–free (b–f) edge at 1.64 μm. There, the background opacity of the solar atmosphere reaches its minimum value, and $\tau_C = 1$ penetrates about 20 km deeper than at visible wavelengths. Longward of the H^- b–f edge, $\tau_C = 1$ ascends rapidly in altitude owing to the λ^2 dependence of the f–f cross section. Beyond about 300 μm, the continuum arises at chromospheric altitudes. For all intents and purposes, the infrared continuous opacities are completely in LTE.

Linear temperature averaging. An often-cited benefit of the spectrum beyond 1 μm is the linear temperature averaging property of the infrared Planck function. In other words, the amount of thermal emission is directly proportional to the local temperature. That means the average intensity of a scene containing a jumble of discrete structures should be an evenly weighted mean of the surface temperatures of those features. In the ultraviolet, on the other hand, the thermal emission is *exponentially* sensitive to temperature ('Wien limit' of Planck function). In that situation,

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

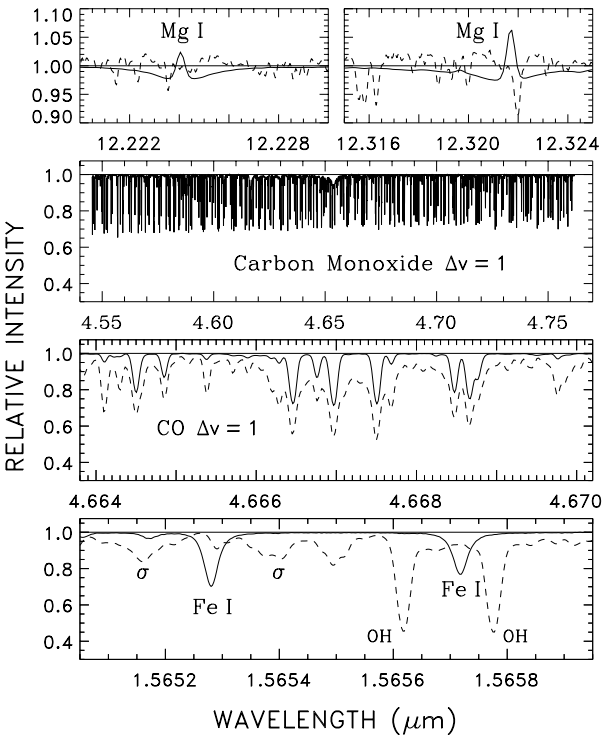

Figure 1. Selected wavelength intervals from the IR spectrum of the quiet photosphere (solid curves), and a sunspot (dashed). The sunspot shows generally greater spectral complexity than the quiet photosphere, owing to enhancement of low-excitation species in the cold umbra, and to Zeeman splitting (the 'σ' components of Fe I λ1.565 in the bottom panel) of magnetically sensitive lines in the multi-kilogauss fields. (Courtesy National Solar Observatory Digital Archive.)

the average intensity of a scene can be completely dominated by a single hot spot, and the deduced average temperature could be quite misleading. Of course, the best approach (although technically challenging) is to view a region simultaneously in the ultraviolet and infrared, to utilize the complementary temperature responses to better constrain the mix of thermal structures present. The full benefit of the linear temperature averaging is achieved for diagnostics that form close to LTE, like the CO $\Delta v = 1$ bands or the f–f continuum. However, one must be cautious in practical applications. In particular, one views the thermal emission at the 'surface' where the gas becomes optically thick (opaque). Where that surface occurs, and thus what temperature is sampled, depends on the opacity of the medium at the wavelength of observation. Even though the infrared thermal emissivity depends linearly on temperature, there is no guarantee that the opacity does as well. For example, the f–f optical depth depends on the electron and proton densities, which vary *exponentially* with temperature over the narrow range 5000–8000 K owing to the ionization of atomic hydrogen. Thus, in a jumble of structures, the $\tau_C \approx 1$ surfaces could occur at a wide range of physical heights and temperatures: the hotter structures become opaque high up, while the colder ones are more transparent, allowing one to view conditions deeper in. The temperature averaging might well be linear, but it could be an uncontrolled average over a wide range of heights, and thus of little diagnostic value.

Magnetic leverage. Magnetic fields are pivotal in shaping the discrete thermal features of the SOLAR PHOTOSPHERE, CHROMOSPHERE, and CORONA, and are probably responsible for a large proportion of the mechanical heating, particularly at high altitudes. The central role of magnetic fields in the solar atmosphere is probably replayed among all late-type convective stars in the cool half of the HERTZSPRUNG–RUSSELL DIAGRAM. The Zeeman splitting of a spectral line in the presence of a magnetic field goes as

$$\Delta\lambda_B \sim g_L B \lambda^2$$

where g_L is a factor that depends on properties of the radiating atom, B is the strength of the longitudinal component of the surface magnetic field, and λ is the wavelength of the spectral line. The intrinsic, non-magnetic width of the line usually is controlled by random thermal and turbulent motions in the gas, and scales as

$$\Delta\lambda_L \sim (v/c)\lambda$$

where v is the velocity dispersion and c is the speed of light. Thus, the magnetic splitting becomes more prominent with respect to the non-magnetic line width as one moves to longer wavelengths, and correspondingly easier to measure. Accordingly, the infrared is well-suited for magnetic investigations, particularly of intrinsically weak fields. Furthermore, cool surface features like sunspot umbrae show much less intensity contrast against the surrounding hotter photosphere in the infrared than in the visible (again, due to linear temperature averaging at the longer wavelengths, versus exponential at the shorter). Consequently, dilution of the umbral light by scattered photospheric radiation is much less of a problem. Thus, the infrared is a good place to measure fine structure in the strong fields of sunspots.

Specific examples

He I λ1.083 μm. The He I λ1.083 μm triplet is the most prominent high-excitation feature that falls in the infrared, and one of the most widely used in ground-based monitoring of chromospheric and coronal structure. The importance of the He I absorption is in how it forms. The high-lying metastable state in the He I term system is populated primarily by recombination of He^+ ions. The latter are produced by photoionization of chromospheric atomic helium by coronal XUV radiation that penetrates into the lower atmosphere. The absorption of the outward streaming photospheric continuum by the highly excited chromospheric He I strengthens in areas that are strongly illuminated by the hard coronal radiation and weakens in areas where the coronal back-radiation is less. High

contrast x-ray features like CORONAL HOLES (which play a central role in the SOLAR WIND and are thus prime targets for SPACE WEATHER PREDICTIONS) leave an imprint on He I λ1.083 absorption maps, and can be identified routinely from the ground. He I also is used in studies of SOLAR FLARES and SOLAR CORONAL MASS EJECTION. High-resolution spectroscopy yields the total absorption strength, the line depth and the Doppler shift. Relating these empirical quantities to the dynamics, heating, and XUV back-illumination of the upper chromosphere requires sophisticated numerical simulations.

Other high-excitation lines. A few features formed under truly coronal conditions (temperatures in excess of a million K) are known in the infrared; mostly forbidden ground-state fine structure transitions in coronal ions, such as a pair of Fe XII lines near 1.08 μm and Si X λ1.43 μm. Although the lines are quite faint, and must be recorded off-limb away from the glare of the photosphere, they have diagnostic potential for coronal densities and perhaps magnetic fields. The infrared coronal spectrum is still largely unexplored at high sensitivity, however, owing to the lack of a suitable large-aperture coronagraphic facility, although the McMath–Pierce telescope undoubtedly will see more use in this area over the coming years.

The opacity minimum. The H^- opacity minimum at 1.63 μm allows one to 'see' deeper into the solar atmosphere than at any other wavelength. By comparing infrared opacity minimum pictures with simultaneous, co-spatial filtergrams taken at shorter continuum wavelengths and in Ca K, one can follow the vertical divergence, for example, of hot gas entrained in flux tube fields from the deep photosphere out to the chromosphere itself (see SOLAR PHOTOSPHERIC MAGNETIC FLUX TUBES). The recent availability of large-format high-sensitivity infrared cameras has made such experiments practical. The diffraction limit of the McMath–Pierce at 1.6 μm is about 0.3″, comparable to the *optical* resolution of the (smaller) windowed evacuated solar telescopes typically used for visible imaging. (The vacuum telescopes are often suitable for 1.6 μm work, but with a correspondingly poorer diffraction limit.)

Magnetic field measurements beyond 1 μm. Solar infrared magnetography was pioneered by J Harvey and D N B Hall in the mid-1970s. Hall's 1974 *Atlas of the Infrared Sunspot Spectrum* contains many low-excitation absorption lines that are completely split in a ∼2 kG longitudinal field: Ti I λ2.23 μm (a^5P_1–$z^5D^o_0$) is the premier example. Solanki, Biémont and Mürset have published a list of interesting lines in the interval 1.5–1.8 μm, including many that exhibit large Stokes V amplitudes in the quiet network. A popular target of recent magnetic studies has been the simple Zeeman triplet Fe I λ1.565 μm. The high-Rydberg transitions of Mg I at 12 μm (see below) also have substantial magnetic sensitivity, although the observations are challenging and the spatial resolution is limited by diffraction. POLARIMETRY in the He I λ1.083 μm line allows magnetic fields in the chromospheric layers to be mapped.

Molecules. A wide variety of diatomic molecules, including many isotopic variants, are found in the infrared spectrum longward of 1 μm. The only triatomic species known is water vapor, and it is found exclusively in the deep high-density layers of cold sunspot umbrae (the formation of polyatomic species generally requires high pressures, in addition to cool temperatures). Many of the abundant diatomics have their principal vibration–rotation bands (arising within the electronic ground state of the molecule) in the 1–15 μm interval.

The low-energy rotationally split vibrational transitions are collisionally excited (and quenched) by the abundant moderate-speed hydrogen atoms, and the 'collisionally-controlled' lines thus form quite close to LTE. Typical atoms and ions, on the other hand, have higher-energy visible/ultraviolet transitions that are collisionally coupled mostly to the much rarer high-speed electrons in the gas. For such lines, photon scattering delocalizes the radiation formation, and degrades the diagnostic potential.

Another advantage of the molecular bands is that they typically contain thousands of very similar lines. The redundancy allows statistical techniques to be applied, and is valuable in the infrared where the spectrum is fragmented by molecular absorptions in the Earth's atmosphere (see §58 of C W Allen's *Astrophysical Quantities*). Furthermore, the populations in the vibrational ladder of a typical molecule are very sensitive to temperature, and the molecular spectra are thus nearly ideal 'thermometers', at least for the cooler zones of the solar atmosphere.

The infrared contains strong absorption bands from CO, CH, OH and NH. Of these, carbon monoxide completely dominates the spectral character of the 1–10 μm region, contributing about half of the strong lines of solar origin. CO is the most abundant molecule at the relatively warm temperatures of the high solar photosphere ($T < 5000$ K), owing to its large dissociation potential (11 eV) and the fact that its photoionization and photodissociation thresholds fall shortward of H I Lyα (121 nm), the strongest emission feature of the ultraviolet chromospheric spectrum. Molecular hydrogen also is quite abundant, but is a homonuclear species and thus lacks the significant dipole moment required for a (permitted) vibration–rotation spectrum.

Near limb observations (for which the extreme slant angle causes the $\tau \sim 1$ emitting surface to move upward to high altitudes) of the $\Delta v = 1$ fundamental bands of CO at 4.7 μm show surprisingly cool gas, with temperatures as low as ∼3700 K, at heights where one ordinarily would place the chromosphere (with its ∼7000 K temperatures, too hot for molecules to form). The existence of CO at high altitudes is completely at odds with the best available one-dimensional reference models (e.g., of the 'Harvard school'). The dichotomy—hot chromosphere seen in Ca II K and cold 'comosphere' deduced from the CO infrared bands—highlights the present uncertainties

concerning the crucial interface where the radiation-dominated photosphere gives way to the mechanically heated chromosphere.

Further discussion of the CO fundamental bands can be found in the entry on CHROMOSPHERE: THERMAL BIFURCATION.

The 12 μm High-Rydberg emission lines. In the early 1980s, F Murcray and his collaborators, and independently J Brault and R W Noyes, called attention to several curious emission features in the 12 μm region of the solar spectrum. These quickly were identified as high-Rydberg transitions of magnesium and aluminum. Mg 7h–6g (12.22 μm) and Mg 7i–6h (12.33 μm), in particular, exhibit striking Zeeman sensitivity.

Subsequently, it was found that Mg I λ12.33 μm showed a large velocity response to the photospheric p-mode oscillations at disk center, with a peak-to-peak amplitude of more than 1000 m s^{-1}, comparable with what is seen in strong CO $\Delta v = 1$ lines. Curiously, however, intensity oscillations like those in CO were lacking. The velocity response pegged the line formation altitude in the high photosphere (rather than the chromosphere where traditional 'emission' lines arise), and the lack of intensity oscillations pointed to a non-LTE formation mechanism.

The latter has been clarified recently by a number of authors, who have demonstrated that population inversions can happen naturally in the high-Rydberg systems of species for whom the next ionization stage up is the most abundant under the conditions of the upper photosphere (e.g. Mg^+, here). The uppermost levels of the neutral atom near the ionization limit are strongly tied by collisions to the (fixed) ion ground state population, but levels further down the ladder are progressively more coupled to the lowest-lying states of the atom by radiative transitions; the resulting 'photon suction' depletes the lower levels of the high-Rydberg transitions more than the upper levels, producing a population inversion that in turn drives the line cores into emission, without the usual agency of a chromospheric temperature rise.

The large Zeeman sensitivity of the 12 μm lines makes them appealing for magnetic studies, although substantial improvements in sensor technology and telescope aperture will be required to fully exploit their diagnostic promise.

Far-infrared continuum. Sub-millimeter continua provide a unique view of the solar chromosphere at a wide range of altitudes, complementary to the more familiar visible tracers like Ca K and Hα. 850 μm maps of the solar chromosphere have been obtained by raster-scanning the 15 m James Clerk Maxwell Telescope (JCMT) on Mauna Kea across an ACTIVE REGION. The resulting sub-millimeter image closely resembles Ca K pictures: the dense hot PLAGE surrounding the spot groups appears strongly enhanced in sub-millimeter brightness temperature. Counterintuitively, the sunspots themselves also are bright, with intensities comparable with their surroundings. Thus, while the heat flux through the lower atmosphere of the sunspot is strongly suppressed, producing the dark umbra at visible wavelengths, the outer atmosphere apparently receives a normal dose of mechanical heating, leading to more uniform chromosphere at the high altitudes where the 850 μm radiation arises.

As with the 12 μm Mg I lines, significant advances in instrumentation will be required to fully utilize the 150–850 μm continuum region (the lower end of which also is mostly blocked by terrestrial absorption and must be recorded from high-altitude balloons). The most pressing need is for higher angular resolution: the JCMT can achieve a diffraction-limited beam of only about 15″.

Summary

The infrared spectrum contains valuable diagnostics of physical conditions in the solar photosphere, chromosphere and corona. Infrared solar studies have a long history, although the pace of discovery has speeded up considerably in the 1990s with the development of sensitive large format cameras for the 1–5 μm region. Detection of ultra-cool gas in the hot chromosphere, traced by carbon monoxide, remains the major controversy that the infrared has brought to present-day solar physics. The infrared undoubtedly will yield additional puzzles, and perhaps new contradictions, as it is further explored; and exploited as a complement to traditional visible and ultraviolet remote sensing of solar atmospheric structure. Nevertheless, a major impediment is the lack of a large-aperture infrared-optimized solar telescope to achieve the high spatial resolution that is mandatory for modern investigations of our nearby star.

Solar Spectroscopy: Ultraviolet and Extreme Ultraviolet Emission

Vacuum ultraviolet (VUV) emission is defined as that electromagnetic radiation with wavelengths shorter than 2000 Å. Its name comes from the fact that light shorter than 2000 Å is strongly absorbed by most gases and, in particular, the atmosphere. VUV is usually divided into far ultraviolet (FUV) extending from 1200 to 2000 Å and the extreme ultraviolet (EUV) in the range 300 to 1200 Å. The spectral features of these wavelengths will be discussed with the focus on the spectral emission lines. Continuum radiation will only be discussed briefly. One can ask why is it interesting to observe the VUV emission from the Sun? There are several important reasons for this as it provides important information on:

- physical properties of the solar and stellar atmospheres
- fundamental mechanisms responsible for heating the corona and accelerating the solar wind
- how VUV variability alters the dynamics and chemistry of the Earth's upper atmosphere
- possible influence on the Earth's climate due to variations in the VUV irradiance from the Sun.

In this article the main focus will be on the first two items while the latter two are discussed in more detail elsewhere (see EARTH'S ATMOSPHERE, SOLAR IRRADIANCE, SOLAR–TERRESTRIAL CONNECTION: LONG-TERM AND SHORT-TERM CLIMATE VARIABILITY.

Historical background of VUV observations

The solar ultraviolet (FUV) and extreme ultraviolet (EUV) emission contain a number of strong emission lines and continua well suited for quantitative plasma diagnostics of the solar atmosphere. Our entire knowledge of temperatures, densities, emission measures, mass motions and elemental abundances comes from high-resolution spectral observations in the vacuum ultraviolet.

The VUV wavelength range is absorbed by oxygen and ozone in the Earth's atmosphere and hence is totally inaccessible to even the largest ground-based telescopes. Below 2000 Å the radiation dissociates molecular oxygen in the upper atmosphere, indirectly resulting in the formation of ozone (O_3). To observe the Sun, stars and other celestial objects in this wavelength range, the instruments must be carried above the absorbing atmosphere by means of sounding rockets, Earth satellites or space vehicles. Space astronomy started in 1946 in the United States when captured V-2 rockets became available to navy scientists for use as free-flying, high-altitude observatories. It was not surprising, under these circumstances, that a group from the US Naval Research Laboratory (NRL) in Washington, DC, became the first to observe the Sun's ultraviolet radiation with a spectrograph mounted on the tail fin of a V-2 rocket. Since then much progress has been made in solar high-resolution spectroscopy from space (see SPACE INSTRUMENTATION, SPECTROGRAPHS: HIGH-RESOLUTION SPECTROGRAPHS). A large number of experiments have been launched to observe the EUV and UV portions of the solar spectrum.

Measurements of the solar UV spectral energy distribution are often divided into two groups. Some instruments use only a spectrometer and observe the spectral irradiance of the integrated solar disk. The irradiance measurements are designed to study the Sun's radiant energy output and its variability, and thus require very high photometric accuracy and instrument stability. Other instruments employ an imaging device followed by the spectrometer and observe the radiance from a limited area of the solar disk. The primary goal with the radiance measurements is to differentiate between various emitting regions on the Sun. However, it is much more difficult to achieve high photometric accuracy because of the more complex optics and the often larger number of reflecting surfaces.

Calibration and instrument degradation

Quantitative measurements of the properties of the solar gas should be carried out from intensity calibrated spectra. Even without an absolute calibration one can extract useful information from the spectral data such as the shapes of spectral lines, their wavelength positions as well as line ratios. However, to determine how many photons actually entered the instrument from the Sun an absolute calibration needs to be applied where the reflectivity of each optical element of the instrument needs to be accounted for. The fact that the reflectivity of the coatings used in UV/EUV instruments often degrades with time complicates the calibration effort.

Ultraviolet intensity measurements are particularly difficult because the very solar radiation to be measured with high precision is itself the main cause of instrument degradation. The effect is attributed to contamination by organic material, which is outgassing from materials used in the instrument design and is subsequently photoactivated and deposited on irradiated surfaces. The process, although now well understood, is very difficult to prevent in complex optical instruments for space flight. Comprehensive cleanliness control programs during integration of the instruments are used to reduce degradation. Most EUV/UV instruments still suffer from some sensitivity losses during their operation. Thus, intercalibration between different instruments, both on satellites and rocket payloads, is being used to determine the absolute level of emission from single features on the Sun.

VUV emission lines

The high-temperature solar atmosphere is the only astrophysical plasma source that can be studied with high spatial resolution. Much of our understanding of STELLAR ATMOSPHERES is based on the understanding of plasma processes that occur in the upper solar atmosphere.

Dirac House, Temple Back, Bristol, BS1 6BE, UK

of our knowledge on temperatures, densities, emission measures, mass motions and elemental abundances comes from high-resolution spectral observations in the far ultraviolet (VUV) to the x-ray wavelength range (2000–1.7 Å).

The solar spectrum in the range 1150–1700 Å contains a large number of bright lines, mainly from plasmas of the CHROMOSPHERE and the lower TRANSITION REGION, i.e. at electron temperatures $T_e \leq 2.5 \times 10^5$ K. However, no lines from the upper transition region ($2.5 \times 10^5 \leq T_e \leq 1 \times 10^6$) are strong enough to be observed, and only a few lines originating at coronal temperatures appear mainly in PLAGES and LIMB spectra. In comparison, the solar spectrum in the range 100–1150 Å includes a large number of lines from the upper transition region and CORONA in addition to lines from the chromosphere and lower transition region.

At wavelengths longward of 1150 Å high spectral and spatial resolutions were achieved by several instruments. In the UV wavelength range there are in particular two instruments that made great impact on solar spectroscopy: the NRL/SO82B EUV spectrograph on Skylab ATM (Apollo Telescope Mount) and the NRL/High Resolution Telescope and Spectrograph (HRTS). More than 3000 emission lines have been observed in the 1150–1700 Å spectral range by these instruments and most of them have been identified. At shorter wavelengths, however, the spectral and spatial resolution was relatively poor and only the strongest lines could be identified. Recent observations with EUV spectrometers on the Solar and Heliospheric Observatory (SOHO) have greatly improved our knowledge about the emission at shorter wavelengths down to 150 Å. The Coronal Diagnostic Spectrometer (CDS) and the Solar Ultraviolet Measurement of Emitted Radiation (SUMER) complement each other since CDS relies heavily on diagnostics to determine the physical parameters in the solar corona and SUMER is designed to study the dynamical aspects of the chromosphere, transition region and corona in more detail. Selected line ratios give the electron temperature and the electron density. Absolute line intensities provide the differential emission line (DEM) distribution, the ion and elemental abundances. The line shift and broadening give information about dynamical phenomena of the emission plasma.

The SUMER spectrometer can observe emission lines in the spectral range 500–1600 Å. Figure 1 shows the quiet Sun spectral radiance spectrum from 800 Å to 1500 Å shown as spectral radiance. Selected prominent emission features are identified. In particular the wavelength range below 1175 Å has never before been observed with such high spectral resolution, and it contains a wealth of spectroscopic detail. More than 1000 emission lines have been observed and many of them have been recorded for the first time. About 98% of the observed spectral features have been identified. SUMER provided for the first time detailed information of high members of the hydrogen Lyman series which are important not only for understanding properties of the solar chromosphere but also of the O I excitation process in the Earth's atmosphere. SUMER is also the first instrument to provide comprehensive spectroscopic information on the solar corona above the limb out to two solar radii. In contrast to past observations, where only a very small number of lines were observed above the limb, more than 600 coronal emission lines have been observed in the quiet corona by SUMER, from which about 400 are still unidentified.

CDS is a dual extreme ultraviolet (EUV) spectrometer covering most of the wavelength range 150–780 Å. It has given the first detailed observations of this wavelength range with higher spectral, spatial and temporal resolution than previous instruments. The different wavelength bands have been carefully selected to cover useful spectroscopic diagnostic lines. An example of a quiet Sun spectrum observed with the normal incidence spectrometer on CDS is illustrated in figure 2. The wavelength range (310–380 Å) is dominated by Mg IX 368 Å and a number of lines from highly ionized ions, in particular from iron. A number of line pairs in this band are useful for density diagnostics using ratios such as the Si X 347/356, Si IX 345/349 and Fe XIII 359/348 lines.

Continuum emission

The UV radiation emitted by the Sun between 1400 Å and 1680 Å originates from the temperature minimum region and the low chromosphere according to calculated model atmospheres. The absolute value of the continuum intensity in the spectral range around 1600 Å is important since it reflects the value of the temperature minimum used in model calculations of the solar atmosphere.

The quiet solar radiation shortward of 1680 Å is primarily due to free–bound transitions from lower lying energy levels of neutral silicon in the temperature minimum region, about 500 km above $\tau_{5000} = 1$ according to model calculations. At wavelengths shorter than 1521 Å the emission is almost entirely caused by recombination to the ground state ($3p^2\ ^3P$) with smaller contribution to the emission from C I and from the Ly_α wing. At wavelengths longer than 1521 Å recombination to the first excited level ($3p^2\ ^1D$) of Si I is the main source of emission together with Fe I and Mg I. Ultraviolet line emission from higher temperatures (and heights) also contributes to the photoionization rate of neutral silicon in the temperature-minimum region. For quiet Sun conditions this contribution is small but is greatly increased during flares.

The continuum emission at shorter wavelengths is also a useful diagnostic tool. The C I, H I and He I continua have upper bounds of 1100 Å, 911 Å and 504 Å respectively. However, few observations of this weak continuum emission have been made until recently when the improved instrument sensitivity on the SOHO satellite became available. The H-continuum (also called the Lyman-continuum) is fairly free from emission lines as can be seen in figure 1. The C I continuum shortward of 1008 Å is contaminated by the He I continuum which tends to appear in the spectral second order of the grating.

Spectral irradiance and solar variability

Only about 1% of the Sun's total energy is emitted at VUV wavelengths less than 3000 Å, while approximately 50% is emitted between 4000 and 8000 Å. However, the variability in the VUV portion of the Sun's spectrum exceeds that at visible wavelengths and contributes significantly to the solar irradiance variability in spite of its minor contribution to the total irradiance itself (see SOLAR IRRADIANCE for more details). The VUV radiation is furthermore the dominant source of energy for heating and ionization in the terrestrial upper atmosphere at altitudes above 90 km. Thus, a good knowledge of the solar EUV spectral irradiance is of critical importance for many analyses of the photochemistry and energy balance of the ionosphere and the thermosphere. Solar UV light is primarily responsible for both creation and destruction of ozone in the Earth's stratosphere and mesosphere (see OZONE HOLE). Stratospheric ozone densities are known to vary with the 11-year SOLAR CYCLE. Solar variability over the solar cycle also causes expansion and contraction of the outward extension of the Earth's atmosphere into space. Thus, satellites in low orbit will feel an increased drag when the Sun is active and the result is reduced lifetime. Another important issue is that changes in the Earth's upper atmosphere induced by variations in solar UV radiation could affect the surface climate through feedback mechanisms. It is therefore important to obtain a reliable specification of the Sun's radiative output variability in order to isolate anthropogenic global changes from natural variability.

Solar Spectroscopy: Visible Emission

There are several perspectives from which to consider the solar spectrum. One is obviously as a tool for studying the Sun itself. The temperature and pressure variation with depth, the composition, the magnetic fields, the changing structure and velocity fields on the surface can be derived from high-resolution, high signal-to-noise spectra that also have high spatial and temporal resolution.

A second perspective is that the Sun is the brightest star; we can study it in the same way that we study other stars, but at higher resolution and higher signal-to-noise. The spectrum must be integrated or averaged over the solar disk to produce the flux spectrum. This is the spectrum seen by all the bodies in the solar system and that determines their atmospheric chemistry and weather. The flux spectrum at the mean distance of the Earth from the Sun is called the irradiance spectrum because it irradiates the top of our atmosphere (see SOLAR IRRADIANCE). However, the high-resolution flux spectrum has not been observed above the atmosphere. It is apparently too basic and fundamental to interest ESA or NASA. The available flux atlases have been made through the Earth's atmosphere and include the telluric absorption by O_2, H_2O, and other molecules. Figure 1 (color plate xx) shows the spectrum observed through the atmosphere from KITT PEAK in Arizona at 2000 m. It is plotted as a 'residual' spectrum with the upper envelope defined to be unity. In this form the overall energy information has been factored out of the spectrum. The actual energy spectrum is discussed below. The strong features in the spectrum were given letter designations in the nineteenth century that are still in use and are marked on the plot. Wavelength regions with strong telluric absorption are indicated. Our eyes have evolved to be sensitive only to the light that passes through the window of maximum transmission which we see as the colors shown in the plot.

The third perspective for studying the solar spectrum is that it serves as a spectroscopic data source for atoms and molecules that goes to higher temperatures and is more stable than what is available in the laboratory. There are many cases where lines can be seen in the Sun that have been difficult or impossible to see in the laboratory. Comparisons of predicted spectra to observed spectra provide a test of theoretical model atmosphere calculations (see also SOLAR ATMOSPHERE: EMPIRICAL MODELS).

In every case we want high signal-to-noise and high resolution, high enough to allow recovery of the true spectrum with instrumental degradation removed. This is resolving power, wavelength/Δwavelength, of one half million or more (0.001 nm at 500 nm) if there are no telluric lines, or resolving power of two million or more (0.000 25 nnm at 500 nm) if there are. Telluric lines are generally much narrower than solar lines because the Earth's atmosphere is much cooler than the Sun's atmosphere such that thermal line widths are about one fourth as great. Physical processes, such as RADIATIVE TRANSFER, always take place at high spectral resolution.

Reviews by the author that list the atlases of observed solar spectra in the visible are given in the bibliography. The reviews include very compressed plots of the spectra like that shown in figure 1 (color plate xx), which is from the Kitt Peak Solar Flux Atlas. Since the Sun is rotating at about 2 km s^{-1}, one limb of the solar disk is moving away from us and is redshifted while the opposite limb is moving toward us and is blueshifted by 2 km s^{-1}. Since the flux spectrum is an average over the disk, it is broadened by this rotation. A spectrum taken from a small area of the disk does not have this broadening so has more detail and reflects local physical conditions. For this reason there are also atlases of intensity spectra taken at the center of the disk, such as the Jungfraujoch atlas, and near the limb (see also SOLAR PHOTOSPHERE: CENTER-TO-LIMB VARIATION). The central intensity spectrum is a better spectroscopic source than the flux spectrum. Most of the atlases are available as large scale plots on paper. The atlases can be found in digital form on the World Wide Web. All existing atlases need much improvement in quality, both in signal-to-noise and in resolution.

Line identifications

The reviews also list published tables of line identifications. However, except for the far infrared, where some lines are isolated, lists of line identifications are not very useful because the features we see in the solar spectrum are not single lines. They are blends of many lines, from atoms and molecules of various species, some with isotopic components or hyperfine components, and both solar and telluric lines. Only a computed spectrum can indicate in any meaningful way what actually makes up each feature. Figure 2 shows a small section of spectrum between 599.0 and 599.2 nm that is relatively free of lines. It shows a theoretically computed solar flux spectrum, a theoretically computed transmission spectrum for Kitt Peak at the time the observation was made, the computed flux spectrum transmitted through the atmosphere to the top of Kitt Peak, and the flux spectrum observed at Kitt Peak. The stronger lines used in the calculation are labelled. These labels provide the indentifications for the observed spectrum (see also SOLAR SPECTROSCOPY AND DIAGNOSTICS. The computed and observed spectra do not match because of missing or inaccurate line data. At present one-half of the lines in the solar spectrum are not identified. Corrections to the line data can be determined by iterating on the spectrum calculations to improve the agreement. The computed spectra in figure 2 have been iterated in this way. Major improvements await new laboratory spectrum analyses and new line strength data for the atomic and molecular species that appear in the spectra.

In progress

New atlases for the flux, central intensity and limb intensity are in preparation with spectra taken by James Brault at Kitt Peak. These atlases will show the computed spectra and line identifications together with the observed spectrum as in figure 2. The irradiance spectrum, the true

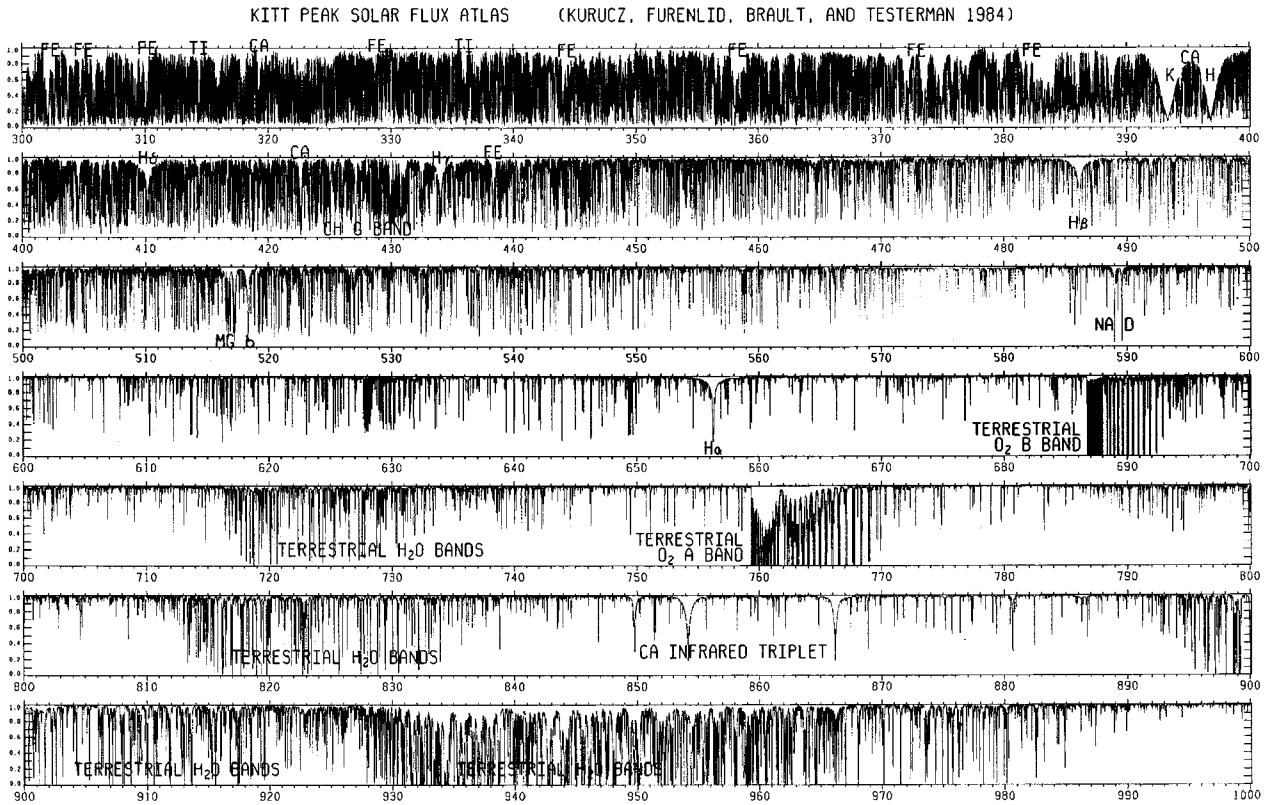

Figure 1. The solar flux spectrum observed through the atmosphere in true color from 300 to 1000 nm. It is plotted as a 'residual' spectrum with the upper envelope defined to be one. The strong features in the spectrum were given letter designations in the nineteenth century that are still in use and are marked on the plot. Wavelength regions with strong telluric absorption are indicated. **This figure is reproduced as Color Plate 49.**

solar spectrum, must still be determined. As the quality of the calculations improves it will be possible to remove many of the telluric features from the observed spectra.

Absolute calibration

Much of the actual irradiance energy distribution has been determined in 2 nm bands by Neckel and Labs. The residual flux spectrum can be integrated in those bands and normalized to produce the corrrect energy scale. Figure 3 shows the absolute irradiance spectrum derived from the Kitt Peak Solar Flux Atlas. In sections where there are telluric lines, the upper envelope of the spectrum is the upper bound to the true irradiance and the spectrum is the lower bound.

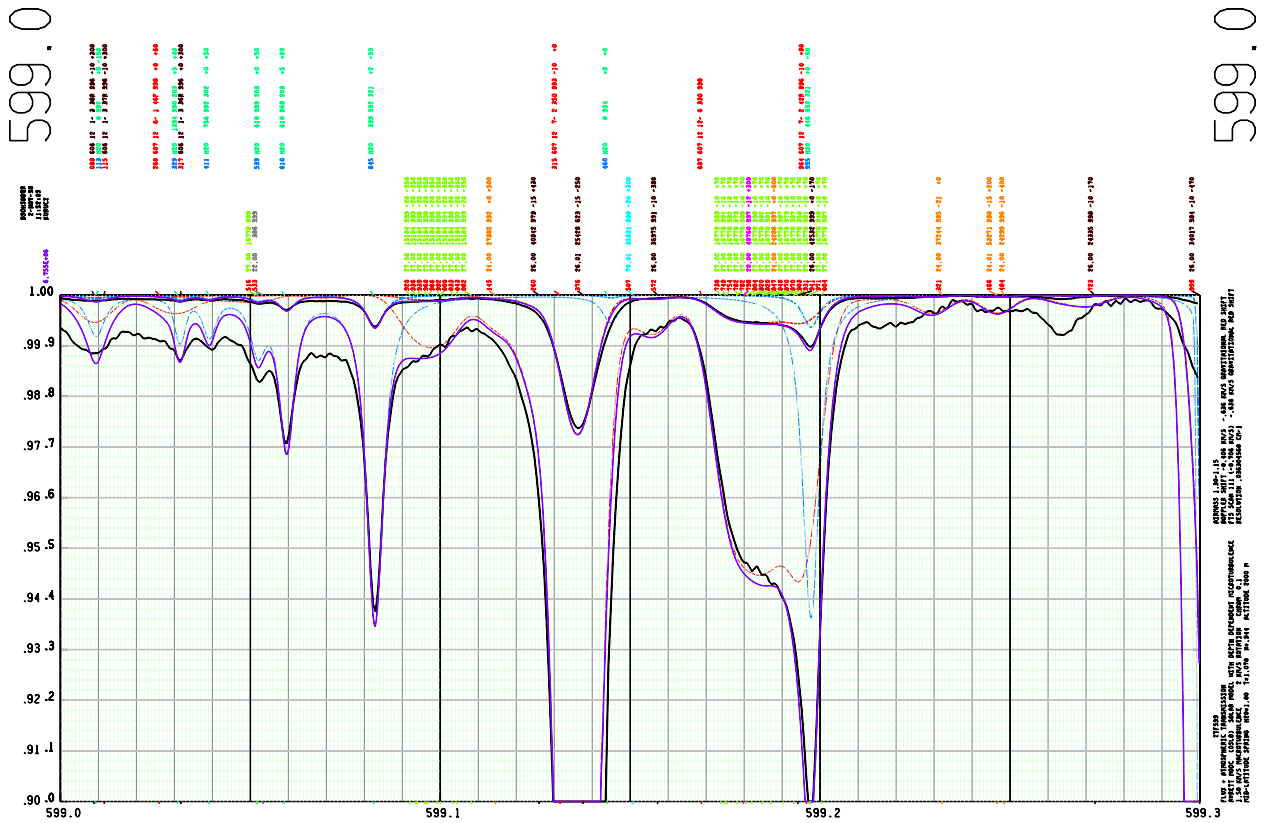

Figure 2. A small section of the solar flux spectrum at 599 nm plotted at full scale and at 10× scale. The heavy black lines show the observed spectrum from James Brault at Kitt Peak. The resolving power is 523 000 and the signal-to-noise is about 3000 which is poor for this work. The thin lines are the computed spectra: in red for the solar flux, in blue for the telluric atmospheric transmission and in purple for their product which should be compared with the observed heavy black lines. There are solar lines of Ca I, Ti I, Cr I, Cr II, Fe I, Fe II, Co I, Yb II, C_2, CN, and telluric lines of H_2O. The first number in each line label is the last three digits of the wavelength and the fourth number is the per mil line depth if the line were computed in isolation. The middle numbers are either the lower energy level in cm^{-1} for atoms or quantum numbers for molecules. Two of the Co I lines have been divided into hyperfine components. The hyperfine and isotopic splittings have not yet been determined for the other lines. Some splittings may be negligible. There are many missing lines. The lines that are present have been adjusted to improve agreement between calculation and observation. That process is continuing. This sample will be part of a forthcoming atlas of Brault's solar spectra. **This figure is reproduced as Color Plate 50.**

Solar System

The region of the universe in which we live, the Solar System, is but one of many clusters of stars and planets in space. Our Solar System lies in a particular region of the universe called the 'Milky Way Galaxy'.

The Solar System originated some 4.6 billion years ago through the accretion of gases and dust grains. Four groups of objects constitute the Solar System: the Sun, the terrestrial planets (including Earth's moon), the Jovian planets and their satellites, and the small bodies (asteroids and comets) (figure 1). Recent discoveries prove that our Solar System is not alone. Astronomers have discovered planets orbiting several other stars.

All the planets move around the Sun in the same direction, and nearly in the same orbital plane, the ecliptic plane. The ecliptic plane is roughly in the equatorial plane of the Sun's rotation. The planets' axes of rotation are nearly perpendicular to this plane, with the exceptions of Uranus and Pluto, which are tilted on their sides (table 1). Other small bodies, such as comets, are in elliptical orbits. Some travel as far out as Jupiter and return close to the Sun, repeating these orbits until disturbed by the gravitational attraction of a passing planet.

The Sun

Most of the mass of the Solar System is contained within the Sun which mass is 330 000 times Earth's mass. It is composed primarily of hydrogen and helium with tiny amounts of other elements, including carbon, nitrogen, oxygen, silicon, and iron. The Sun is more than 1390 000 km across. Like the planets, the Sun rotates on its axis; its rotation period is 27 d. At its center temperatures are thought to reach nearly 15 000 000 °C. The Sun's energy comes mainly from the thermonuclear fusion of hydrogen to form helium. This thermonuclear reaction takes place in the Sun's core (see also SUN: BASIC PROPERTIES).

This energy works its way gradually outward through the Sun's inner layers (i.e. the radiative and convective zones) until it reaches the photosphere, the visible surface of the Sun and the site of the sunspots and (boiling) convective motions. Above the photosphere is the chromosphere into which huge flares and loops of hot gas often shoot, extending tens of thousands of kilometers above the Sun's surface; the flares shoot electrically charged particles into the Solar System, causing aurorae when they reach the Earth. The CHROMOSPHERE is the transition from photosphere to the Sun's outermost region, the corona, which consists of a very thin layer of extremely hot gas.

The SOLAR WIND is a gale of relatively low-energy atomic particles, protons and electrons, that form a hot, magnetized gas, a plasma. Solar wind comes from great rips in the Sun's corona, called coronal holes. These holes appear to be predominant in the polar regions and are fairly small. The fast wind blows at a steady 750 km s^{-1}, but the typical solar wind emerging from the Sun's equatorial zone is variable but relatively slow, at 350–400 km s^{-1}. The solar wind flows straight out in all directions and carries the magnetic field lines with it.

The Sun's magnetic field is generated by plasma motions below the Sun's surface and extends out to shape and control the solar atmosphere and the entire heliosphere. It is uniform at all latitudes in the heliosphere. Close to the visible surface of the Sun, the magnetic field is strongest over the poles. The magnetic field lines carry other particles that have greater energy than those in the solar wind (see also SOLAR MAGNETIC FIELD). Each of the high-energy particles has an energy of up to millions of electron volts. The highest-energy particles are few in number, so their density is low compared with that of the solar wind.

The terrestrial planets

The terrestrial planets consist of Mercury, Venus, Earth, Mars, and the Earth's moon. Although by strict definition Earth's MOON is not a planet, it is usually included in the terrestrial planets' category because of its large size, its rock composition, and the similarity of its early geologic history to the other terrestrial planets.

The terrestrial planets, also called the inner planets because of their place in the Solar System, show several common characteristics. Their relatively high densities suggest that, like Earth, they are composed of elements such as silicon, iron and nickel. These dense elements would have been retained close to the Sun, while lighter elements, such as hydrogen and helium, would have escaped to the outer reaches of the Solar System during its formation and early evolution (see SOLAR SYSTEM: FORMATION). The individual planets evolved by the collection of smaller bodies, planetesimals, through accretion. As they grew in size, their increasing mass attracted still more bodies. Within the first half-billion years of Solar System history much of the debris had been swept up by the planets. The terrestrial planets began to cool and form crusts as elements combined and crystallized as rocks and minerals. Various combinations of silicon, oxygen, iron, magnesium, sodium, calcium, potassium and aluminum produced the silicate minerals of most rocks composing the Earth and lunar crusts, and probably most of MERCURY, VENUS and MARS. With the formation of a crust, the geologic evolution was initiated, and each developed along different paths.

Venus, Earth, and Mars all have significant atmospheres. Probably some gases were accumulated by each protoplanet from the original solar nebula, but these original atmospheres have been lost to space. Secondary atmospheres were outgassed from their hot interiors (with a possible contribution also coming from meteoritic impacts) and subsequently modified by chemical interactions with their surfaces. Mercury and the Moon are too small to retain anything but the most tenuous atmospheres.

Mercury is the planet closest to the Sun. It has the most elliptical orbit of any planet except Pluto. Because of its elliptical orbit, Mercury's closest distance to the Sun is only 46 million km while its greatest distance is 70 million km. Because Mercury is so close to the Sun, noontime

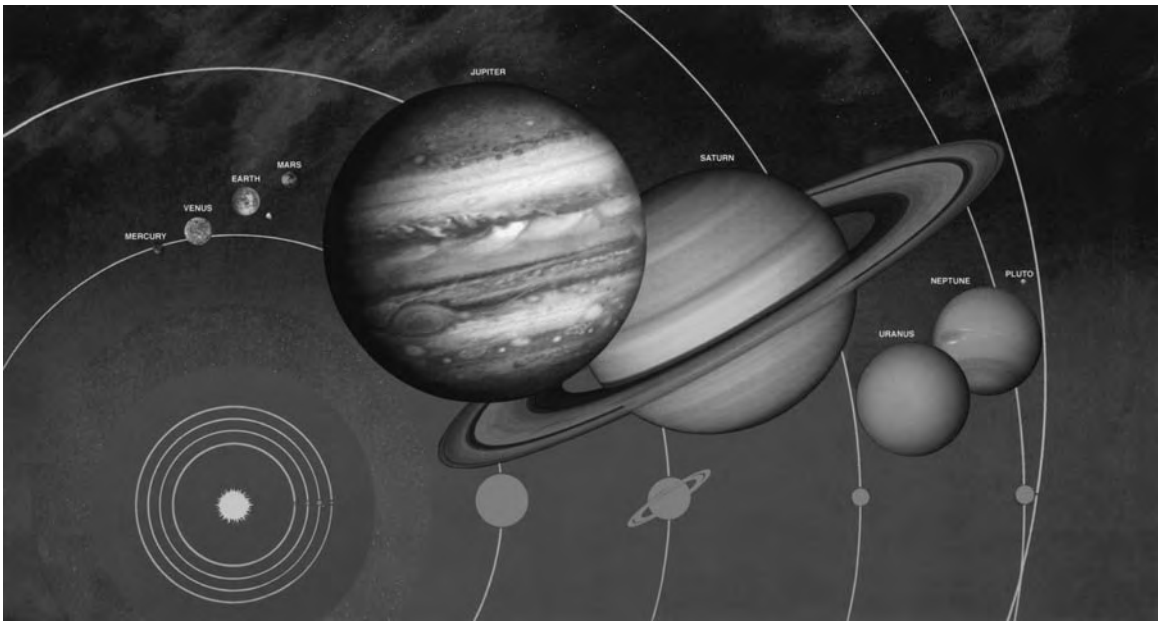

Figure 1. Our Solar System (NASA lithograph LG-1997-12-475-HQ).

temperatures soar to 370 °C. But because it has almost no atmosphere to hold in the heat, temperatures plummet to almost −185 °C at night. Mercury rotates on its axis once every 58.6 d and circles the Sun once every 87.9 d. Mercury is smaller than any other planet except Pluto, and is about one-third the size of Earth. However, Mercury's density (5.4 g cm^{-3}) is about the same as Earth's and, therefore, it is assumed to have an enormous iron and nickel core some 75% of the planet's diameter (42% of the volume), surrounded by a rocky mantle and crust only 600 km thick. As Mercury spins on its axis, the iron in its core generates a weak magnetic field that surrounds the planet.

Although the surface of Mercury superficially resembles that of the Moon, there are significant and geologically important differences. Like the Moon, it has heavily cratered upland regions and large areas of smooth plains that surround and fill impact basins. The heavily cratered terrain records the period of heavy meteoroid bombardment that occurred throughout the Solar System during its early history and ended about 3.8 billion years ago. Unlike the Moon, however, Mercury's heavily cratered terrain contains large regions of gently rolling intercrater plains, the major type of terrain on the planet. Both the smooth plains and intercrater plains are attributed to volcanism early in Mercury's history. Mercury also has experienced a unique history of crustal deformation which has resulted in a global system of compressive structures. The general geologic history of Mercury is that soon after the planet formed it nearly melted by heating from the decay of radioactive elements and the inward migration of

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

the large amount of iron to form its enormous core. This led to expansion of the planet and extensional fracturing of the surface that provided an exit for lavas to reach the surface and form the intercrater plains. As the core and mantle began to cool, Mercury's radius decreased by about 2–4 km, and the crust was subjected to compressive stresses. At about this time, a large basin was formed by a gigantic impact. Further eruptions of lava within and surrounding this large basin and other large impact craters formed the smooth plains. Volcanism finally ceased when lithospheric compressive stresses became strong enough to close off magma sources. All these events probably took place very early, perhaps in the first 700 or 800 million years, in Mercury's history.

Venus is the hottest world in the Solar System. It is blanketed by a thick layer of clouds that generate a greenhouse effect and consequently heat its surface up to 480 °C. The atmospheric pressure at the surface is 90 times more than that at Earth's surface. The atmosphere of Venus is 98% carbon dioxide and contains virtually no water vapor. The upper clouds are composed of sulfuric acid droplets. Astronomers have called Venus Earth's twin because of their apparent similarities: their mass and volume (and hence their density and gravity) are remakably alike. However, Venus is very different in other respects. Venus has no satellite. A magnetic field has not been detected. A day on Venus (243 Earth days) is longer than its year (225 Earth days). Venus rotates in a direction opposite that of Earth and most other planets.

Venus' surface consists of about 27% lowlands, 65% rolling plains, and 8% highlands. The density of craters on Venus is much lower (about two craters per million square km) than densities on the Moon and Mars, which suggests a relatively young average surface age. Volcanism (vast lava plains, thousands of volcanoes) and tectonism (highly fractured elevated terrains, mountains over 11 km high above the plains) are widespread and fundamentally important processes in the formation and evolution of Venus' crust. Models of the rate of volcanic resurfacing based on crater inventory suggest that local surfaces can have an age from very young to 800 million years old.

Like the other terrestrial planets, Venus was probably formed by accretion of small bodies about 4.6 billion years ago. With time and cooling, a crust, mantle, and core developed. The lithosphere could be 100 km thick, and the core could be about the same size as Earth's core. The lack of abundant impact craters on Venus suggests that most of the crust that formed early in its history has been destroyed by burial by lava flows. The formation of both large and small volcanoes and the presence of extensive lava flows over hundreds of millions of years on Venus were accompanied by crustal deformation that led to the development of large tectonic structures (e.g. faults and rifts).

Earth is surrounded by a gaseous atmosphere composed primarily of nitrogen and oxygen (see EARTH'S ATMOSPHERE). Beneath the atmosphere, the solid surface is nearly (70%) covered by a global, 4 km deep ocean. The atmosphere and ocean balance incoming solar radiation and outgoing terrestrial radiation to maintain surface temperatures whithin the small range which permits life. Earth is special in many respects. Of all the planets in our Solar System, Earth is the only one that can support life. No other planet has oceans of water and an oxygen-rich atmosphere. It is also the largest body in the Solar System with a solid surface and the only planet with ongoing plate tectonics. However, Earth is just an average planet. It is bigger than four planets in the Solar System and smaller than the other four (table 1).

Earth formed about 4.6 billion years ago, and it is still evolving. Earthquakes and volcanoes are violent proofs of Earth's shifting crust. In the early stages of its history (4.6–4.0 billion years ago), heat from planetary accretion melted most, if not all, of the mass. It is usually thought that volatile elements such as oxygen, carbon, and nitrogen were implanted in the accreting Earth by planetesimals. Dense elements, such as iron, settled into the interior of the molten protoplanet to form the core, while lighter elements rose to the surface, leading to chemical differentiation of our planet (see EARTH'S INTERIOR). Cooling of the surface of the protoplanet led to the formation of a thin crust. However, continued impact bombardment fractured the crust, allowing parts of the still molten interior to flow to the surface. Gases trapped in the interior were released to the surface from these volcanic processes and formed Earth's early atmosphere. With time, rainfall accompanied the evolution of the early atmosphere and led to the accumulation of liquid water on the surface. The constant weathering and renewal of Earth's crust have obliterated nearly all of the craters which were formed during this period of time.

Tectonic deformation of the crust and volcanism contributed to the formation of mountains and valleys, generating topographic relief. Erosional processes, including running water, glaciers and weathering, have continually reduced the high areas, and deposition of transported sediments have filled up the low areas to form plains. However, much of the Earth's surface results from internal processes, i.e. convection within the mantle. The mantle that surrounds the iron–nickel core is composed mostly of hot, plastic, silicate materials and is subdivided into the mesosphere, the astenosphere (a plastic layer about 250 km thick), and the lower part of the lithosphere (a cool rigid layer about 100 km thick). The upper part of the lithosphere corresponds to the crust whose average thickness ranges from 8 km (the oceanic crust composed of silicate rocks rich in iron and magnesium) up to 70 km (the continental crust composed of silicate rocks rich in aluminum, silica, and calcium). The lithosphere consists of seven major plates, and many smaller plates, sliding about on the underlying astenosphere. The energy responsible for the plate motion comes from the heat generated by the decay of radioactive elements, plus residual heat resulting from planetary accretion some 4.6 billion years ago. Because of plate motion, most of the record earlier than 600 million years ago has been lost through plate

tectonics and crustal recycling. Consequently, some 80% of Earth's history is not well understood.

Because of synchronous rotation, the *Moon* revolves once on its axis each time it orbits the Earth, thus always presenting the same face, the nearside, toward our planet. The lunar nearside shows two contrasting types of landscape: dark, plains-like areas of low relief, and brighter, more rugged regions which cover about two-thirds of the surface. The smooth dark areas were named *maria*, and the name *terrae* was given to the bright upland regions. The *terrae* are seen to be densely cratered highlands. Craters of all sizes up to about 250 km across are scattered over the surface in great profusion, frequently overlapping one another. The *maria* vary from almost circular features to more irregular-shaped regions. Their dark surfaces are apparently smooth, broken only by a few large craters. The *maria* are younger than the *terrae* whose cratered surfaces may be relics of a primordial landscape.

Two different processes have been responsible for the present-day landscape: crater-forming impact of countless meteorites, and igneous and volcanic activity from within the Moon. Early in its history the Moon was subjected to intensive meteorite bombardment, including catastrophic basin-excavating impacts of massive asteroidal bodies. The crust probably has been intensely fractured by those basin-excavating impacts to a depth of 20 km or more. These huge basins, which range in size from 300 to more than 2500 km across, were subsequently filled by tremendous surface outpourings of volcanic lava (i.e. basalts) to form the *maria*. Although lacking the large, lava-filled basins so characteristic of the nearside, the farside of the Moon displays a mostly terra-type landscape, formed almost entirely by heavily cratered highlands, and several large crater-like basins. Since large impact basins are evenly distributed over the Moon's surface, impact histories for the two sides are about the same. The absence of extensive spreads of lava in farside basins may be related to the tidal forces exerted by the Earth on a partly molten Moon in its history. It may also reflect the farside presence of a much thicker layer of crustal rocks through which there were no large-scale outpourings of lava like those through the comparatively thin-crusted nearside. The lunar crust appears variable in thickness, ranging from a few tens of km beneath some basins to more than 100 km under some highland regions.

The Moon may have formed during a collision between the early Earth and a Mars-sized rocky planet about 4.6 billion years ago. The collision of this object with the proto-Earth threw a cloud of debris into orbit around Earth. This debris, which probably formed a disk-like body in Earth orbit, quickly collected into a single, large body, our Moon. The rapid rate of lunar formation released large amounts of heat which produced near-global melting, a stage called the magma ocean. As minerals began to crystallize in this magma ocean, the low-density, aluminum-rich minerals floated upward, forming the lunar crust (about 70 km thick). High-density, iron-rich minerals crystallized in the lower levels of the magma ocean, forming the lunar mantle, which represents most of the mass of the Moon, and probably an iron-rich core that may be partly molten and is perhaps 800 km in diameter. This differentiation of the Moon was accomplished around 4.5 to 4.4 billion years ago. The early Moon was very hot, and magma continued to permeate the solidified crust for at least the next 300 million years. Some magmas produced by the melting of the lunar mantle flowed out onto the Moon's surface as volcanic eruptions that began about 4.3 billion years ago. Most surfaces of these lava flows were obliterated by large impacts. The dark plains that dominate the lunar nearside are lava flows that erupted mostly between 3.8 and 3.0 billion years ago. The principal process operating on the Moon for the last 3 billion years has been impact cratering, dominated by bodies in the microscopic size range. This bombardment of micrometeorites has ground up the lunar bedrock into a chaotic mass of powdery, fine debris and rock fragments, several metres thick. This material, called regolith, is directly exposed to both cosmic radiation and the solar wind. Thus, the regolith preserves a record of the history of the Sun's output for the past 3 billion years.

Mars is the outermost of the terrestrial planets. At 6788 km, its diameter is intermediate in size between Earth and Mercury. Mars is generally redddish-orange in color due to abundant iron oxide in its surface materials. Mars moves in a distinctly elliptical orbit, in contrast to the Earth's nearly circular orbit. Its orbit is so elliptical that Mars varies in distance from the Sun by 20%, which results in a 45% variation in solar radiation received at the surface and a 30 °C range in temperature at the subsolar point. This effect, combined with the effects from the Martian seasons and the absence of an ocean that acts as a heat sink, produces an extraordinarily wide range in surface temperature. The surface warms to about 22 °C in summer at mid-latitude and cools to about −125 °C at the south pole during mid-winter. Mars has a thin, cool atmosphere made primarily of carbon dioxide. The average pressure at the surface is about one hundredth that of Earth's atmosphere. The global circulation of the atmosphere is dominated by the seasonal exchange of volatiles as they migrate from the summer pole to the winter pole. Occasionally winds on Mars are strong enough to raise dust and initiate a dust storm.

The surface of Mars has recorded evidence of a wide range of geological and atmospheric processes that have operated over the history of the planet. On a global scale the Martian surface is divided into roughly two hemispheres separated in places by a kilometre-high scarp. This escarpment extends around the planet at a 35° angle from the equator. To the north of the escarpment are sparsely cratered lowlands, the northern plains, and to the south are regions of elevated and heavily cratered terrain. On a regional scale the northern plains are featureless with only a few impact craters. But locally these plains exhibit a wide variety of surface features indicative of wind action, water erosion, ground ice action, and volcanism. The high density of impact craters in

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

the southern terrain suggests that this terrain is ancient (about 4 billion years old). Channel systems are common in the old cratered terrain, suggesting fluvial erosion and dramatic climate change early in Martian history, from a warmer wetter environment to the present cool dry conditions. Because liquid water cannot exist on the surface of Mars under present conditions (the atmosphere is too thin and cold), Mars probably had a warmer, denser atmosphere at the point in its history when the channels were eroded. However, frozen water still might exist in Martian subsurface layers.

Located just north of the equator is the Tharsis dome, a gigantic volcanic and tectonic bulge, 5000 km across and 7 km high. Three enormous volcanos, the Tharsis Montes, are located in line near the top of the bulge. They are all 300–400 km across. Olympus Mons, the tallest volcano on Mars, is located on the northwest flank of the Tharsis bulge. It is about 600 km across, and like the other large volcanos its absolute elevation is about 27 km. An extensive array of faults radiates from the Tharsis bulge. A 5000 km long interconnecting canyon system, called Valles Marineris, radiates outward on the eastern flank of the Tharsis bulge. In places, the single canyon is 700 km across and 7 km deep. Enormous landslides are common along the canyon's wall. This canyon system is one of the major tectonic features of the planet and may have resulted from tectonic extension, or rifting. Valles Marineris merges eastward with canyons that contain arrays of jumbled blocks that appear to have formed by collapse. Large outflow channels originate in this area and extend northeast into the lowlands. These channels are thought to be produced by the catastrophic release of subsurface ground water.

Mars probably has a central, high-density core composed mostly of iron with small amounts of sulfur, oxygen, and nickel. Outward from the core is a thick iron-rich mantle. The outermost shell is the low density crust, a few tens of km thick, and probably composed of basaltic rocks. Though Mars is made of generally the same materials as the other terrestrial planets, its mean density is 3.9 g cm^{-3}.

Two small moons, PHOBOS AND DEIMOS, orbit the planet. They are thought to be captured asteroids composed of dark, carbon-rich rock. Each satellite has been heavily cratered.

The Jovian planets

JUPITER, SATURN, URANUS, and NEPTUNE are referred to as the Jovian planets. All are gaseous objects and lack solid surfaces. Unlike the terrestrial planets, they are enormous and contain most of the mass in the Solar System outside the Sun.

The Jovian planets formed by the accretion of smaller solid bodies to form a nucleus of sufficient size to capture gravitationally the lighter elements that escaped from inner parts to the outer parts of the Solar System. As this process continued, the Jovian planets grew to consist mostly of hydrogen and helium. They grew and evolved to have a family of smaller bodies in orbit about them. These moons are typically composed of ices as well as rocky materials. One of them, Titan, a satellite of Saturn, has a thick atmosphere of nitrogen, along with methane, ethane, acetylene, ethylene, hydrogen cyanide, and other carbon–nitrogen components. The satellites of the Jovian planets represent a collection of objects of different sizes, compositions, and geologic histories. Some, such as the Jupiter moons Ganymede and Callisto, are about the size of Mercury. Others, such as the Saturnian satellite Enceladus and the Uranian satellite Miranda, have experienced spectacular crustal deformation. Others appear to have remained relatively unaltered since their initial formation. Two of them, Jupiter's Io and Neptune's Triton, are currently volcanically active.

Jupiter is the largest planet in the Solar System. The characteristics of its interior are highly speculative. Toward the center of the planet, the pressure is estimated to be 100 million times greater than the atmospheric pressure on the Earth's surface, and the temperature may reach 30 000 °C. Under this conditions, hydrogen would have a density of 4 g cm^{-3} and would form a metallic phase. Some models suggest a central solid core as large as 20 000 km across, which may contain small amounts of rocky material. The planet completes one orbit of the Sun each 11.8 yr and its day is 9 h 55 min. The rapid spin rate may explain the huge magnetic field that surrounds Jupiter. The cloud patterns (i.e. zonal jets, eddies, storms, Great Red Spot) apparently result from convection cells that are driven by the escape of heat from Jupiter. A faint dusty ring of material encircles Jupiter. Its outer edge is 129 000 km from the center of the planet, and it extends inward about 30 000 km.

Jupiter is now known to possess at least 16 satellites (see JUPITER: SATELLITES). The Galilean satellites, Io, Europa, Ganymede, and Callisto, are the largest. Io is the most famous satellite because active volcanos dot its surface. They erupt frequently, spewing sulfur dust up to 300 km high. Io's volcanos are apparently due to heating of the satellite as it is perturbed in its orbit by Europa and Ganymede then pulled back again by Jupiter. It appears that volcanism on Io affects the entire Jovian system, in that it is the primary source of matter that pervades Jupiter's magnetosphere. Europa, the next farthest moon from Jupiter, is covered by a thin crust of water ice (30 km thick), possibly floating on a H_2O ocean which might be about 50 km deep. The surface of the next satellite, Ganymede, shows two distinct types of terrain, cratered and grooved, suggesting that its entire icy crust has been under tension from global tectonic processes. Callisto, the Galilean farthest from Jupiter, has a very old, heavily cratered surface showing remnant rings of enormous impact craters.

Jupiter's rings and satellites exist within an intense radiation belt of electrons and ions trapped in the planet's magnetic field. These particles and fields comprise the Jovian magnetosphere, which extends 3–7 million km toward the Sun, and stretches in a windsock shape at least as far as Saturn's orbit, a distance of 750 million km. As the

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

magnetosphere rotates with Jupiter, it sweeps past Io and strips away about 1000 kg s^{-1} of material. The material forms a torus, a doughnut-shaped cloud of ions. The torus's heavy ions migrate outward, and their pressure inflates the Jovian magnetosphere to more than twice its expected size.

Saturn is the second largest planet in the Solar System and takes 29.5 Earth years to complete one orbit of the Sun. Saturn has at least 18 satellites and a complex ring system (see SATURN: SATELLITES; RINGS). Measured from edge to edge, Saturn's rings span about one million km. Saturn's rings are made of ice and rock. They are not solid, but consist of small chunks of frozen material in a relatively thin layer. Some of the rings show elaborate structures such as kinks and spokes that are due to the gravitational effects of nearby satellites. Radial, spokelike features are believed to be composed of fine, dust-size particles. Electrostatic charging may create spokes by levitating dust particles.

Saturn shows broad atmospheric banding similar to but much fainter than that found on Jupiter, and ovals and other atmospheric features are generally smaller than those on Jupiter. An enormous white cloud has been discovered near the equator that grows and spreads rapidly, and rises higher and higher in the atmosphere. This cloud is believed to be composed mainly of ammonia ice crystals.

Saturn holds a wide variety of satellites in its orbit, ranging from Phoebe, a small satellite that travels in an orbit in the opposite direction from the other satellites (probably a captured asteroid), to Titan, the planet-sized satellite with a thick nitrogen–methane atmosphere which may strongly resemble the Earth's atmosphere before life evolved. The most active surface of any of Saturn's satellites is that of Enceladus. Its bright surface is marked by faults and valleys, showing evidence of tectonic motions of the icy crust. One other satellite, Mimas, is scarred with a crater so huge that the impact that caused it nearly broke the satellite apart.

Uranus has a cloudy atmosphere of primarily hydrogen and helium with a small amount of methane that causes its bluish-green color. Uranus is unusual in several ways. Unlike any other planet in the Solar System, it spins sideways. Uranus also rotates in the opposite direction from most of the other planets. Its magnetic field is also tipped by about 50° with respect to the planet's axis, making the magnetic field of Uranus, along with that of Neptune, unique among the planets. Surrounding Uranus are several very thin dark rings, similar to those around Jupiter.

Five large moons, OBERON, TITANIA, MIRANDA, UMBRIEL, and ARIEL, and 10 smaller ones orbit Uranus. Their orbital paths are sideways compared to other planets and moons because of Uranus' sideways spin. The largest moon, Titania, is 1610 km in diameter and its icy surface shows a lack of large craters that may have been erased by some internal process. Miranda is the smallest of the five large satellites of Uranus. Its icy crust displays a puzzling array of geologic forms, including huge oval features and complex systems of faults and ridges that may result from either internal processes, or the random reassembly of Miranda's fragments after it was broken apart by impact with an asteroid-sized body.

Neptune is the fourth, outermost, and smallest gas giant of our Solar System. Even though Neptune receives only 3% as much sunlight as Jupiter does, it is a dynamic planet. Neptune's atmosphere, mostly composed of hydrogen with methane in its upper part, exhibits several large, dark spots reminiscent of Jupiter's Great Red Spot. The magnetic field of Neptune, like that of Uranus, is highly tilted (47° from the axis of rotation).

Neptune has at least eight satellites. TRITON, the largest, is one-third as massive as Earth's Moon. Triton is also the most unusual moon, because it orbits Neptune in the opposite direction from all the other satellites (see also NEPTUNE: MINOR SATELLITES). Triton has an extremely thin atmosphere extending to about 800 km above its surface. The atmospheric pressure at the surface is about 1/70 000th the surface pressure on Earth, and the surface temperature is about −235 °C. Triton's surface, mostly frozen methane and nitrogen, shows evidence of a remarkable geologic history, with active geyser-like eruptions spewing invisible nitrogen gas and dark dust particles several kilometres into its tenuous atmosphere.

Small bodies and Pluto

ASTEROIDS, COMETS, and the smaller planetary satellites are often called small bodies. However, some are not so small; the largest asteroid, Ceres, is more than 1000 km across.

Most *asteroids* occur in the zone between the orbits of the planets Mars and Jupiter, the 'asteroid belt'. In addition to the asteroid belt, asteroids are found elsewhere in the Solar System. Two sets of asteroids, named Trojan asteroids, are found in the same orbit as Jupiter. Three populations of asteroids, referred to as near-Earth asteroids, reside in the inner Solar System. Among these three populations, two of them, the Atens and the Apollos, cross Earth's orbit and occasionally collide with the Earth and the Moon. The third population, the Amors, is found between Earth and Mars. More than 18 000 asteroids have been identified, of which the orbits of some 5000 have been determined. It is estimated that there are at least 1000 asteroids larger than 30 km, of which some 200 are larger than 100 km. Asteroids are classified both by type, related to their inferred composition, and by their location in the solar system. Because many meteorites seem to be derived from asteroids, a classification of asteroids is based on the comparison of their spectral reflectance measurements with compositional signatures of meteorites. This classification includes three groups: C-type for carbonaceous asteroids, rich in carbon and complex organic compounds, considered to be the most primitive, with unaltered material similar in composition to the terrestrial planets; S-type for siliceous asteroids, composed of silicate materials lacking the carbon-rich compounds, considered to be slightly processed; M-type for metallic asteroids, considered to be chemically

Dirac House, Temple Back, Bristol, BS1 6BE, UK

differentiated as the result of extreme heating. In addition, a unique asteroid, Vesta, appears to consist of rocks similar to the basaltic lava flows found on Earth and the Moon.

Comets are probably primordial material left over from the early stages of the Solar System's formation. Commonly described as 'dirty snowballs', comets appear to be composed of solid dust grains embedded in water ice. The main component of a comet is the nucleus, a mass of ice and dust that typically is 1–10 km across. As comets travel toward the Sun, at about the distance of the orbit of Mars they begin to release gases in response to solar energy. The released gases form a glowing mass, the coma, surrounding the nucleus, 100 000 km across. Streaming away from the coma is the cometary tail which extends over 1–10 million km and is always oriented away from the Sun, regardless of the comet's trajectory. The cometary tail includes two components: the plasma tail composed of carbon dioxide, nitrogen, and water ions and a broad, slightly curved tail composed of dust grains. Most comets reside in the 'Oort cloud', and the 'Kuiper belt', beyond the orbit of Pluto. It is assumed that perturbations from passing stars may reset the orbits of some comets residing in the Oort cloud. Once travelling on an elliptical path through the inner solar system, comets may not survive in terms of Solar System history. Many of them are thought to collide with planets (e.g. the collision of Comet Shoemaker–Levy 9 into Jupiter in July 1994), satellites, the Sun, or other objects. With each fly-by of the Sun, a comet loses material into deep space by gas jetting at a typical rate of about a million tons per day. At this rate, comets would shrink by several meters with each orbit and would have lifetimes of only thousands of years.

Pluto does not fit into the subdivision of planets as well as terrestrial and Jovian objects. Little is known of its properties; almost nothing is known of its surface. Although Pluto is the outermost of the Sun's known planets, its elliptical orbit occasionally brings Pluto inside the orbit of Neptune. Pluto has a satellite, Charon, which is 1190 km in diameter, or about half the size of its parent planet. Thus, the Pluto system is considered to be a double planet. Moreover, PLUTO AND CHARON are dynamically locked, always showing the same face to each other. Ground-based observations and from the Hubble Space Telescope show that Pluto's surface contains methane, while Charon is mostly water ice. Pluto also has a thin atmosphere of methane and may contain carbon dioxide or molecular nitrogen. Both Pluto and Charon are dense objects (>2 g cm^{-3}), and are thought to consist of a rocky core surrounded by a water-ice mantle. Because of their peculiar orbits and high densities, the origin of Pluto and Charon remains speculative: they could be either satellites of Neptune that escaped, or remnants of a large satellite of Neptune that was broken apart by a collisional impact, and knocked out from Neptune's orbit.

Solar System: Dating of Events

The formation of the solar system began with the collapse of a fragment of an interstellar molecular cloud to a protoplanetary disk (the solar nebula) and continued through a complex process of accretion, coagulation, agglomeration, melting, differentiation and solidification to build the planets. Added to this were the secondary influences of aqueous alteration and thermal metamorphism and the tertiary effects of bombardment, collision, break-up and re-formation. Since all traces of the original materials that formed the Earth have been obliterated by bombardment and by geological processing, the rocks that are accessible for study at the Earth's crust are not representative of material that aggregated from the solar nebula. Thus the chronology of events taking place during the early solar system can only be determined by the study of meteorites and lunar material brought back to Earth by the Apollo and Luna missions.

Chondrites

Meteorites are pieces of rock and metal that fall to the Earth — fragments broken from asteroids — with varying compositions that span a wide range of planetary materials, from completely unmelted and unfractionated stony chondrites to highly fractionated and differentiated iron meteorites. These materials and the components within them carry records of all stages of solar system history.

The most significant meteorites for early solar system chronology are the chondrites, which are the most primitive of all meteorites, having experienced only mild thermal or hydrothermal metamorphism since accretion into parent bodies. Chondrites are composed of high temperature components — CAIs (calcium, aluminum-rich inclusions) and chondrules (spherical to subspherical assemblages, up to ~5 mm in diameter, of iron- and magnesium-rich silicate minerals that were partially or totally melted prior to parent-body accretion) — set in a matrix of fragmented chondrules mixed with sulfides, metal and minerals formed at lower temperatures (clay minerals, carbonates, sulfates, organic matter). The CAIs are refractory inclusions (up to ~1 cm in size) of spinel, hibonite, melilite, etc.

Radioactive isotope dating

The principle behind radioactive isotope dating is the fixed rate with which an unstable radioactive isotope (the parent) decays to a stable isotope (its daughter). The time taken for a radionuclide to decay to half its initial abundance is the half-life ($T_{1/2}$) of the system. The half-lives of several radioisotope systems used for chronology are given in table 1. In practice, absolute abundances are not measured; rather, the isotopes are normalized to the amount of a related stable isotope, and isotope ratios measured.

Table 1. Radionuclide decay systems used for solar system chronology.

Parent	Daughter	Half-life
^{147}Sm	^{143}Nd	106 Gyr
^{87}Rb	^{87}Sr	48.8 Gyr
^{238}U	^{206}Pb	4.45 Gyr
^{40}K	^{40}Ar	1.25 Gyr
^{235}U	^{207}Pb	0.70 Gyr
^{41}Ca	^{41}K	0.15 Myr
^{26}Al	^{26}Mg	0.73 Myr
^{10}Be	^{10}B	1.5 Myr
^{60}Fe	^{60}Ni	1.5 Myr
^{53}Mn	^{53}Cr	3.7 Myr
^{107}Pd	^{107}Ag	6.5 Myr
^{182}Hf	^{182}W	9 Myr
^{129}I	^{129}Xe	16 Myr

Several isotope systems with different half-lives are used to measure different events in solar system history. Long-lived radionuclides (given in the top section of table 1) are used to date the age of formation of meteorites. Short-lived radionuclides (lower half of table 1) date specific processes that meteoritic material has experienced. So, for example, the Al–Mg and Ca–K systems are used to determine the formation interval between stellar processing of material and its incorporation into meteoritic components, while the I–Xe chronometer is used to investigate the formation of secondary salts produced by aqueous processes, and the Hf–W system is used to trace planetary core formation.

Stages in Solar System formation

The main stages resulting in formation of the Earth and the solar system can be summarized as follows in figure 1.

Aggregation of planets

Gravitational instability within an interstellar molecular cloud resulted in the collapse of a fragment of the cloud to form a protoplanetary disk. The mechanism that triggered cloud collapse is not clear but, whatever the mechanism, the collapse of the cloud and the subsequent aggregation of material must have been sufficiently fast to carry a complement of 'live' short-lived radionuclides into the protoplanetary disk. Evidence for the speed of this process comes from the presence of ^{26}Mg (from the decay of ^{26}Al) within CAIs in chondritic meteorites. It has been generally accepted that freshly synthesized ^{26}Al and other short-lived radionuclides (such as ^{41}Ca) were injected into the molecular cloud fragment from a

Copyright © Nature Publishing Group 2002
Brunel Road, Houndmills, Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS21 6BE, UK

supernova just prior to solar system formation (indeed, the supernova is assumed to have triggered cloud collapse). The occurrence of ^{26}Mg in the inclusions shows that the CAIs formed while ^{26}Al was still 'live' in the solar nebula, that is agglomeration took place over a very short timescale, < 3 Myr. The ^{41}Ca–^{41}K chronometer, with even shorter half-life, implies even more rapid formation of CAIs, with an interval between nucleosynthesis and agglomeration of < 0.3 Myr. Absolute dating of the components within meteorites uses the U–Pb isotope system, which is very precise, and places the time of formation of CAIs as 4566 Myr ago. Chondrules, which are the most abundant component within chondrites, show little evidence for live ^{26}Al, implying that the chondrule-forming process took place ~2–3 Myr after the formation of CAIs. The aggregation of interstellar dust ($\leq$ 0.1 μm in diameter) into increasingly large bodies, eventually forming kilometer-sized planetesimals and culminating in the asteroids and planets, took place over a time interval of some 8 Myr following formation of the CAIs. The chronology of these different events is shown schematically in figure 1.

Note, however, that use as a chronometer of isotope abundance differences between chondritic components is dependent on the models of short-lived isotope formation. Over the past few years, an alternative mechanism for short-lived radionuclide formation has been proposed, whereby the species are formed by nuclear reactions in the energetic X-wind of a young stellar object. In this scenario, no chronological significance can be attached to the lack of daughter products from short-lived isotopes in chondrules — the effect is spatial, rather than temporal.

Differentiation

Igneous activity on differentiated stony asteroids is traced by data from ^{53}Mn–^{53}Cr chronometry. For the basaltic achondrites (a group of meteorites whose parent body is believed to be the asteroid 4 Vesta), core formation apparently occurred < 4 Myr after CAI formation; subsequent volcanic activity on the asteroid continued for a further 4 Myr or so (see figure 1). This compressed timescale indicates the relatively short period that elapsed between accretion of primordial dust into small protoplanets and the onset of volcanism, melting and differentiation.

Core Formation

Once the proto-Earth had aggregated, internal heat from radioactive decay, combined with gravitational energy and collisional energy from planetesimal bombardment, kept the planet molten. As the proto-Earth cooled, reduction reactions within the convecting system resulted in the production of a metal-rich core and silicate-rich crust–mantle structure. The timescale over which core formation occurred can be deduced using several radiometric decay schemes, one of the most telling of which is the newly established ^{182}Hf–^{182}W chronometer. The strongly lithophilic ^{182}Hf is partitioned into silicates, relative to the more siderophilic W, during differentiation, and subsequent variations in Hf/W are caused by decay of ^{182}Hf to ^{182}W. Models based on the ^{182}Hf–^{182}W chronometer indicate that formation of the Earth's core

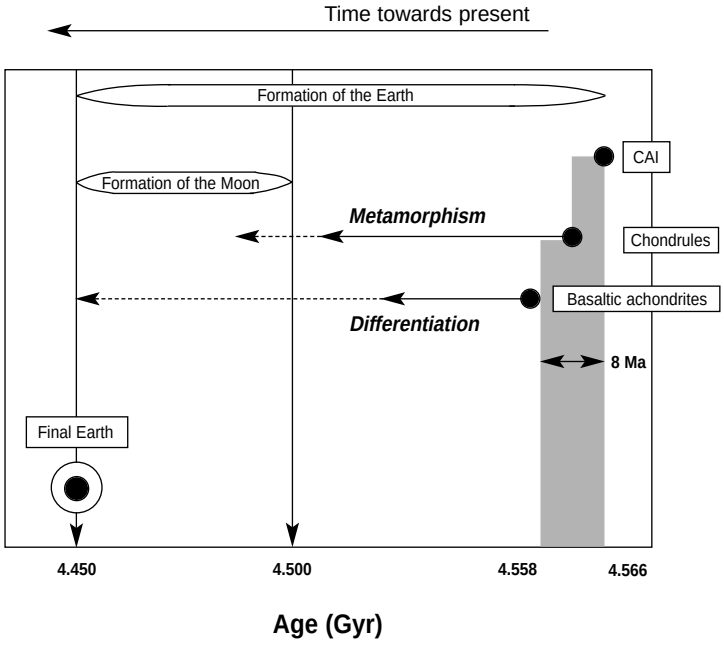

Figure 1. Schematic chronology of early solar system history (after Allègre *et al*, 1995).

took place gradually, some 50 Myr or so after the differentiation of iron meteorite parent bodies.

Formation of the Moon

The last major event in the history of the proto-Earth was the formation of the Moon. The most widely accepted hypothesis is that in which a Mars-sized body collided with the Earth. Refinements of this hypothesis indicate that the impact occurred after the Earth's core had formed and that the crust–mantle regions of both the impactor and the proto-Earth were vaporized and then mixed during the impact. This hypothesis accounts satisfactorily for the geochemical, mineralogical and isotopic compositions of the lunar samples as represented by material returned by the Apollo and Luna missions. The timing of the giant impact event is set at around 4.51 Gyr ago.

Solar System: Exploration

We are now close to the 40th anniversary of the first missions to the MOON: the LUNA 1 fly-by, which set a very low upper limit on the magnetic field of the Moon, the suicide mission Luna 2, which impacted the nearside, and the Luna 3 fly-by, which imaged the far side for the first time were launched by the Soviet Union in 1959, less than two years after the first Sputnik. These 40 yr of exploration of the solar system by spacecraft have represented one of the major scientific and technical adventures of the 20th century. Our view of the solar system is now vastly different from that provided by ground-based planetary astronomy in the first half of this century. There is no example of a major planetary mission which did not discover quite unexpected features. Each of the dots of light or marginally resolved objects which could be observed from the ground is now revealed as a diverse and complex world in its own right.

This long-term effort was initiated as a spin-off of the development of intercontinental missiles at the peak of the cold war. The commitment of the US to the first manned landing on the Moon was mainly motivated as a demonstration of the American leadership in launchers, which was challenged by the launch of Sputnik 1 in 1956 by the Soviet Union. These political and military undertones justified budgets of more than 1% of the GNP in the US during the 1960s and even more for the Soviet Union. After the APOLLO program, space budgets sharply decreased, reaching a plateau which has remained nearly level (with wide fluctuations) until recently. A new technological impetus was given by the American 'star wars' program in the early 1980s, which triggered major advances in the miniaturization of spacecraft subsystems. The 10 yr since 1989 can be considered as a transition period, with the demise of the Soviet planetary program and budgetary limitations in the US and Europe, Japan constituting an exception with its expanding planetary program.

The exploration of the solar system can therefore be separated in three phases. From 1956 to 1972, programs are dominated by political considerations and are mainly focused on the race to the Moon. From 1972 to the mid-1990s, the missions are mainly driven by scientific goals, and the emphasis is on very ambitious programs such as Viking and Voyager for NASA, or Phobos 1 and 2 on the Soviet side. The third phase is characterized by much smaller missions with a handful of experiments, the major missions of ESA's program such as CASSINI (in collaboration with NASA) and ROSETTA constituting an exception. Considerations of public interest ('outreach' is the present catch-word) became increasingly important, in particular in the US, with emphasis on such topics as extraterrestrial life, 'resources' (another catch-word) or potential catastrophes (asteroidal or cometary impacts on the Earth). The 4 m class telescopes equipped with increasingly sensitive instrumentation, the development of interferometry and adaptive optics have completely renewed ground-based planetary astronomy which plays an increasing role in the exploration of the solar system.

From the point of view of science, there is a logical sequence of investigations of solar system bodies, which will be presented in the next section. The political and programmatic hazards have strongly biased the mission definition process, so that there are significant inconsistencies in the present status of knowledge on the three major types of solar system bodies: the inner planets, the giant planets and their environments (satellites, rings, magnetospheres) and the small bodies, comets and asteroids.

The solar system is the only stellar environment which can be studied *in situ*. This unique status is unlikely to change until well into the next century (or millenium). However, with the recent discoveries of planetary companions around more than 30 stars, the solar system is now revealed as one of possibly billions of planetary systems in our galaxy alone. Its exploration can therefore be put in this more general context, so as to define what is generic and what is specific about our star and its companions. The characteristics of other planetary systems and the information from the new generation of missions to small bodies will much improve our understanding of the formation of planetary systems, one of the major goals of the quest for knowledge since the origins of science.

Physical constraints for the exploration of the solar system

The major breakthrough provided by space exploration for planetary science has been the capability to get very close to solar system bodies. Up to now, planetary missions have all relied on chemical propulsion systems derived from the missile technology developed in the years following the Second World War. The hot gases formed in the combustion chamber leave the rocket at a speed of 3–4.5 km s^{-1}. The highest velocities are obtained with liquid hydrogen and oxygen as reactants, a technology which requires cryogenic temperatures and very large systems such as the Shuttle (NASA) or Ariane 4 and 5 (ESA). The higher the velocity increment, the larger the proportion of the mass in fuel. As a rule of thumb, a single rocket stage can provide a velocity change similar to the ejection velocity. This is why three-stage rockets are needed to leave Earth, as its escape velocity is 11.2 km s^{-1}.

Even higher velocities are needed to reach directly solar system bodies. The optimum transfer is not possible all the time. These 'planetary windows' occur when the Earth and the planetary body return to the optimum relative position. After the body is reached, more fuel is needed to get into orbit, and even more to land, unless one can take advantage of the atmosphere (if any). The total velocity changes give a measure of the difficulty of the missions. These parameters are listed in table 1 for the different classes of planetary bodies, together with the repeat interval between mission opportunities, which is a major constraint for space programs. The values given

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

Table 1. Constraints on missions to various bodies.

	Launch velocity − escape velocity (km s^{-1})	Orbit insertion (3 day period) (km s^{-1})	Window repetition (yr)
Moon	−0.17	0.24	Daily
Venus	0.3	0.6	1.6
Mars	0.35	0.73	2.1
Mercury	3.5	4.5	1.0
Jupiter	3.0	1.7	1.1
Saturn	4.1	1.4	1.03
Asteroid (main belt)	1.3–1.7	3–5	1.25–1.5
Comet (short period)	3–3.3	0.9–1.5	5.5–6

do not take into account the inclination and eccentricity of actual orbits except for Mercury and comets, for which these parameters are so large that they severely constrain the transfer trajectories.

Table 1 clearly separates two classes of objects. The Moon, Mars and Venus are relatively easy targets, for which the launcher requirements are close to the escape threshold, and a single chemical stage is adequate even for an orbiter mission. Mercury, outer planets and small bodies require either a very large launcher or a more efficient mission scenario. A direct rendezvous with Mercury or a main belt asteroid is particularly difficult as it requires the largest on-board propulsion capabilities. A lander or entry probe mission is much easier if there is an atmosphere (Venus, Mars, giant planets, Titan), in which case it is less demanding than an orbiter mission. The return of a sample from a planetary body is the most demanding of all missions, requiring a launch capability from the object back to the Earth.

With chemical propulsion systems, the only solution for such ambitious missions is to trade mass against time using planetary swing-bys. Such 'gravity assists' can provide large velocity changes at little or no cost in fuel. The first mission of this type was MARINER 10, which used VENUS to perform three fly-bys of MERCURY in 1974. The strategies can be quite surprising: recent missions to the giant planets first visited Venus, which is closer to the Sun than the Earth. The drawback is the very long mission time: 8 yr of travel are required to rendezvous with Saturn or a comet with large spacecraft, which has an impact on mission costs and sets an interval of 15 years between the definition of instruments and the scientific results. The brilliant successes and promises of the gravity assist strategy will be described later. The limits of this approach are being reached, and new technologies such as ion propulsion must be developed for the future.

These dynamical constraints have defined to a large extent the sequence of missions to solar system bodies, from the easiest to the most difficult. Fortunately, this is also what is needed for a logical sequence of scientific investigations.

Experimental techniques

Once a spacecraft has succeeded in getting close to a planetary body, the range of possible scientific investigations is quite broad. They can be separated into two major categories: remote sensing techniques and *in situ* or laboratory techniques.

Remote sensing techniques take advantage of the whole electromagnetic spectrum to obtain information on a solar system body at distances of hundreds or thousands of km. High-energy photons such as gamma-rays and x-rays give information on individual nuclei and atoms, and hence the chemical composition. Electronic transitions dominate the UV region, with the best signatures of radicals and ions. The visible part of the spectrum provides the best spatial resolution, giving it a privileged role for photogeology and topography. At longer wavelengths, molecular vibrations and rotations dominate the infrared and submillimeter parts of the spectrum, and hence information on the molecular composition of atmospheres and the mineralogical composition of surfaces. Finally, the bulk physical characterisistics (porosity, conductivity and dielectric constant) are critical for radar observations which, together with laser echos, also provide accurate altimetric information. Radio techniques are extremely useful for characterizing the dynamics of the ionized environment, which can be studied *in situ* by particle detectors. Apart from photons, the gravitational and magnetic fields can also be measured, providing critical information on the internal structure and the state of the core.

Remote sensing techniques have been extensively used on space missions, from Earth orbit (Hubble Space Telescope, IUE, ISO) and from the ground at observable wavelengths. They can be considered relatively mature, as such experiments are now close to the limit in performance set by the statistical noise on collected photons over most of the electromagnetic spectrum. This was not the case even 10 yr ago for infrared detectors. Technological advances can still be expected in terms of mass and power budgets, but the photon noise links directly the size of the collecting optics to the science return, so that going too far down in size and mass does jeopardize the science.

In situ techniques require direct contact to the surface, the atmosphere or the ionized environment of the object to be studied. The whole range of Earth, atmosphere and plasma sciences can then be considered, but they have to be adapted to very stringent constraints in mass and power.

Among the most important techniques, one can quote seismology and electromagnetic sounding for the internal structure, gas chromatography and mass spectrometry of neutral species and ions for analyses of the surface, atmosphere and environment. These experiments are improving very rapidly in terms of capabilities, making possible within a few kg investigations which required quite large laboratory experiments in the early 1980s.

On the basis of these experimental capabilities and the constraints of table 1, it is possible to define a logical sequence of scientific missions for the exploration of a solar system body.

- *The discovery mission (or missions).* This first step is a fly-by mission which provides the first high-resolution remote sensing information on the body. It reveals its lot of unexpected features and helps to define the specific scientific goals of future missions. The Luna 3 image of the far side, in 1959, was the first to demonstrate the discovery potential of such missions (figure 1), as it revealed a hemisphere drastically different from the near side, with little or no dark flat regions (the mare). Other examples are the PIONEER and VOYAGER fly-bys of the systems of giant planets, from 1977 to 1989, which discovered the bewildering diversity of the satellites and ring structures, or the GIOTTO and VEGA fly-bys of comet P/Halley in 1986.
- *The in-depth exploration missions.* The second step is a series of orbiter missions which make possible a comprehensive mapping of the planetary bodies by a wide range of remote sensing techniques. These missions provide the first global view of the body and make possible the selection of areas of interest for *in situ* studies. VIKING orbiter, in 1976, around MARS, and GALILEO, which has orbited JUPITER since 1995, are good examples of such missions.
- *The in-situ studies missions.* This third step is provided by modules which land on the planet, providing information on its atmosphere, if any, during the descent. Such missions are required to obtain detailed and direct information on the internal structure and composition of the body. Only a few points can be characterized (eventually traverses with a rover or balloon). However, the *in situ* results provide 'ground truth' which calibrates the remote sensing techniques, hence improving our knowledge for all the regions of the body.
- *The sample return mission.* Because of the mass and power constraints, many critical investigations cannot be done *in situ*, even accounting for technological advances. The high-precision determination of isotopic abundances is particularly critical, as it provides the only absolute chronometers and information on solar system formation processes (isotopic anomalies). The return of samples to the laboratory is then required. The potential of such missions has been demonstrated by the wealth of data obtained from the lunar samples returned from 1969 to 1983.

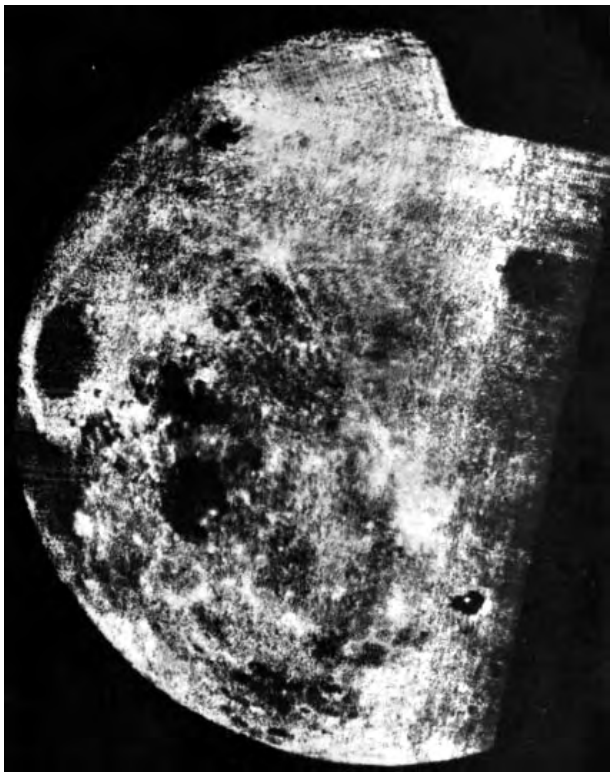

Figure 1. This image of the far side of the Moon obtained by Luna 3 is the first example of the discovery potential of space missions for solar system exploration. The far side, which can never be observed from the Earth, appeared completely dominated by the bright continents which constitute only 60% of the near side.

- *The field geology mission.* Given the enormous cost impact of a manned mission, such a step cannot be proposed on the basis of science alone. If a manned mission is decided for political or technological reasons (the Apollo program to the Moon, possibly a future lunar base or manned Mars mission), there are significant advantages in having a field geologist on site, such as improved procedures for the selection and documentation of samples.

In this sequence, each step is required as a stepping stone for the next. The comprehensive coverage defines the regions of interest for *in situ* studies, which in turn prepare the selection of sample return sites. This sequence also ranges from the easiest (fast fly-by of discovery missions) to the most demanding in terms of mission capabilities (orbiter, then landers, then sample return, then a huge gap to manned missions). It is therefore not surprising that it has been followed for most solar system objects, the exceptions resulting from political considerations or from a specific favorable condition such as the presence of an atmosphere, which greatly helps for landers or entry probes.

The inner planetary bodies

Apart from the Earth, there are four large inner planetary bodies: Mercury, Venus, Mars and the Moon. As we have seen, the Moon, Venus and Mars are the easiest to reach in the solar system, in particular the Moon which is only 400 000 km away. Therefore all planetary missions during the first 20 yr of the space era have been dedicated to inner planets.

The Moon is unique in the history of PLANETARY EXPLORATION. With its proximity and modest mission requirements, it was the obvious stepping stone to other planets. In 1963, J F Kennedy defined the landing of an American on the Moon before the end of the 1960s as a national goal, demonstrating the US leadership in rocket technology (and hence nuclear strike capabilities) as a response to the Soviet achievements in space (the first artificial satellite, in 1956, then the first man in space, Yuri Gagarin, in 1961). This greatly accelerated the sequence of missions: after the first fly-bys, in 1959, only 3 yr separated the first lander (Luna 9) and orbiter (Luna 10) from the first manned landing and sample return, Apollo 11, in July 1969. The sixth and last Apollo landing, in 1972, and then the last automated Soviet sample return, in 1976, marked the end of the first phase of lunar exploration. The 'lunar jeeps' implemented by the Apollo program and two soviet automatic rovers have traveled several tens of km on the lunar surface. 400 kg of rocks and soil samples have been brought back from nine sites, six from Apollo and three with Soviet robotic missions.

The wealth of science results from this hectic sequence of missions is impressive, and the Moon is indeed in many respects the best-known solar system body apart from the Earth. However, the 'race to the Moon' left much on the roadside. Indeed, the orbiter missions were mainly focused on the characterization of potential landing sites and the remote sensing techniques of the 1960s were much less sophisticated than what is now available. Only a few per cent of the surface were covered at a resolution of less than 10 m, and there were big gaps in information on the mineralogy, chemistry and internal structure (the Apollo seismometers were quite close to one another). The sample distribution is extremely biased, with very little continental material and no sites at high latitudes or on the far side. These gaps are now being filled by a new generation of lunar missions. Two small American missions, CLEMENTINE in 1994 and LUNAR PROSPECTOR in 1998, have much improved the global characterization of the surface, with altimetry, color imaging, chemical mapping, determination of the magnetic and gravity fields. Lunar Prospector has provided convincing evidence for significant ice crystal deposits in the very cold regions near the lunar poles. The next step is the Japanese mission LUNAR-A, in 2002, with two antipodal seismometers which should set strong constraints on the size of a possible lunar iron core. The Japanese have programmed for 2003 a major remote sensing and landing mission, SELENE, which will complete the global characterization phase for the Moon. These missions will help to define a new program of lunar sample returns. A manned lunar base is unlikely to be built until at least 2010.

Venus was a high-priority target during the early phases of planetary exploration. Its size and mass make it a near twin to our Earth, and hence it has a great interest for comparative planetology. As shown in table 1, it is an easy target for fly-by and orbiter missions, and the dense atmosphere (90 bar) can be used to deploy entry probes and balloons. Indeed, the first planetary fly-by, the American mission Mariner 2, was performed as early as 1962, and the first succesful *in situ* mission, the Soviet VENERA 4 descent probe, was in 1967. Venus has been the main target of the Soviet planetary exploration effort, with 15 successful missions from 1967 to 1984: entry probes, landers with cameras and chemical analyzers, and finally balloons deployed by the VEGA missions on the way to comet P/Halley. The two major American missions have been PIONEER VENUS in 1979 (an elliptical orbiter associated with a set of 4 entry probes) and MAGELLAN, in 1989, a radar mapping mission. The thick atmosphere is nearly opaque to all but the longest wavelengths, severely complicating the remote sensing characterization of the surface. The altimetric information of PIONEER VENUS revealed a surface radically different from that of the Earth, with smaller altitude variations. The radar images obtained in 1983 by Venera 13 and 14 of the northern hemisphere and then the global coverage of Magellan in 1989 (with a higher resolution of a few hundred meters) showed extensive signatures of a volcanic activity driven mainly by hot spots (similarly to Hawaii) and not by plate tectonics as on the Earth.

The major problem for the next steps in the exploration of Venus is the extremely high surface temperature (700 K) which has restricted the probe lifetime on the surface to less than 1 h. High-temperature technologies are required for the *in situ* phases, seismic stations and rovers, or the sample return. Until they become available, the exploration of Venus will be limited to the middle and upper regions of the atmosphere, such as the Venus multiple-probe mission which is now being considered by NASA.

The exploration of Mars is mainly driven by comparative planetology objectives. Mars is nearly twice as small as the Earth, but its surface and atmosphere processes are much more similar in many respects than in the case of Venus. In terms of mission requirements, Mars is equivalent to Venus. Missions to Mars are unfortunately unique in the history of planetary exploration for their failure rate. 20 spacecraft were launched to this planet from 1964 to 1996. None of the 11 Soviet missions and only six of the nine American missions were complete successes. The discovery phase, with the two first fly-bys of Mariner 6 and 7 in 1969, revealed a surface pockmarked with craters, so that Mars was then considered as a larger version of the Moon. This view was completely reversed by Mariner 9, in 1971, an orbiter which observed for the first time the northern hemisphere and revealed the

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

giant volcanoes and canyon systems which are now the trademark of the planet. This episode underlines the importance of global coverage before drawing conclusions on a given planetary body. The Moon, Mars and even the Earth, with its Pacific Ocean exhibit such a planetary dichotomy. The first major step for the global characterization phase has been the American mission Viking Orbiter, in 1976, which obtained a global coverage in the visible at medium resolution (100 m), very high resolution images and broad band spectrometry in the near and thermal infrared with a resolution of about 10 km. The Soviet mission PHOBOS 2, in 1989 (Phobos 1 failed one month after launch) was mainly dedicated to a very close rendezvous with Phobos, the largest satellite of Mars. It was lost during approach, but it obtained significant information on Mars during its two months in orbit, such as the first spectral images in the near infrared.

The recent failure of two ambitious global characterization missions had a major impact on Mars exploration. In 1992, the American Mars Observer mission was lost during orbit insertion. Its extensive set of instruments included a very-high-resolution camera, several spectrometers dedicated to the study of the surface and the atmosphere, a gamma-ray chemical mapper and a plasma package. The MARS GLOBAL SURVEYOR recovery program is based on small orbiters each carrying part of the spares of Mars Observer. The first orbiter was launched in 1996 and started close-range observations in the fall of 1998, after a long phase of progressive orbit reduction by the atmosphere of Mars. This recovery program will be completed in 2002. The Russian MARS 96 mission which failed during launch in November 1996 was arguably the most ambitious mission to Mars, with a 400 kg orbiter payload as well as four entry modules. There was a large international collaboration involving most European countries. A smaller mission, MARS EXPRESS, has been programmed by the European Space Agency for a launch in 2003. It will include five instruments derived from Mars 96 and tackle new scientific goals, such as the detection of subsurface ices with a radar.

The *in situ* phase was initiated by the Viking landers in 1976, which obtained panoramas of the surface, chemical analyses of the surface and atmosphere, climatological information on winds and seasonal cycles at two sites of the northern hemisphere. After a gap of 20 yr, an intensive phase of surface missions was initiated by NASA's MARS PATHFINDER, which deployed a small rover and obtained information on the chemical composition of soils and rocks. A landing mission is programmed by NASA for each Mars window, every 2 yr (see table 1). That launched in 1998 is targeted for the polar caps. A sample return is scheduled for a launch in 2005. Such an ambitious program requires a high level of international collaboration, with major contributions now being considered from Europe (among others, a French-provided Ariane 5 launcher and ESA's Mars Express as a relay satellite).

Mercury is a very difficult target. As the innermost planetary body, it is critical to our understanding of the planetary formation sequence in the solar system. The Mariner 10 mission, in 1974, imaged nearly half of the surface. The smooth plains and ubiquitous craters show many similarities and significant differences to lunar features. The other hemisphere is expected to be similar, although some caution is required (as shown by the example of Mars). Orbiter missions are now considered by ESA as part of its long-term program, NASA and Japan. Given its proximity to the Sun, Mercury is a very good target for a mission using solar energy to drive a plasma or ion engine.

The outer planets

The four outer planets, Jupiter, Saturn, Uranus and Neptune, have complex satellite and ring systems and extensive magnetospheres (with the possible exception of Uranus). The discovery phase has been accomplished by two pairs of missions: Pioneer 10 and 11, launched in 1973, and Voyager 1 and 2, launched in 1977. After encountering Jupiter, Pioneer 10 was set on a trajectory leaving the solar system, while Pioneer 11 was retargeted to SATURN, which it reached in 1979. The more capable Voyager spacecraft used the gravity assist strategy and a unique configuration of the giant planets (which repeats only every 200 yr) to visit all four outer planets from 1979 to 1989 (fly-by of NEPTUNE by Voyager 2).

The Pioneer missions obtained the first information on the interplanetary medium beyond the orbit of Mars. They also obtained high-quality images during the planetary encounters. These results have been superseded by the outstanding scientific results of Voyager, one of the most successful missions in the history of planetary exploration. Possibly the most remarkable discovery is the bewildering variety of the satellites of giant planets, from the lunar-like, frozen surface of icy CALLISTO to the tidally driven sulfur volcanism of IO, the innermost satellite of Jupiter, the billiard ball look of EUROPA, the tectonic processes on icy satellites of Saturn and URANUS and the thick nitrogen atmosphere of TITAN, the largest satellite of Saturn. One can also mention the fractal structure of Saturn's ring systems, the discovery of rings around Jupiter, the demonstration of the relationship of the great red spot of Jupiter to large-scale cyclonic and anticyclonic structures and the observation of similar features on Saturn and Neptune.

Two global characterization and *in situ* missions have been defined to address the wide range of scientific issues opened by Voyager for surface, atmosphere and plasma sciences: Galileo for Jupiter and CASSINI–Huygens for Saturn. The launch of Galileo, arguably the most complex spacecraft ever built, was delayed owing to Shuttle development delays and the Challenger disaster from 1983 to 1989. Galileo reached Jupiter late in 1995 and was injected in a highly elliptical orbit after releasing an entry probe in the atmosphere. Orbital changes using satellite swing-bys have been programmed to explore as

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

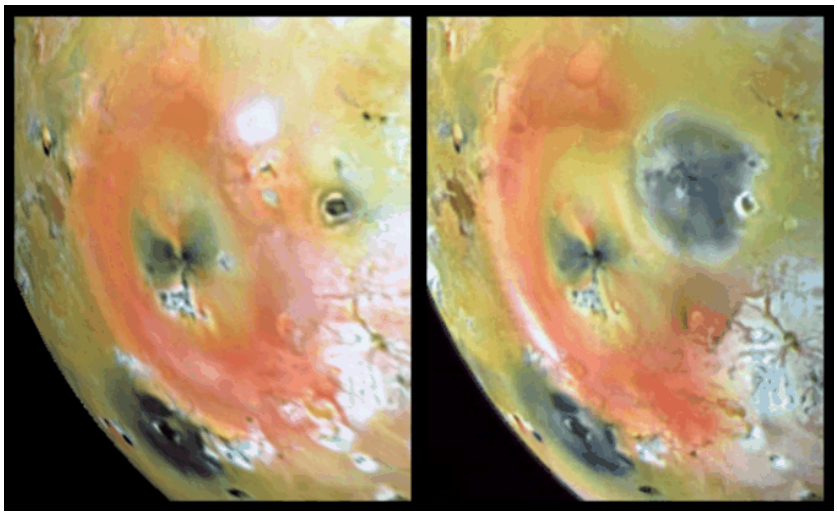

Figure 2. The surface of Io as observed by Galileo is extremely young. No impact craters are observed and sulfur volcanoes completely dominate the landscape. Major features have markedly evolved from Voyager (1981) to Galileo (1996).

much as possible of the Jovian environment. The failure of the main antenna to deploy resulted in a reduction of the available data rate from 100 kbits s^{-1} to a few 10 bits s^{-1}. In spite of this severe limitation, an outstanding science return has been obtained, such as the first profile of temperatures and chemical composition in the atmosphere of Jupiter, the first high-resolution images of the satellites (figure 2) and the discovery of an internal magnetic field for GANYMEDE, the largest of the four satellites discovered by Galileo. These successes have led to an extension by 3 yr of the mission until the end of 2000.

The next major step in the exploration of the giant planets is Cassini–Huygens, a collaborative mission between NASA, which has the responsibility for the orbiter, and ESA, which provides an entry probe in the atmosphere of Titan. This mission was successfully launched in 1996 and will reach Saturn in 2004 after swing-bys of Venus, the Earth and Jupiter. A orbital tour of four years will visit all the major satellites, explore the magnetosphere at various latitudes, characterize the ring systems and provide continuous coverage of the meteorology of Saturn. Titan, Saturn's largest satellite, constitutes a major target of the mission. The European entry probe will perform a descent of several hours in the dense nitrogen atmosphere, rich in hydrocarbons and aerosols, and is likely to reach the surface itself. Similarly to Venus, Titan's atmosphere is nearly opaque in the visible. Radar and near-infrared observations will map the surface during the 40 scheduled fly-bys of Titan.

The next steps will include small missions focused on specific scientific questions, such as the Europa orbiter mission dedicated to the characterization of a possible ocean buried under the smooth ice shell of Europa, which has been selected by NASA for a launch in 2004. Global characterization missions to Uranus or Neptune similar to Galileo and Cassini will eventually be programmed. Because of the very long travel times using classical propulsion (already 7 yr for Saturn), it is likely that such missions will require advances in technology, such as an ion drive powered by a nuclear reactor. The huge gravity well of giant planets precludes the implementation of sample return missions until well into the next century.

The small bodies of the solar system

The small bodies, COMETS and ASTEROIDS, are late comers on the scene of solar system exploration. The main science driver is to obtain information on the formation of the solar system, as these small bodies are the last survivors of the vast swarm of planetesimals which participated in the accretion of planetary bodies.

The first discovery missions were the five fly-by missions to comet P/Halley in 1986: two distant Japanese fly-bys dedicated to plasma measurements, the two Soviet VEGA spacecraft which came within 10 000 km of the nucleus and the kamikaze GIOTTO mission of ESA which approached the nucleus at a distance of 600 km. The nucleus as revealed by these missions (figure 3) was much darker and hotter than expected, showing that these objects are covered by a refractory mantle.

For main belt asteroids, the discovery phase was initiated by Galileo on its way to Jupiter, which observed two medium-size objects, GASPRA and IDA, in 1991 and 1993. The highlights of these fly-bys were the discovery of a satellite a few km in size around Ida and the observation of a magnetic field around Gaspra. These two main belt asteroids were rocky ('S' type). These results were complemented by the fly-by of Mathilde, a carbonaceous asteroid, by the American NEAR mission in 1997. The evolution of the surface of asteroids appears to be dominated by collision processes, the surfaces being saturated by craters at all scales.

Dirac House, Temple Back, Bristol, BS1 6BE, UK

Figure 3. The nucleus of Halley as imaged by the camera of the European mission GIOTTO. The very low albedo (3%) and small proportion of active areas were quite unexpected and led to the revision of the 'dirty ice ball' model of cometary nuclei in favor of a much higher proportion of refractory material.

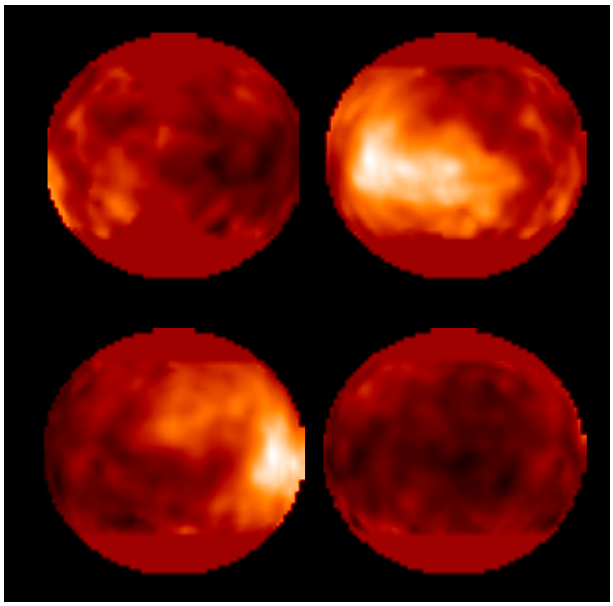

Figure 4. The surface of Titan as imaged by the Hubble Space Telescope in the near-infrared. The dark and light features reveal a significant surface differentiation. The relationship to topography and much higher resolution will become available with the Cassini–Huygens mission in 2004.

This discovery phase is far from complete. There is of course no chance of visiting each of the hundred of comets and thousands of asteroids. This comprehensive coverage is a key objective of Earth-based observations. However, the close-range observations of a few short-period comets and of the major missing types of asteroids (metallic and basaltic) would provide extremely useful information. Most missions to the outer solar system will include as many asteroid fly-bys as possible. Two cometary fly-by missions are programmed by NASA before 2008, STARDUST and CONTOUR.

The global characterization of asteroids has started with the first rendezvous with asteroid 433 EROS by the NEAR mission in early 2000. The major global characterization and *in situ* mission for comets is the ROSETTA mission of ESA, which will carry a comprehensive set of remote sensing instruments and two analyzers for dust and gas in the cometary environment. A lander provided by a collaboration of European countries will perform analyses of the physical and chemical characteristics of the cometary material and serve as a beacon for a radar sounding of the internal structure. This ambitious mission will be launched in 2003 for a rendezvous in 2011.

The ground-based discovery of a second belt of small bodies, the KUIPER BELT, beyond the orbit of Neptune, has significantly modified our view of the outer solar system. There are now only four outer planets, PLUTO AND CHARON, its companion, being considered by most planetary scientists as the largest members of this new family. A discovery mission to one or several Kuiper belt objects is now being considered by NASA, so as to obtain information on objects dynamically related to short-period comets.

The role of Earth-based observations

Earth-based observations have made major progress during the last 10 yr with the development of adaptive optics, which correct most of the atmospheric perturbations, the large ground-based interferometers (VLA, IRAM), the launch (and repair) of the HUBBLE SPACE TELESCOPE of NASA and the launch of the Infrared Space Observatory of ESA. Apart from direct imaging, much can be learned from occultations of stars about the environment of solar system bodies. Among the most important discoveries made with Earth-based observations, one can mention the rings of Uranus and Neptune, the Kuiper belt (already more than 30 objects larger than 200 km on orbits similar to that of Pluto), the detailed composition of the atmosphere of giant planets or the recent images of the surface of Titan obtained by Hubble in the near-infrared (figure 4). The discovery in 1995 of planets around other stars by ground-based telescopes sets the exploration of the solar system in the broader context of the characterization of stellar environments.

Three main objectives can be set for Earth-based observations: continuity, diversity and very-high-resolution spectrometry. They can fill the long gaps between space missions for observing variable phenomena, such as meteorology. For small bodies, Earth observations extend the

Dirac House, Temple Back, Bristol, BS1 6BE, UK

knowledge obtained from the few visited targets to hundreds of objects, providing statistical information and criteria for selecting the next targets of space missions. The highest spectral resolutions still require large instruments incompatible with spacecraft resources. The recent observations of solar system objects by ISO have demonstrated the interest of such methods, in particular for planetary atmospheres and comets.

The future of planetary exploration

All the major classes of solar system objects have been observed at close range, with the exception of Kuiper belt objects. Past, present and programmed missions should go a long way to complete the global characterization phase: SELENE for the Moon, the MGS series and Mars Express for Mars, Galileo for the system of Jupiter, Cassini–Huyghens for the system of Saturn, ROSETTA for short-period comets and then a Mercury orbiter mission. After the turn of the century, the emphasis will progressively shift to *in situ* and sample return missions. After 30 yr of very large programs, it is however likely that much will be done by smaller missions (the 'faster, better, cheaper' approach first implemented by NASA with its Discovery program) with a limited set of instruments. This new type of mission has been made possible by the technological developments triggered by the Strategic Defense Initiative (miniaturization of subsystems) and the growing industrial capabilities worldwide for building cheap spacecraft. The short development and implementation time (4–5 yr) provides more flexibility, increases the frequency of missions within a given budget and gives a chance for the latest instrumental developments to be used. The reduction of travel times is a major constraint for such missions. It requires the development of high-capability propulsion systems, such as the ion and plasma drives, with ejection speeds 10 times higher than those of classical rockets. Small test missions of this type have been approved by NASA, by Japan and by ESA, so that this technology should be fully demonstrated by 2005. A balance will eventually be reached, as the ambitious science objectives of the *in situ* and sample return phase cannot all be reached with such missions, which are also more risky as demonstrated by a series of minor and major problems. There will still be a need for large-scale international missions such as that building up for a Mars sample return before 2010.

The discovery of other planetary systems (EXOPLANETS) will eventually link solar system exploration to interferometric missions able to image other planetary systems. Indeed, once this is achieved, it is likely that exploration missions to the closest stars with planetary systems will be considered.

Solar System: Formation

Cosmogony tells us about the origin and evolution of our SOLAR SYSTEM in general, and of the planets in particular. Planet formation seems to be a by-product of star birth. Current models have indicated the births of stars observed now occur in almost the same conditions as the formation of the Sun and its planets 4.55 billion years ago.

Recent observations of what we interpret as PROTOPLANETARY NEBULAS (the first has been seen around β Pictoris, see figure 1), together with the detection—although indirectly—of planets orbiting other stars (more than 20 already known; see EXOPLANETS) confirm our current ideas. Very young stars have been observed by the Hubble Space Telescope, the new VLT (the European Very Large Telescope) and space infrared telescopes (like ISO). Some young stars seem to be naked while others are dressed by disks of gas and dust which probably live for only a few million years; this is the most interesting period for us here, because we think that our own planetary system formed from such a disk.

The study of meteorites, of lunar rocks (brought back by the Apollo astronauts and Soviet automatic machines) and of interplanetary dust (analysed by space probes which have encountered comets, e.g. Giotto when it visited the nucleus of Comet Halley in March 1986) has allowed us to give a precise value for the age of the solar system and to better understand the processes which lead to formation of planets from an interstellar cloud. Among the difficulties of modelling such a process a particular problem is how to separate fundamental general mechanisms from fortuitous local ones; comparison with other planetary systems would be very useful. This is a very rapidly developing field of study.

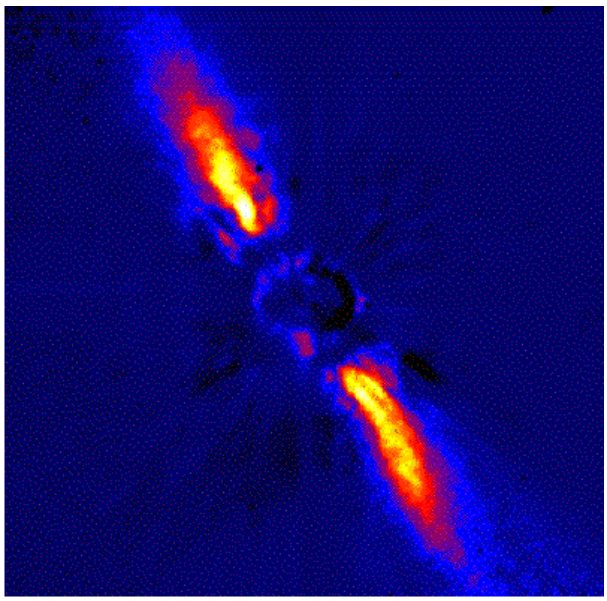

Figure 1. The beta Pictoris protoplanetary disk. Image taken with the 3.6 m ESO telescope using the adaptative optics system Adonis by David Mouillet (Observatoire de Grenoble) and colleagues; high resolution allows us to observe the disk at less than 25 AU from the star, and to distinguish the warping of the disk which could be induced by gravitational perturbations of a massive planet on an inclined orbit. (See http://www.iap.fr/LaboEtActivites/ThemesRecherche/BetaPic/images) **This figure is reproduced as Color Plate 58.**

The solar nebula

General ideas about the formation of the solar system arose in the seventeenth century, when Copernicus' heliocentric model became credible after Galileo's observations and Kepler's laws of planetary motion; the origin of this planetary system then became a subject of scientific research. One of the firsts models was proposed by René Descartes in 1644: primordial matter, rotating globally as a fluid, shows vortices; most of the matter may then accumulate in the center of a large central vortex and there the Sun forms; at the other vortices planets form and, due to the global rotation, they orbit the Sun. Although this explanation is obsolete, it contains a fundamental element which will be found in almost all subsequent models: the formation of the planets is linked to the formation of the Sun.

In the following century, Emmanuel Kant, in his *Natural Philosophy* (1755), proposed an explanation of the origin of the solar system by condensations in a flat rotating cloud, i.e. a disk of gas and dust rotating around the center where the Sun was forming; condensations in the disk gave birth to the planets. Although some basic elements, such as the condensation mechanism, were then still unexplained, the concept of a rotating disk, what we call the *solar nebula*, is the basis of modern theories. A little later, Pierre Simon de Laplace, in his *Exposition du Système du Monde* (1796), proposed a mechanism to explain this structure where a few large planets rotate in almost circular orbits largely separated from each other: contraction of the disk increases the rotation velocity so that the centrifugal force separates matter into several concentric rings, from which planets may then form.

But this model did not explain convincingly why matter should separate into a vast amount which contracts (the Sun) and a minor quantity in which contraction is stopped, or why the latter separates into rotating rings (the planets) instead of staying as a disk with continuously varying density. In particular the Sun should rotate considerably faster than it does, because its current rotation rate is much too slow for centrifugal force to counterbalance gravity. These (temporary) failures prevented the solar nebula hypothesis from receiving serious consideration for more than a century.

There have been attempts to explain planetary formation independently from that of the Sun; the most well known is the catastrophe thesis, where a comet—following Buffon—(or, more impressively, another star—following Jeans) passed very near the Sun (already formed) and pulled out some of the solar matter which

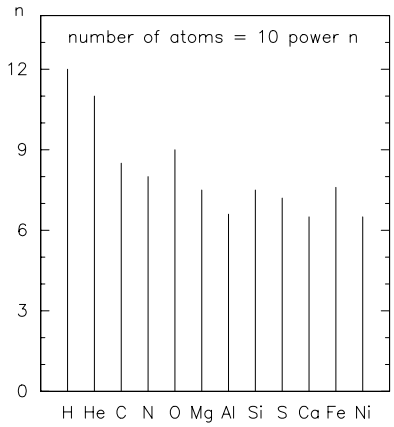

Figure 2. Cosmic abundances of the elements.

they orbited the Sun and finally formed the planets. These ideas have now been abandoned.

The nebula hypothesis, indirect descendant of the Cartesian theory, came back into favour at the end of the first half of the twentieth century, and eventually came to be the 'standard model'. Theories have been constructed to describe how gravitation could bring about the collapse of an interstellar cloud; in particular a fundamental criterion has been defined with regard to the limiting mass necessary to trigger gravitational instability, called the *Jeans' mass*. Astronomers now think that formation of the solar system began with the collapse of such an interstellar cloud, a very dense, very cold cloud where molecules might form—an INTERSTELLAR MOLECULAR CLOUD. The collapse was followed by the fast structuring of a rotating disk and the fall of the remaining matter of the cloud down this ACCRETION DISK, at the heart of which the Sun was forming.

Some properties of the nebula

Chemical elements can be placed in the well-known Periodic Table, where their position depends upon the number of protons in the atom's nucleus. The increase in this number, from the light elements (essentially hydrogen (H) and helium (He)), produced soon after the 'Big Bang', to heavier elements made through nuclear reactions in the center of stars and then ejected into the interstellar medium, is reflected in the so-called COSMIC ABUNDANCES which, at least in the vicinity of the Sun, do not vary much through space, particularly for the INTERSTELLAR MATTER (gas and grains) which will give birth to the next generation of stars.

Hydrogen and helium are very much more abundant than the other elements (figure 2); moreover, they are still gaseous down to temperatures very near 0 K (0 K = $-273.16\,^{\circ}$C, 'absolute zero'), which implies that almost 98% of the solar nebula remain gaseous even at very low temperatures. The behavior of the other elements is different; they are often assembled into molecules which can condense at much higher temperatures, up to tens or even a hundred kelvin; these molecules are called ices and their constitutive elements are essentially hydrogen, carbon (C), nitrogen (N) and oxygen (O), the latter three being the most abundant (almost 2%) apart from H and He; for example, CO (carbon monoxide), although very volatile, condenses at around 25 to 30 K, and H_2O (water) condenses at more than 110 K; it could be deduced that ices may be very frequent in all sufficiently cold parts of the nebula, i.e. the outer regions. All other elements (less than 0.3%) react above all with oxygen to form oxides; an important process is formation of silicon dioxide (SiO_2, silica) with which other elements (such as magnesium (Mg), sulphur (S), iron (Fe), aluminum (Al) or nickel (Ni)) react to form silicates. These molecules condense at high temperatures, up to 1000 degrees, and are called refractories (which are therefore essentially silicates and metals), and which therefore could exist as solids even in the innermost parts of the nebula.

Let us compare the planetary compositions with the nebula. Telluric planets are essentially refractories: a more or less large metallic nucleus covered with a thick mantle of silicates, the amount of ices and volatiles being almost negligible. Therefore, the Earth could form in the solar nebula only if an Earth's mass of refractories was available. However, refractories contribute only 0.3% to the nebula's mass (i.e. around 1/300); then we need 300 Earth's masses (M_E) of the nebula to form the Earth; the same estimates can be done for Mercury ($15M_E$), Venus ($300M_E$), Mars ($30M_E$) and the asteroids ($0.15M_E$). Jovian planets are different and contain essentially hydrogen and helium, with a small proportion of ices and refractories (probably more in the case of Uranus and Neptune than for Jupiter and Saturn), which is not far from nebula abundances; this implies that the nebula mass in the region of formation of the Jovian planets can be estimated respectively as $1000M_E$ (Jupiter) and $500M_E$ for Saturn, Uranus and Neptune. When we add all these values, we obtain around $3000M_E$, which is 1% of the mass of the Sun. Even if the nebula did not end steeply at Neptune's orbit, taking into account the nebula mass corresponding to the KUIPER BELT would not significantly increase this value. Such a nebula mass of even several per cent of the solar mass is a model of a light NEBULA; there also exists a model where this mass can increase up to several tenths of a solar mass and even one solar mass; this is a massive nebula. Until now, observations have not allowed us to clearly decide between the two models, but here we will discuss the light nebula model.

Observations of nebulae around other stars

To our eyes, regions of star birth are very dark: they are interstellar clouds of high density (high compared with the common interstellar medium) where dust and grains are sufficiently numerous to hide the stars which lie behind.

Fortunately, radio telescopes allow us to observe inside these clouds and, particularly, to verify that these dark clouds are very rich in molecules. The most easily observed is CO, but the most abundant is dihydrogen,

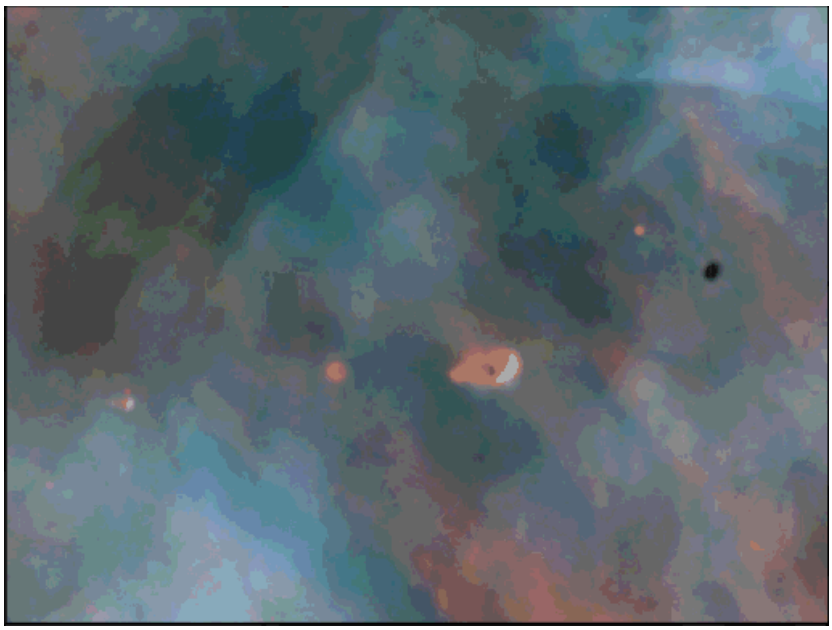

Figure 3. Proplyds in Orion. A Hubble Space Telescope view of a small portion of the Orion Nebula star-birth region; several very young stars are surrounded by gas and dust which are possibly protoplanetary disks, or 'proplyds', that might evolve on to agglomerate planets; the field of view is only 0.14 light-years across; image taken on 29 December 1993 with the HST's Wide Field and Planetary Camera 2. H_2. The measured temperatures are very low, down to 10 K. This extreme cold has two origins: first, the infrared radiation emitted by the molecules escapes easily out of the clouds, an efficient mechanism for exhaust of heat; second, dust prevents star light and heat from penetrating. We observe that gas is concentrated in a disk rotating around a central mass, an indication in favor of Kant- and Laplace-like models. Moreover, the rotation of the disk obeys Kepler's laws, so that we can estimate the value of this central mass. In the internal regions, which have almost the dimension of our planetary system, this value barely exceeds one solar mass; this looks good for the light nebula hypothesis, nevertheless it is possible that the actual disk extends beyond the visible part.

In the beginning the molecular clouds were very dark and cold. At a certain time, the gravitational instability was triggered so that a central source of energy 'switches on', surrounded by dark dust which, when warmed, emits infrared radiation.

Later, the newborn star and its disk become progressively clear of the cloud, allowing visible light emitted by the star to travel very large distances, to the Earth for example. The Hubble Space Telescope, as well as the first unit of the VLT, due to their very high angular resolution, have observed such disks, for example in the great molecular cloud in Orion where numerous structures have been identified as accretion disks (named *proplyds*, for 'proto-planetary disks'; see figure 3), although classical observations showed only simple stars, known for a long time as T TAURI STARS from the variable star of this name in Taurus. The luminosity of this class of stars varies because of their very turbulent environment, and they are often identified through spectral lines characteristic of the surrounding gas.

During this early stage of a star's life, the star itself ejects large quantities of gas in every direction. This stellar wind progressively blows the disk away, and we observe a class of T Tauri stars which have no disk: we call them 'naked' T Tauri. A chronology has been established; emerging from the cloud to the blowing away of the disk (i.e. the lifetime of the solar nebula) occupies a time interval of only some million years—a mean estimation is around 5 million. This corresponds to only one-thousandth of the age of our solar system, and this is during this very small fraction of time that the formation of the planets occurs.

From dust to planetesimals

The composition of the solar nebula was almost 99% gas (hydrogen, helium and volatiles) and 1% solid grains; these latter are very tiny, of the order of 0.1 μm, but they are the most interesting objects from the point of view of the history of solid matter in the solar system.

These grains already had a long history; born in the atmospheres of giant red stars by condensation of the chemical species (depending on the conditions of temperature and pressure), they progressively acquired a three-layer structure (figure 4): a nucleus of refractories (silicates and metals), a mantle of carbonaceous materials,

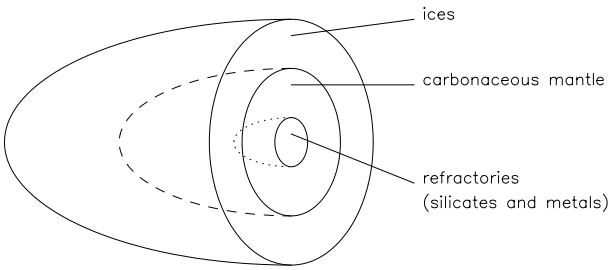

Figure 4. Model of an interstellar grain.

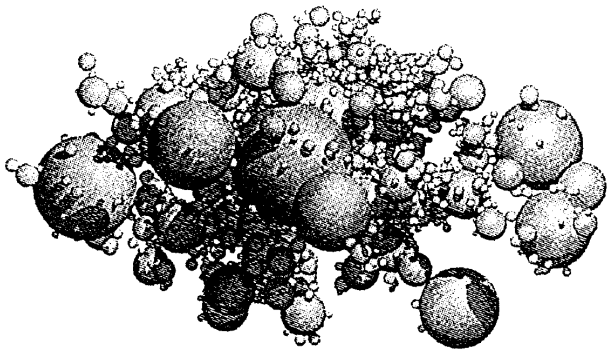

Figure 5. Numerical simulation of an aggregate (from Blum *et al* 1994).

which can also be considered as refractories but condensing at lower temperatures (around 500 to 400 K), and which have suffered physico-chemical transformations due to irradiation by cosmic rays, for example; and finally this mantle is covered by ices. The main ice species is amorphous H_2O, a form different from the crystals we know on Earth and which exists only at very low temperatures; several other molecules can be found—like CO, carbon dioxide (CO_2), methane (CH_4), ammonia (NH_3) and so on—in proportions which depend on the place where ices form because the ability of H_2O ice to incorporate them varies with temperature.

The hydrogen and helium molecules of the cloud move randomly and collide with each other due to Brownian motion. Grains, although very tiny, are real giants in comparison with these simple molecules; they are nevertheless slightly knocked and then gain some thermal velocity. These grains therefore encounter each other from time to time and, as we assume that their surface is somewhat sticky, aggregate into larger structures. Because the mass of these aggregates is of course heavier than the masses of individual grains, their thermal velocity decreases when they grow; when their size increases to several μm the influence of shocks becomes negligible and the process stops.

At least it would stop if there was not the turbulence of the gas, because the solar nebula in which grains and aggregates exist and grow is a very turbulent medium. Micrometer-sized particles are indeed sufficiently small to stay strongly coupled with the motion of the gas in which they live, and are pulled by vortices of the turbulence. Then, when two vortices encounter each other, pulled particles can come into contact and, as long as the relative velocity is sufficiently low, form larger and larger aggregates. Nevertheless, such growing aggregates uncouple progressively from the motions of the gas, because more and more powerful vortices are necessary to move them. Their width may then attain several centimeters. Figure 5 presents an example of such a particle, which can be described as a kind of porous fluffy aggregate, and is therefore of low density. Note that the porosity of the flakes may decrease during collisions when the relative velocity becomes sufficiently high to induce an increase in compactness and density; moreover, the velocity may attain a critical value where particles begin to break instead of sticking together. At this point, turbulent aggregation is no longer efficient.

Fortunately, another mechanism takes over. Centimeter sized particles, once decoupled from the turbulence of the gas, fall down to the equatorial plane of the nebula, and their velocities follow Kepler's laws. But gas moves more slowly because the effect of gravity is partially compensated by its internal pressure, which increases toward the interior. Therefore the flakes have to move against a kind of contrary wind, thus they lose energy and velocity, and their motion becomes a slow spiral toward the center. This spiral motion is the last step where the biggest flakes catch and 'eat' the others. The resulting size of the particles is estimated to be around several tens of meters.

These 'super-grains' form a very flat disk. It has been shown that such a disk is not stable if its constituent particles do not have sufficiently high relative velocities: otherwise, it fragments into condensates which orbit around the center. However, this is precisely what we need, at least in the light nebula model proposed by the Russian physicist V S Safronov and, later, the Americans P Goldreich and W R Ward. This is called a gravitational instability, which results in a new disk composed of the 'lumps' formed during the condensation: each lump has an approximate size of 5 to 10 km; these are the PLANETESIMALS, really the bricks for building the planets.

As has been said, the scenario of the formation of the planetesimals is linked to the light nebula hypothesis and the corresponding relatively thin disk. The massive nebula model gives a different evolution: there is neither flat dust disk nor gravitational instability of this disk, instead it is probably the entire nebula (not only its dust) which becomes unstable and fragments into large condensations of gas and dust from which planets form. But observations seem more and more to indicate that the four giant planets could have a rock-ice core and that these central masses each have about the same quantity of refractories (around one-tenth of Earth mass). This would be relatively easy to explain with the planetesimals, i.e. in the light nebula hypothesis, but much more difficult with the great condensates of the massive nebula model.

This is one of the arguments which convinces a majority of astronomers of the validity of the planetesimal scenario; and this is the scenario which is considered here. But how can we date its different steps?

The age of the chondrites and isotopic anomalies

When searching for the time-scale of the origin of the solar system, it would be useful to have small bodies whose composition and internal structure have not been modified by geological processes, such as occur inside the main planets by differentiation of minerals. On Earth, the most ancient rocks are 3.8 billion years old (sedimentary rocks, Isua, Greenland), and the most ancient minerals (zircons, 4.2 to 4.3 billion years) are the only remnants of continents from this epoch; but both had already lost the memory of the organization of primitive matter from which our planet formed. Some of the lunar rocks brought back from the Apollo missions date from 4.4 billion years, but they are transformed too. We hope that samples from comets and asteroids will be at our disposal relatively soon; fortunately every day Earth receives extraterrestrial matter in the form of meteorites, among which CHONDRITES are the most frequent (almost 85%) and the most primitive and therefore the most interesting for us here. Chemical and isotopic analysis of chondrites has led to two conclusions: (a) their age is almost 4.6 billion years, given with a good precision; (b) their composition is almost the same as in the cosmic abundances and then in the solar nebula, at least for refractories (because they contain few ices and very little gas; nevertheless, variations of elementary ratios among chondrites are very much less compared with the other types of meteorites, whose minerals come from differentiated parent bodies).

Sometimes, chondrites have very refractory inclusions, in which we can find particularly calcium (Ca) and aluminum, and even the most refractory solids (for example Al_2O_3). Mineralogical analysis of chondrites reveals the presence of unstable isotopes, some of which have a very long half-life, for example, rubidium-87 which decomposes into strontium-87 with a half-life of 49 billion years. This allows to measure the ages of very ancient minerals—in fact, this is the 'solidification age', i.e. the time elapsed since the agglomeration of the minerals. By this method, and other analogous ones (like lead–lead), ages of refractory inclusions in the Allende meteorite (which fell at Pueblito de Allende, in Mexico, in 1968) have been measured: these ages are the greatest ever found in the solar system, and these inclusions indeed represent the first bodies which formed at the beginning of our history; the age of the solar system is then 4.560 billion years. On the contrary, the ages of chondrites without refractory inclusions is around 4.555 billion years, that is 5 million years after the formation of the refractory inclusions. But 5 million years is precisely the lifetime of the solar nebula we have discussed previously: the inclusions would therefore have formed during the initial process of the fall of the cloud downward into the nebula, while the chondrites themselves formed at the end of the life of the nebula.

Finally, carbonaceous chondrites (one of the three most important groups of chondrites, the composition of which seems the nearest to the solar one) comprise minerals which survived even the thermal processes inside the nebula; this brings us back to the interstellar grains wandering through the Galaxy before the birth of our solar system. This is the case of microscopic grains of silicon carbide and diamond which have been studied only recently using new techniques: although quantification is not yet possible, it is hoped that the abundances of the different isotopes will allow us to ascertain their great age.

ISOTOPIC ANOMALIES can give us other important information. Let us consider for example the three stable isotopes of oxygen: ^{16}O, ^{17}O and ^{18}O; ^{16}O is the most abundant one on Earth and, more generally, in the universe; however, ^{17}O and ^{18}O ratios with ^{16}O vary enormously from place to place in the Galaxy, because isotopes come from nuclear reactions inside stars and each star produces its own isotopic ratios depending on its mass and history. Let us take as reference the isotopic ratios in water of the Earth's oceans: a plot of $^{17}O/^{16}O$ versus $^{18}O/^{16}O$ shows clearly that all terrestrial matter lies on a line of slope 1/2 (because in the Earth's gravitational field, any fractionation of the ^{17}O and ^{18}O isotopes with respect to ^{16}O is proportional to the difference of their masses, that is $^{17}O/^{16}O = 1/2\ ^{18}O/^{16}O$), called the *fractional line*, and the global composition of the Earth plus the Moon—as for ordinary chondrites and Martian SNC meteorites—is not much different (figure 6). Besides, the refractory inclusions of the carbonaceous chondrites have a clearly different behavior: they lie along a line of slope 1, which implies the presence of a pure ^{16}O component in these inclusions. There were therefore several oxygen reservoirs in the nebula, coming from several pre-solar sources; among which one, maybe a supernova, had furnished almost pure ^{16}O. But what should have been oxygen's fate if all the matter of the nebula were entirely gaseous (i.e. have been sufficiently hot everywhere) at a given time? In this case, all isotopes would have been mixed into a 'hot soup', and we could not now distinguish between the initial reservoirs. An important conclusion can then be made: the refractory minerals of carbonaceous chondrites never did evaporate, and so kept the memory of their pre-solar history in the interstellar grains.

The carbon isotopes ^{12}C and ^{13}C tell the same story; in comets, it is even clearer.

The final step to planets

The basis of the scenario is that any planetary mineral passed through the planetesimal stage during the formation process of the Sun and the solar system in the solar nebula. It is highly probable that the planetesimals had primary compositions varying with distance from the center. In the internal regions, where the terrestrial planets formed, planetesimals consisted mainly of rocks and metals but, farther, where we now find the giant Jovian planets, they were 'icy', i.e. they contained much ice and volatiles.

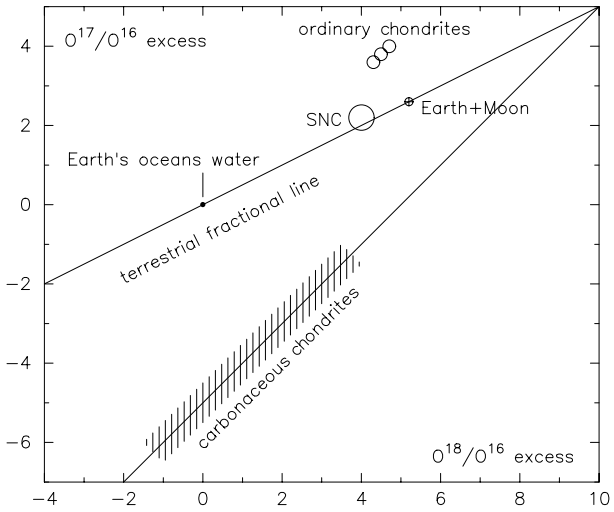

Figure 6. Isotopic anomalies for oxygen in Earth's materials and in meteorites.

The sizes of the planetesimals are estimated to be of the order of some tens of kilometres, their masses were therefore of the order of 10^{15} kg (a thousand billion tons). To build the Earth with such bricks, we would need about 10^{10} of them, i.e. ten billion. Here is the disk of planetesimals: several tens of billions of bodies only in the region of the terrestrial planets, orbiting the proto-Sun nearly circularly almost in the same plane. In each region, they move on almost concentric orbits with almost the same velocity but, given their enormous number, collisions frequently occur and, when they collide, they encounter each other with a slow relative velocity, of the order of some meters per second. During such low-velocity collisions, a kind of 'gluing' occured and therefore formation of greater and greater aggregates. This is how a population of aggregates of different sizes was progressively established, where the size distribution is simply the result of a game of probabilities: the greater the aggregate, the smaller the probability of forming it in a given time. But an important process will perturb this simple game, when the gravity of the aggregates becomes sufficiently high to attract other aggregates and planetesimals: an aggregate which initially has the luck to become large increases its efficiency to attract others; then the more it grows, more its gravity increases, and the more it grows, and so on ....

We have here an unstable process, which led to runaway ACCRETION, where the largest body in a given part of the disk enlarges at the expense of the others and so forms embryonic planets. When they attain the size of the Moon or of Mercury (i.e. around 1/4 to 1/2 of the Earth), they have exhausted the building blocks in their immediate neighborhood and their growth stops. This seems to have been the case in the region of the terrestrial planets, but how many Moons or Mercuries do we need to form these latter? Probably around a hundred. Then, after the runaway stage, which lasted maybe several million years, a *sparse stage* follows where a hundred planetary embryos revolve around the proto-Sun on orbits much more widely spaced than the orbits of the previous planetesimals. In this scenario, Jupiter has grown faster and accreted much of the gas of the nebula, so that its gravity perturbs the orbits of these embryonic terrestrial planets which then will cross each other; we are then in the final stage of the formation of the terrestrial planets where giant impacts occur between bodies width sizes of hundreds to thousands of kilometres. These impacts may be hard indeed, and we can see their scars on the surface of many bodies, for example on the Moon and Mercury (the impact craters on Earth and on other planets with an atmosphere have been mostly eroded away); moreover, such an impact can completely destroy an embryonic planet or, at least, fragment it into two bodies and so give birth to a 'binary planet' as, for example, Earth and the Moon (see the entry on the MOON for more details about its origin).

We know that the total mass in the asteroid belt is very much less than the masses contained in the other planetary regions, i.e. the region of the terrestrial planets as well as the region of the Jovian planets; the Kuiper Belt shows the same lack of mass. It does not seem likely that the density of the solar nebula should have decreased so much either in the asteroid zone or just beyond Neptune; so we may suppose that matter in these regions was blown away during stages after the formation of the planetesimals (asteroids and Kuiper Belt objects are probably 'fossils' of the early formation of the solar system). And indeed a mechanism still operates nowadays; for example, the resonances which cross the asteroid belt (mean motion resonances between asteroidal orbits and the orbit of Jupiter, as well as the so-called 'secular resonances' between some orbital elements of asteroids and the two largest Jovian planets) are like traps where any body inside is blown away in a relatively short time because of the planetary perturbations. The result is that the asteroidal orbits become very eccentric and so cross the orbits of the terrestrial planets (or even fall into the Sun), which may lead to catastrophic collisions with these latter and explains—at least in part—the lack of mass in the asteroidal region. In the Kuiper Belt, too, many objects have probably been ejected by planetary perturbations since the beginning of the solar system.

But stars are not all alone ...

Up to now we have considered only, although implicitly, processes occurring around the Sun, which is a single star. Our star, although accompanied by several bodies like planets or comets, is indeed alone, because its nearest neighboring star, Proxima Centauri, is more than 4 light-years away, i.e. almost 8000 times farther than Neptune. But more than half of all stars are not alone: they exist mainly in pairs, the 'binary stars', and even sometimes in threes ... or more. Two questions then arise: can

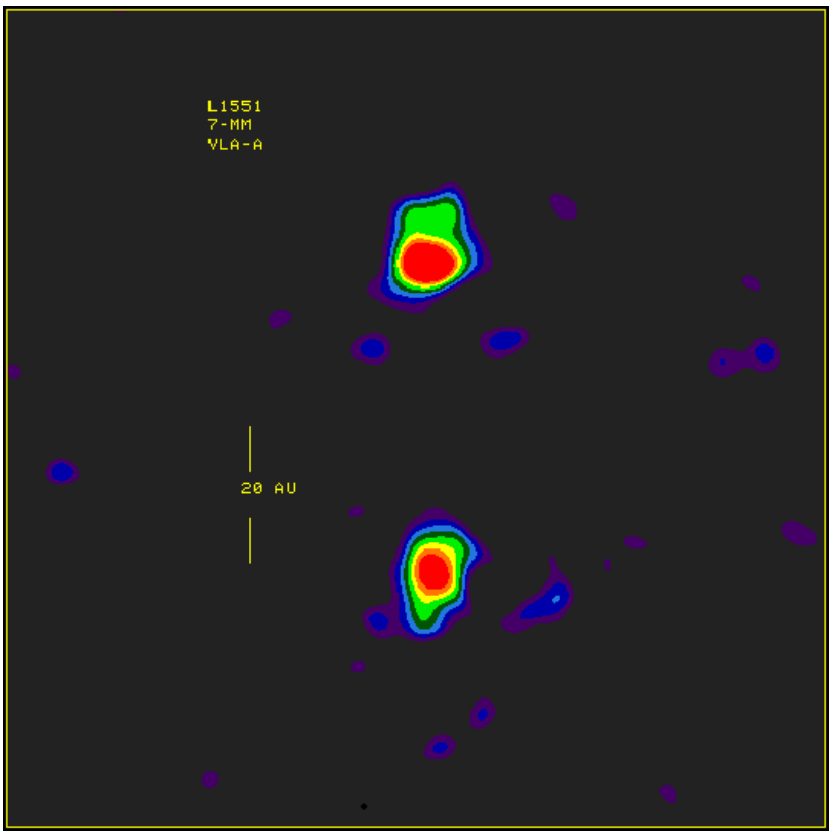

Figure 7. Protoplanetary disks around each component of a young double star in a molecular cloud designated L1551, in the constellation Taurus. VLA image: the colors represent relative intensity, or brightness, of the radio emission coming from these disks, red is strong emission and blue is weak emission; the scale bar corresponds to a distance of 20 AU; for comparison, in our own solar system, the planet Uranus is about 19 AU from the Sun. (Credit: L.F. Rodriguez *et al* National Radio Astronomical Observatory.) **This figure is reproduced as Color Plate 60.**

planets form in such environments and, if yes, do long-term stable orbits exist for such planets? Recently, more and more theoretical studies seem to show that the answers to these questions may be positive. Moreover, recent observations of what we may interpret as protoplanetary disks in binary systems (see for example figure 7), as well as several examples among the indirectly detected exo-planets being in double systems (e.g. around 16 Cyg B or Gl 86 A, detected by the radial velocity method, and the gravitational microlensing event MACHO-97-BLG-41), are very encouraging.

Some open problems

Since late 1995 the discovery, although indirect, of dozens of giant gaseous planets (the first around 51 Pegasi, discovered by Michel Mayor and Didier Queloz from Geneva Observatory in Switzerland with the 1.93 m telescope of Saint-Michel de Haute-Provence Observatory in South France) very near their 'sun' (i.e. very much nearer than Mercury's orbit), such a position for the formation of such a Jovian planet previously being ruled out by the theoreticians, led to the idea that these planets actually formed at large distance then migrated to their present place through interactions with either the solar nebula (not yet evaporated) or the disk of planetesimals. Even our own solar system, which seemed so perfectly constructed (let us recall Bode's 'law' ...) that the actual positions of the planetary orbits correspond to the location of their birth, may too have been affected by this kind of mechanism. For example, some new theoretical models describing the distribution of the Kuiper Belt objects imply that the structure of the Kuiper Belt give clues about the history of the Jovian planets and, particularly, indicates that the latter's orbits would had progressively changed after their formation, e.g. Neptune moved outwards by several AU over some tens of millions of years, Uranus and Saturn moved outwards too but by a smaller amplitude, while Jupiter moved inwards only a little. Nevertheless, note that there exist rival explanations about the distribution of the Kuiper Belt objects.

Moreover, we may have an example of another planetary system, around the star υ And (upsilon Andromedae), studied by Paul Butler and co-workers, where three Jovian planets (of masses respectively, at least,

0.7, 2 and 4 Jupiter masses) orbit their star at respectively 0.06, 0.8 and 2.5 AU; but here theoretical models of distant formation followed by migration have great difficulties in explaining the actual structure of this planetary system.

As a conclusion, astronomers need much more time before they can confirm a theory which presents a convincing explanation of all details of the formation and the evolution of planetary systems in general and of our solar system in particular.

Solar System: Nomenclature

This article describes the various schemes used for assigning names to solar-system objects with visible surfaces, other than the Earth, and their surface features. The schemes are known collectively as planetary nomenclature.

Planets and satellites

The outer planets that were discovered in modern times were named after principal figures from Roman mythology, following the tradition for the planets known in antiquity (though the first two letters of 'Pluto' also commemorate Percival Lowell, whose calculations led to its discovery). Planetary satellites, discovered from the seventeenth century onwards, were given names of figures from mythology and literature associated with that of the parent planet, a practice which has been adhered to for the many minor satellites discovered in the late twentieth century. For example, the Galilean satellites of Jupiter were named by Simon Mayr (or Marius) after four paramours of the god Jupiter; names of other female figures in the Jupiter myth have been assigned to the smaller satellites. Likewise, most of the minor satellites of Uranus are named after characters from William Shakespeare's plays, the precedent having been set when John Herschel gave names to the planet's four largest satellites in the nineteenth century.

Satellites are also given numerical designations. For example, the first two outer satellites of Uranus to be discovered were temporarily referred to as S1997 U1 and S1997 U2, indicating that they were respectively the first and second new Uranian satellites to be detected in 1997. Once their orbits were confirmed they received the permanent designations Uranus XVI and Uranus XVII, labeling them as the sixteenth and seventeenth of all the planet's satellites to be discovered.

Comets

Comets are identified by name and number. In the great majority of cases a comet's name commemorates its discoverer(s). The numbering system, similar to that used for asteroids, specifies the year and month in which a comet was discovered. In addition, a prefix identifies the comet as of short or long period, and short-period comets are given permanent numbers, in order of their discovery.

The practice of naming comets dates from the eighteenth century, after Edmond Halley demonstrated in 1705 that the comets of 1531, 1607 and 1682 were one and the same object, which became known as Halley's Comet. Similarly, in 1819 Johann Encke showed that four apparitions between 1786 and 1818 were of the same comet, now known as Encke's Comet. ('Comet Halley', 'Comet Encke', and so on, are preferred in more formal usage.) Other comets were named after their discoverers. Some comets bear two or even three names. Comet Grigg–Skjellerup, for example, was found by John Grigg in 1902, and by Frank Skjellerup at a later apparition in 1922. On the night of 23 July 1995, Alan Hale and Thomas Bopp independently discovered the comet subsequently named after them. Comet IRAS–Iraki–Alcock was discovered independently by Genichi Iraki and George Alcock, and also detected by the IRAS satellite, in 1983. Since 1995 such triple-barreled names have not been admitted. Different discoveries by the same individual(s) are distinguished by the addition of an arabic numeral: Comet Shoemaker–Levy 9, for example, was the ninth discovery by the team of Carolyn and Eugene Shoemaker and David Levy.

Numerical designations for comets were introduced by the editors of the *Astronomische Nachrichten* (AN) in 1846. In the original scheme, comets were assigned roman numbers according to the order of their perihelion passages in a particular year; in 1870 the AN editors introduced subsidiary designations in which comets were assigned a lower-case roman letter reflecting the order of discovery announcements in a particular year. Both schemes had their problems: some perihelion times turned out to be inconsistent with the numbers assigned; comets received a new designation with each apparition; some comets mistakenly had more than one letter applied to them.

Despite these problems, the systems persisted until the 1990s. In 1994 the International Astronomical Union announced (in *Minor Planet Circulars* numbers 23803 and 23804) new designations, to take effect from 1 January 1995. A comet's designation consists of the year of its discovery, a letter for the half-month in which it was discovered, and an arabic numeral indicating its order of discovery in that half-month. So A is January 1–15, B is January 16–31, C is February 1–15, D is February 16–28/29, and so on (I and Z are not used). Prefixes are assigned as follows: 'P/' for a short-period comet, 'C/' for a long-period comet, 'D/' for defunct comets (such as Shoemaker–Levy 9), 'X/' for comets for which orbits cannot be computed (or whose existence is doubtful) and 'A/' for any comet that might turn out to be an asteroid. Once the orbit of a short-period comet is well established, it receives an arabic number indicating its order of discovery; the first in this sequence is 1P/Halley.

One example will illustrate the old and new systems. Comet Pons–Brooks, with a period of 70 years, was discovered by Jean-Louis Pons in 1812, before numerical designations were introduced. When it was rediscovered in 1883 by William Brooks, it received the designations 1884 I (the first comet to perihelion in 1884) and 1883b (the second comet discovery announced in 1883). On its return in 1954, it was given the additional designations 1954 VII and 1953c. Under the new system the three corresponding designations are 1812 O1, 1883 R1, and 1953 M1; the first of these indicates that the comet was first seen in the second half of July 1812. The comet has the prefix 12P/, putting it twelfth in the sequence of established short-period comets. It is therefore referred to as '12P/Pons–Brooks'; if one wanted to specify its most recent apparition, 'Comet 1953 M1' would be the form to use. Correspondences between all the old- and new-style designations are give in Marsden and Williams (1999). See also METEOR SHOWER.

Asteroids

Like comets, asteroids are identified by name and number. The system of provisional and permanent numerical designations is similar to that used for comets (see above). Unlike comets, asteroids are given names chosen by their discoverers. The sheer number of asteroids discovered in recent times has seen a steady increase in the number of categories from which asteroid names are chosen. Names of people (from all walks of life, famous or otherwise), mythological figures and geographical names are the main sources.

When the first asteroids were discovered in the early 1800s, nomenclature was not an issue. As 'minor planets' they were simply named for classical figures, following the established practice for the major planets. In 1850 the naming of the twelfth asteroid as Victoria in honor of the reigning British monarch (though also the name of the Roman goddess of victory) sparked a controversy that persisted for decades. At the end of the century the classical rule was relaxed, and any female name was deemed acceptable. This rule too was stretched, feminine endings '-a' or '-ia' being added to geographical names, giving for example 'Washingtonia'. After the Second World War the female rule too was relaxed.

Naming of asteroids is now under the control of the IAU's Minor Planet Names Committee. The present rules actually proscribe very little. Names must be pronounceable, of sixteen letters or fewer, and should not commemorate military or political figures who died less than a hundred years previously. Other than that, discoverers have free rein; they must, however, justify the significance of the name they choose. The largest category is personal names. As well as astronomers (e.g. Hubble) and other scientists (e.g. Turing) there are composers and musicians, both ancient and modern (e.g. Mozartia, Zappafrank); other names commemorate relatives, mostly wives and children, of discoverers. Geographical names include Dresden and Hanoi, and the fictitious Neverland (from *Peter Pan*). Observatories (e.g. Goethe Link), and telescopes (e.g. Spacewatch) are also represented. Some choices are unusual or even whimsical. Swissair is named for the discoverer's favorite airline. The name Tooting, a district of London, was inspired by the asteroid's provisional designation, 1992 SW_{17} (SW17 being Tooting's postal code).

There are special rules for two groups of asteroids. The Trojan asteroids, which orbit at the L_4 and L_5 Lagrangian points of Jupiter's orbit, take their names from figures from the Trojan War legend, such as Achilles (in the L_4 group) and Patroclus (in the L_5 group). The Centaurs, which orbit in the outer solar system, are given appropriate names: the largest two are Chiron and Pholus.

The numbering of asteroids was begun by Benjamin Valz, who named the asteroid Massalia in 1852, and added the number 20, written in a circle, to indicate that it was the twentieth to be discovered. This system of permanent numbering is still used today, but with the number in parentheses rather than a circle. Thus the first asteroid to be discovered is designated (1) Ceres; the ten-thousandth is (10000) Myriostos. In the nineteenth century, the editors of the AN assumed responsibility for numbering, assigning asteroids a number on the announcement of their discovery. Confusion over the order of discovery arose as the pace of discovery quickened. Also, as some 'discoveries' failed to be confirmed, 'spare' numbers began to accumulate.

A solution was proposed in 1892 by Adalbert Krüger, then editor of the AN: henceforth new discoveries would first be assigned a provisional designation consisting of the year of discovery plus a capital letter to indicate the order of the discovery in that year. Once the orbit had been satisfactorily established, the editors of the *Berliner Astronomisches Jahrbuch* would assign a permanent number. Krüger's system, which was soon expanded to accommodate increasing numbers of discoveries each year, forms the basis of the system currently used by the IAU's Minor Planet Center. A provisional designation consists of the year of discovery plus two capital letters and, as is usually necessary, a number. The first letter indicates the half-month of discovery, in the same way as for comets (see above). The second letter indicates the order of discovery within that half-month. The letter I is not used here, allowing for 25 discoveries per half-month. For the 26th discovery in a given half-month the second letter returns to A, but with '1' appended. For discoveries 51 to 75, a '2' is appended, and so on. Where typography allows, it is recommended that these numbers be written as subscripts.

Thus, for example, the sequence of discoveries in the first 15 days of January 2000 are assigned provisional designations in the following order: 2000 AA, 2000 AB, ..., 2000 AZ, 2000 AA_1, 2000 AB_1, ..., 2000 AZ_1, 2000 AA_2, and so on. The asteroid with the provisional designation 1992 SW_{17} mentioned above—now with the permanent designation (8380) Tooting—was the 542nd to be discovered in the second half of September 1992.

Surface features

In the seventeenth century the first selenographers (makers of Moon maps) all devised their own schemes for naming lunar features, and the same thing happened in the nineteenth century when observers first mapped Mars. In the twentieth century the IAU assumed the task of standardizing planetary nomenclature, which became all the more important with the mapping of increasing numbers of planets and their satellites by space probes from the 1960s onwards. Assigned names are binomial, consisting of a generic term describing the type of feature, plus a specific name. Terrestrial placenames, names of famous people, and names from the world's mythologies and literature are the main sources of specific names. For each body, appropriate themes are chosen for each category of surface feature. See also MOON MAPS.

With the advent of the telescope, selenographers began to chart the surface features of the Moon. They assumed that the surface they saw was Earthlike, and

that the dark areas were water, to which they gave Latin names representing among other things terrestrial weather and states of mind, for example Mare Serenitatis (the Sea of Serenity) and Lacus Timoris (the Lake of Fear). Craters were named after prominent people, a practice begun by Michael Van Langren with his map of 1645; in 1651 Giovanni Riccioli set the precedent for naming them after ancient and modern astronomers and scientists, such as Plato and Copernicus. A consistent nomenclature for the most prominent features, based on Riccioli's scheme, emerged during the nineteenth century, but for the smaller features there was no consensus and selenographers frequently assigned names of their own choosing.

A similar situation had arisen with Mars. A combination of improved telescopes and favorable oppositions allowed the first good maps to be prepared in the late nineteenth century. Several astronomers had mapped the planet's elusive features, each applying their own nomenclature. The system that would eventually prevail was that adopted by Giovanni Schiaparelli on his map of 1877, for which he used names derived from classical literature and the Bible.

The chaotic state of lunar and Martian nomenclature was a concern of the IAU from the time of its foundation in 1919. Building on preliminary work by Mary Blagg, the first IAU planetary nomenclature committee tackled the problem of lunar nomenclature. The result was *Named Lunar Formations* (1935) by Blagg and Karl Müller, the first systematic nomenclature for the Moon. This work was greatly expanded in the 1960s with the publication of *The System of Lunar Quadrants* (in four parts) by D W G Arthur *et al*. In 1958 the nomenclature for Mars was put on a firm basis when an IAU committee under Audouin Dollfus adopted a standard list of albedo features (areas appearing light or dark) based on Eugène Antoniadi's expansion of the system introduced by Schiaparelli.

With the dawn of the space age came the realization that a systematic approach to planetary nomenclature was necessary. In the 1960s, *ad hoc* committees dealt with naming the host of new lunar features imaged by the Zond, Lunar Orbiter and Apollo missions, and also with the Martian features photographed by the Mariner probes. In 1973 the IAU set up the Working Group for Planetary System Nomenclature (WGPSN), which continues to be the body with responsibility for assigning new names. It operates through six task groups, covering the Moon, Mercury, Venus, Mars, asteroids and comets, and the outer solar system.

When a body is first imaged, a few prominent features are assigned names based on an appropriate theme. Initially names are suggested by, for example, project scientists, but thereafter anyone can propose a name to the appropriate task group. When the IAU was faced with the task of naming several hundred newly mapped features of Venus, for example, members of the public were invited to submit names of women whose achievements they felt deserving of honor. The task groups are guided by various rules and conventions. Nearly all names are binomial in form: one part is a 'descriptor' (see table 1), a generic term derived from Latin or Greek that characterizes the type of feature—thus continuing the scheme used by the early selenographers; the other, which is the specific name, goes before the descriptor in some cases, after it in others. Exceptions, which bear only a specific name, are craters, albedo features (on Mercury and Mars), volcanic eruptions and plumes (on Io and Triton), and some large ringed structures (e.g. Valhalla on Callisto). Other rules prohibit the use of names of political or military leaders, and encourage the task groups to draw on a broad selection of the world's cultures.

For each body, the appropriate IAU task group is left to develop interesting and appropriate conventions for naming surface features. Some examples will suffice.

Craters on Mercury are named after celebrated figures in the arts. Examples are Beethoven, Chekhov, Ōkyo (Japanese painter), and Vyāsa (Indian poet). Planitiae take their names from words for 'Mercury' in different languages, for example Budh Planitia (Hindu) and Tir Planitia (Norwegian). The names of rupēs are those of famous ships of discovery: Discovery Rupes, for example, commemorates James Cook's flagship on his last Pacific voyage. Radio telescopes, with which important discoveries about the planet have been made, lend their names to valles; an example is Arecibo Vallis.

For Mars the lunar practice of naming craters after scientists is followed, and many large craters bear the names of those who have contributed to the study of the planet, such as Lowell, and writers who have used Mars as a setting for their fiction, such as Verne. After the Moon, Mars has more charted craters than any other body, and to avoid duplication of lunar names, smaller craters are named after towns and villages with fewer than 100 000 inhabitants. Valles are given the names for 'Mars' or 'star' in various languages if they are large (e.g. Bahram Vallis, Persian) or terrestrial rivers if they are small (e.g. Mad Vallis, in Vermont). An exception is the huge canyon system Valles Marineris, which takes the name of the Mariner probes which returned the first close-up images of the planet. The names of albedo features charted by Schiaparelli are not lost: they are transferred to nearby or coincident topological features. Thus, for example, the light-colored albedo feature Hellas becomes the impact basin Hellas Planitia.

Satellites also have their own appropriate themes for nomenclature. In the Uranian system, for example, surface features take their themes from the satellites' names: on Oberon, from tragic Shakespearean heroes (e.g. the crater Romeo); on Titania, from female Shakespearean characters (e.g. the crater Elinor); on Umbriel, from malevolent spirits (e.g. the crater Gob, king of the gnomes); on Ariel, from benevolent spirits (e.g. Pixie Chasma); and on Miranda, from characters and settings from Shakespearean drama (e.g. Verona Rupes).

Asteroids too have themes assigned to them. Gaspra, the first to be imaged from close hand, by the Galileo probe,

Table 1. Descriptors for planetary nomenclature used by WGPSN. A blank in the descriptor column indicates that only the plural form is in use, and a blank in the plural column that only the singular form is used.

Descriptor	Plural	Meaning	Description	Example
Catena	Catenae	Chain	Chain of craters	Kraken Catena (Triton)
Cavus	Cavi	Hole	Hollow, irregular depression	Sisyphi Cavi (Mars)
Chaos	—	Chaos	Distinctive area of broken terrain	Arsinoes Chaos (Mars)
Chasma	Chasmata	Chasm	Deep, elongated, steep-sided depression	Avalon Chasma (Mimas)
—	Colles	Hills	Small hills or knobs	Scandia Colles (Mars)
Corona	Coronae	Circle	Ovoid-shaped feature	Heng-o Corona (Venus)
Dorsum	Dorsa	Back	Ridge	Kepler Dorsum (Phobos)
Facula	Faculae	Little torch	Bright spot	Lyctos Facula (Amalthea)
Farrum	Farra	Farro (variety of grain)	Pancake-like structure, or a row of such structures	Seoritsu Farra (Venus)
Flexus	Flexūs	Bend	Very low curvilinear ridge with a scalloped pattern	Sidon Flexus (Europa)
Fluctus	Fluctūs	Flow	Flow terrain	Tung Yo Fluctus (Io)
Fossa	Fossae	Ditch	Long, narrow, shallow depression	Nike Fossae (Venus)
Labes	Labēs	Blemish	Landslide	Ius Labes (Mars)
Labyrinthus	—	Maze	Complex network of intersecting valleys	Noctis Labyrinthus (Mars)
Lacus	Lacūs	Lake	Small plain on the Moon	Lacus Oblivionis
Lenticula	Lenticulae	Lentil	Small dark spot on Europa	(not yet used)
Linea	Lineae	Thread	Dark or bright elongate marking, may be curved or straight	Telephassa Linea (Europa)
Macula	Maculae	Spot	Dark spot, may be irregular	Akapura Maculae (Triton)
Mare	Maria	Sea	Large circular plain	Mare Ingenii
Mensa	Mensae	Table	Flat-topped prominence with cliff-like edges	Nepenthes Mensae (Mars)
Mons	Montes	Mountain	Mountain	Maat Mons (Venus)
Oceanus	—	Ocean	Very large dark area on the Moon	One instance only: Oceanus Procellarum
Palus	Palūs	Swamp	Small plain on the Moon	Palus Putredinis
Patera	Paterae	Shallow dish	Irregular crater, or a complex one with scalloped edges	Shakuru Patera (Io)
Planitia	Planitiae	Plain	Low plain	Sipapu Planitia (Triton)
Planum	Plana	Plain	Plateau or high plain	Planum Angustum (Mars)
Promontorium	Promontoria	Cape	Headland on the Moon	
Regio	Regiones	Region	Large area marked by reflectivity or color distinctions from adjacent areas	Nicholson Regio (Ganymede)
Reticulum	Reticula	Net	Reticular (net-like) pattern on Venus	(not yet used)
Rima	Rimae	Crack	Fissure on the Moon	Rima Hyginus
Rupes	Rupēs	Cliff	Scarp	Pourquoi-Pas Rupes (Mercury)
Scopulus	Scopuli	Crag	Lobate or irregular scarp	Xanthe Scopulus (Mars)
Sinus	Sinūs	Bay	Small plain	Sinus Iridum
Sulcus	Sulci	Furrow	Subparallel grooves and ridges	Samarkand Sulci (Enceladus)
Terra	Terrae	Land	Extensive land mass	Lada Terra (Venus)
Tessera	Tesserae	Mosaic tile	Tile-like, polygonal terrain	Kutue Tessera (Venus)
Tholus	Tholi	Cupola	Small domed mountain or hill	Apis Tholus (Io)
—	Undae	Waves	Dunes	Al-Uzza Undae (Venus)
Vallis	Valles	Valley	Valley	Niger Vallis (Mars)
Vastitas	Vastitates	Wasteland	Extensive plain	Vastitas Borealis (Mars)

Solar System: Stability

The question of the stability of the SOLAR SYSTEM was raised with the discovery of Newton's law of gravitation, published in 1687. Since then, for 300 yr mathematicians and astronomers have searched for evidence for the stability of the planetary motions, and this quest led to many mathematical developments, and several successive 'proofs' of stability for the solar system: first by Laplace and Lagrange, in the 18th century, then Poisson and more recently by the Russian mathematician V I Arnold in 1963. With Poincaré (1898), one can be surprised by this succession of proofs. 'Were the old demonstrations insufficient, or the new ones unnecessary?' In fact, all this evidence of stability was based on approximations, and it was shown recently, using numerical simulations, that the motion of the solar system is chaotic: although over 10 million years the motion of the planets can be forecast with great accuracy, there is no hope of extending these predictions beyond about 100 million years owing to the exponential divergence of the orbits.

Historical introduction

The problem of the stability of the solar system has fascinated astronomers and mathematicians since Antiquity, when it was observed that, among the seemingly fixed stars, there were also 'wandering stars'—the planets. Efforts were first focused on finding a regularity in the motion of these wanderers, so their movement among the fixed stars could be predicted. For Hipparchus and Ptolemy, the ideal model was a combination of uniform circular motions, the epicycles, which were continually adjusted over the centuries to conform to the observed course of the planets. Astronomy had become predictive, even if its models were in continual need of adjustment.

From 1609 to 1618, Kepler fixed the planets' trajectories: having assimilated the lessons of Copernicus, he placed the Sun at the center of the universe and, based on the observations of Tycho Brahe, showed that the planets described ellipses around the Sun. At the end of a revolution, each planet found itself back where it started and so retraced the same ellipse. Although seductive in its simplicity, this vision of a perfectly stable solar system in which all orbits were periodic would not remain unchallenged for long.

In 1687 Newton announced the law of universal gravitation. By restricting this law to the interactions of planets with the Sun alone, one obtains Kepler's phenomenology. However, Newton's law applies to all interactions: Jupiter is attracted by the Sun, as is Saturn, but Jupiter and Saturn also attract each other. There is no reason to assume that the planets' orbits are fixed invariant ellipses, and Kepler's beautiful regularity is destroyed.

In Newton's view, the perturbations among the planets were strong enough to destroy the stability of the solar system, and divine intervention was required from time to time to restore planets' orbits to their place. Moreover, Newton's law did not yet enjoy its present status, and astronomers wondered whether it was truly enough to account for the observed movements of bodies in the solar system.

The problem of solar system stability was a real one, since, after Kepler, Halley was able to show, by analyzing the Chaldean observations transmitted by Ptolemy, that Saturn was moving away from the Sun while Jupiter was moving closer. By crudely extrapolating these observations, one finds that 6 million years ago Jupiter and Saturn were at the same distance from the Sun. In the 18th century, Laplace took up one of these observations, which he dated 1 March 228 BC: at 4:23 am, mean Paris time, Saturn was observed 'two fingers' under Gamma in Virgo. Starting from contemporary observations, Laplace hoped to calculate backward in time using Newton's equations to arrive to this 2000 yr old observation.

The variations of planetary orbits were such that, in order to predict the planets' positions in the sky, de LALANDE was required to introduce artificial 'secular' terms in his ephemeris tables. Could these terms be accounted for by Newton's law?

Laplace–Lagrange stability of the solar system

The problem remained open until the end of the 18th century, when Lagrange and Laplace correctly formulated the equations of motion. Lagrange started from the fact that the motion of a planet remains close, over a short duration, to a Keplerian ellipse, and so had the notion to use this ellipse as the basis for a coordinate system (figure 1). Lagrange then wrote the differential equations that govern the variations in this elliptic motion under the effect of perturbations from other planets, thus inaugurating the methods of classical CELESTIAL MECHANICS. Laplace and Lagrange, whose work converged on this point, calculated secular variations, in other words long-term variations in the planets' semi-major axes under the effects of perturbations by the other planets. Their calculations showed that, up to first order in the masses of the planets, these variations vanish (Poisson and Poincaré later showed that this result remains true through second order in the masses of the planets, but not through third order).

This result seemed to contradict Ptolemy's observations from Antiquity but, by examining the periodic perturbations between Jupiter and Saturn, Laplace discovered a quasi-resonant term $(2\lambda_{\text{Jupiter}} - 5\lambda_{\text{Saturn}})$ in their longitudes. This term has an amplitude of 46′50″ in Saturn's longitude, and a period of about 900 yr. This explains why observations taken in 228 BC and then in 1590 and 1650 could give the impression of a secular term.

Laplace then calculated many other periodic terms, and established a theory of motion for Jupiter and Saturn in very good agreement with 18th century observations. Above all, using the same theory, he was able to account for Ptolemy's observations to within 1 minute of arc, without additional terms in his calculations. He thus showed that Newton's law was in itself sufficient to

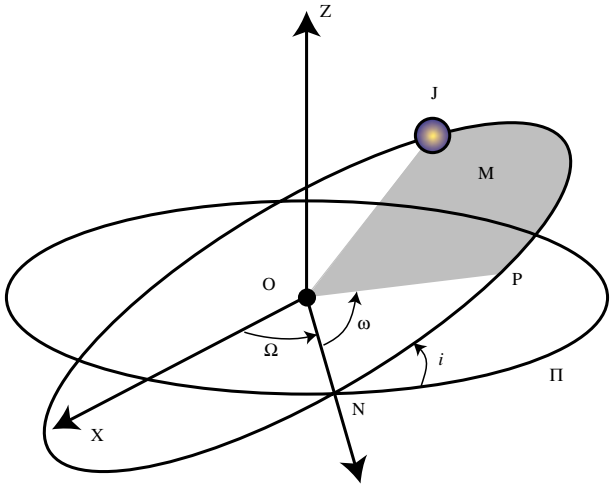

Figure 1. Elliptical elements. At any given time, a planet (J) can be considered to move on an elliptical orbit, with semimajor axis a and eccentricity e, with the Sun at one focus (O). The orientation of this ellipse with respect to a fixed plane Π, and a direction of reference OX, is given by three angles: the inclination i, the longitude of the node Ω, the longitude of perihelion $\varpi = \Omega + \omega$, where ω is the argument of perihelion (P). The position of the planet on this ellipse is given by the mean longitude $\lambda = M + \varpi$, where M (mean anomaly) is an angle which is proportional to the area OPJ (Kepler's third law).

explain the movement of the planets throughout known history, and this exploit no doubt partly accounted for Laplace's determinism.

This result, where Laplace and Lagrange demonstrated that the planets' semimajor axes undergo only small oscillations and do not have secular terms, was the first major result of stability for the solar system. At the same time, Laplace firmly established Newton's law as the universal explanation for the motion of the celestial bodies.

The problem of the eccentricities

The stability of the semimajor axes of the planets is not sufficient to ensure the stability of the solar system. Indeed, if the eccentricity of the Earth becomes larger than 0.1 and the eccentricity of Mars becomes larger than 0.3, then collisions between these two planets can occur. The problem of the stability of the eccentricities and inclination of the planets was addressed by Laplace and Lagrange in an additional set of papers.

Taking into account only terms of first order in the perturbation series, they showed that the system of equations describing the mean motions of eccentricities and inclinations may be reduced to a system of linear differential equations with constant coefficients depending on the planetary masses and semimajor axes:

$$\frac{\mathrm{d}}{\mathrm{d}t}\begin{bmatrix} z_1 \\ \vdots \\ z_k \\ \zeta_1 \\ \vdots \\ \zeta_k \end{bmatrix} = \sqrt{-1}\begin{bmatrix} A_k & 0_k \\ 0_k & B_k \end{bmatrix}\begin{bmatrix} z_1 \\ \vdots \\ z_k \\ \zeta_1 \\ \vdots \\ \zeta_k \end{bmatrix}$$

where for each planet j, $z_j = e_j \exp\sqrt{-1}\varpi_j$, $\zeta_j = \sin(i_j/2)\exp\sqrt{-1}\Omega_j$, A_k and B_k are (k,k) matrices with real coefficients depending on the values of the planetary masses and semimajor axes. 0_k is the (k,k) zero matrix and $(a_j, e_j, i_j, \lambda_j, \varpi_j, \Omega_j)$ are classical elliptical elements (figure 1).

Using the conservation of ANGULAR MOMENTUM, Laplace demonstrated that, provided that all the planets rotate around the Sun in the same direction, polynomial or exponential solutions cannot exist for this system. He concluded that the eigenvalues g_i, s_i of A_k and B_k are real and that the solutions for this differential system are quasiperiodic expressions of the form

$$z_j = \sum_{i=1}^{k} \alpha_{ij}\, \mathrm{e}^{\mathrm{i}g_i t} \qquad \zeta_j = \sum_{i=1}^{k} \beta_{ij}\, \mathrm{e}^{\mathrm{i}s_i t}$$

where α_{ij} and β_{ij} are complex quantities. The frequencies g_i, s_i are called the secular frequencies of the solar system, and their values, as computed with a more complete model (Laskar 1990), are given in table 1 (see also figure 2).

Table 1. Fundamental frequencies of the precession motion of the solar system (excluding Pluto). These values are taken as the mean values over 20 million years from the recent solution La90. For the inner planets, because of chaotic diffusion, the frequencies can change significantly with time (Laskar 1990).

	ν ($''$ yr^{-1})	Period (yr)
g_1	5.596	231 000
g_2	7.456	174 000
g_3	17.365	74 600
g_4	17.916	72 300
g_5	4.249	305 000
g_6	28.221	45 900
g_7	3.089	419 000
g_8	0.667	1 940 000
s_1	−5.618	230 000
s_2	−7.080	183 000
s_3	−18.851	68 700
s_4	−17.748	73 000
s_5	0.000	
s_6	−26.330	49 200
s_7	−3.005	431 000
s_8	−0.692	1 870 000

The inclinations and eccentricities of the orbits are therefore subject to only small variations about their mean values. However, it must be stressed that Laplace's solutions are very different from Kepler's, because the

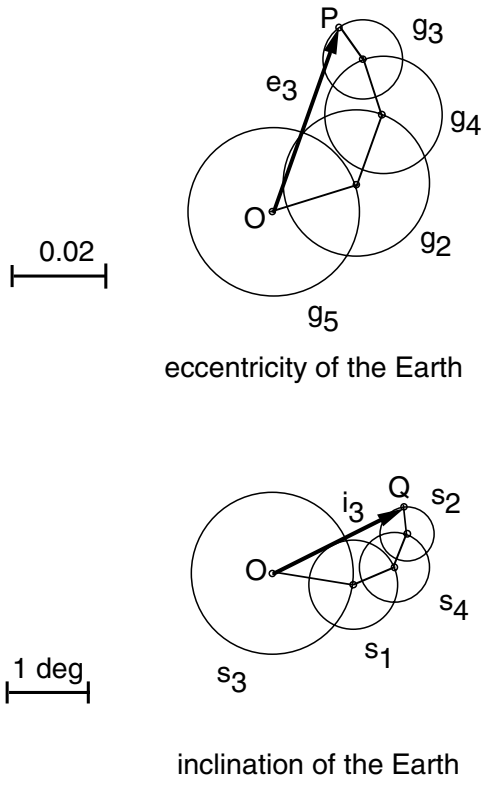

Figure 2. The solutions of Laplace–Lagrange for the motion of the planets are combinations of circular and uniform motions with the precession frequencies g_i and s_i of the solar system (table 1). The eccentricity e_3 of the Earth is given by OP, while the inclination (i_3) of the Earth with respect to the invariant plane of the solar system is OQ (Laskar 1992).

orbits are no longer fixed. They are subject to a double precessional motion with periods ranging from 45 000 to several million years: precession of the perihelion, which is the slow rotation of the orbit in its plane, and precession of the nodes, which is the rotation of the plane of the orbit in space.

Later, Leverrier, famed for his discovery in 1846 of the planet Neptune through calculations based on observations of irregularities in the movement of Uranus, took up Laplace and Lagrange's calculations and considered the effects of higher-order terms in the series (Leverrier 1856). He showed that these terms produced significant corrections and that Laplace's and Lagrange's calculations 'could not be used for an indefinite length of time'. He then challenged future mathematicians to find exact solutions, without approximations. The difficulty posed by 'small divisors' showed that the convergence of the series depended on initial conditions, and the proof of the stability of the solar system remained an open problem (see Laskar 1992 for more details on this point).

Between 1892 and 1899, Poincaré formulated a negative response to Leverrier's question. In so doing he rethought the methods of celestial mechanics along the lines of Jacobi's and Hamilton's work. In his memoir 'On the three body problem and the equations of dynamics', Poincaré showed that it is not possible to integrate the equations of motion of three bodies subject to mutual interaction and not possible to find an analytic solution representing the movement of the planets valid over an infinite time interval, since the series used by astronomers to calculate the movement of the planets were not convergent.

In the 1950s and 1960s, the mathematicians Kolmogorov and Arnold took up Poincaré's work and showed that, for certain values of the initial conditions, it was nonetheless possible to obtain convergent series. If the masses, eccentricities and inclinations of the planets are small enough, then many initial conditions lead to quasiperiodic planetary trajectories, similar to the Laplace–Lagrange solutions. However, the actual masses of the planets are much too large for this result (known as the KAM theorem) to apply directly to the solar system and thereby prove its stability.

Although the constants required for the application of Arnold's theorem correspond to extremely small values of the planetary masses, this result reinforced one more time the idea that the solar system was stable, by any reasonable acceptance of this term, on a time comparable with its age.

The results obtained through numerical integration in the past decade show the contrary.

Recent studies

In very recent years, the problem of solar system stability has advanced considerably, largely as a result of computers which allow extensive analytic calculations and numerical integrations over model time scales approaching the age of the solar system.

One part of these efforts consists of direct numerical integration of the equations of motion (Newton's equations, sometimes with additional relativistic corrections or perturbations due to the Moon). Initial studies were limited to the motion of the outer planets, from Jupiter to Pluto. In fact, the more rapid the orbital movement of a planet, the more difficult it is to numerically integrate its motion. To integrate the orbit of Jupiter with a conventional integrator, a step size of 40 days will suffice, while a step size of 0.5 days is required to integrate the motion of the whole solar system (Cohen *et al* 1973; Kinoshita and Nakai 1984; Carpino *et al* 1987). These studies, reaching 100 million years, essentially confirmed the stability of the system and the validity of the old perturbative approach of Laplace and Lagrange. At about the same time, calculations of the same system were carried out at MIT over even longer periods, corresponding to times of 210 and 875 million years. These calculations were carried out on 'Orrery', a vectorized computer specially designed for the task (Applegate *et al* 1986; Sussman and Wisdom 1988). This integration showed that the motion of Pluto is chaotic, exhibiting exponential divergence with respect to the initial conditions, with a characteristic (Lyapunov) time of 20 Myr. However, since the mass of Pluto is very small

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

(1/130 000 000 the mass of the Sun), this does not induce macroscopic instabilities in the rest of the solar system, which appeared relatively stable in these numerical studies.

The other possibility, in order to overcome some of the limitations of numerical integrations, consists in a semi-analytical approach. Using perturbation methods developed by Lagrange, Laplace and Leverrier, Laskar (1989) derived an extended averaged system for the whole solar system except Pluto, including all contributions up to second order with respect to the masses, and through degree 5 in eccentricity and inclination. For the outer planets, some estimated corrections of third order were also included. The system of equations thus obtained comprises some 150 000 terms and does not model the motion of the planets, but rather the averaged motion of their orbits. It thus can be integrated numerically on a computer using a very large step size, on the order of 500 yr. An integration over 200 million years showed that the solar system, and more particularly the system of inner planets (Mercury, Venus, Earth and Mars), is chaotic, with a Lyapunov time of 5 million years (Laskar 1989). An error of 15 m in the Earth's initial position gives rise to an error of about 150 m after 10 Myr, but this same error grows to 150 million km after 100 Myr. It is thus possible to construct EPHEMERIDES over a 10 million year period, but it becomes essentially impossible to predict the motion of the planets with precision beyond 100 million years.

This chaotic behavior essentially originates in the presence of two secular resonances among the planets: $\theta = 2(g_4 - g_3) - (s_4 - s_3)$, which is related to Mars and the Earth, and $\sigma = (g_1 - g_5) - (s_1 - s_2)$, related to Mercury, Venus and Jupiter (the g_i are the secular frequencies related to the perihelia of the planets, while the s_i are the secular frequencies of the nodes) (Laskar 1990). The two corresponding arguments change several times from libration to circulation over 200 million years, which is also a characteristic of chaotic behavior.

The improvement of computer speed and the development of new methods for numerical integration allowed most of these results to be confirmed by the direct integration of Newton's equations (figure 3) (Quinn *et al* 1991; Laskar *et al* 1992; Sussman and Wisdom 1992).

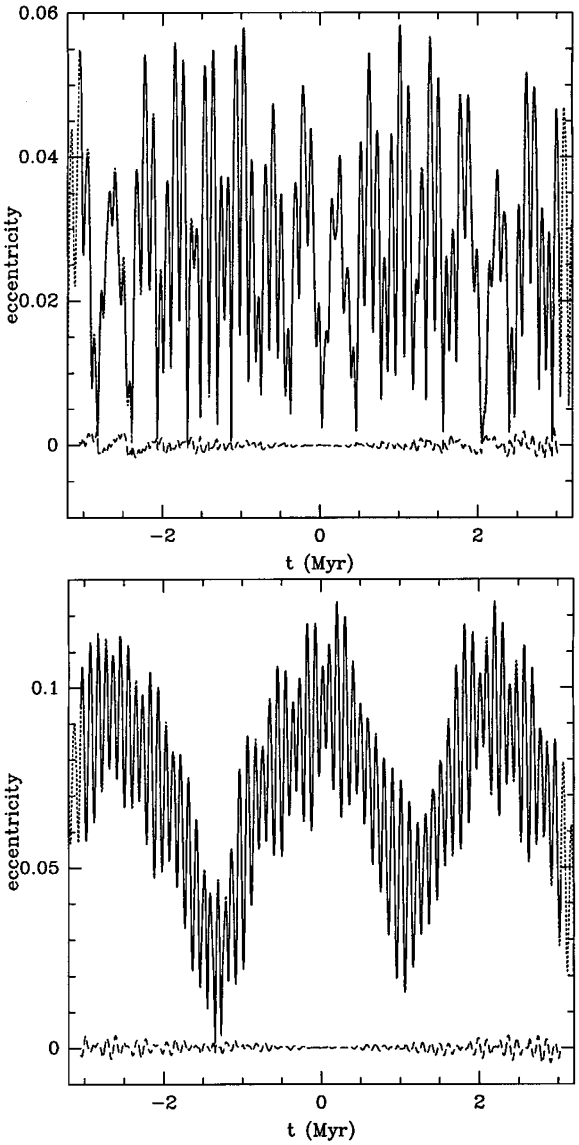

Figure 3. The eccentricity of the Earth (top) and Mars (bottom) during a 6 Myr timespan centered at the present. The solid curve is the numerical solution from Quinn *et al* (1991), and the dotted curve the integration of the secular equations (Laskar 1990). For clarity, the difference between the two solutions is also plotted (from Laskar *et al* 1992).

Evolution of planetary orbits

Over less than 1 million years, a quasiperiodic model such as the one of Laplace–Lagrange (figure 2) gives a fair representation of the evolution of the planetary orbits. This linear model, although not very precise, provides in particular a good account of the variations of the eccentricity and inclination of the Earth which will be at the origin of the variation of the orientation of its axis of rotation, and thus of the insolation on its surface. Indeed, a similar model derived by Leverrier (1856) was used by Milankovitch for the establishment of his astronomical theory of paleoclimates (see CLIMATE).

Over a longer period, of a few millions of years, a quasiperiodic approximation of the solution is still possible, but it should take into account the effect of the resonances between the secular motion of inner planets. It will thus not be possible to obtain it with the classical perturbative method of Leverrier and its successors. On the other hand, such approximation can be obtained by some refined Fourier techniques, after the numerical integration of the averaged equations (Laskar 1988, 1990).

The question of the maximum possible variations of the planetary orbits over the age of the solar system becomes now even more difficult to answer, as, because of

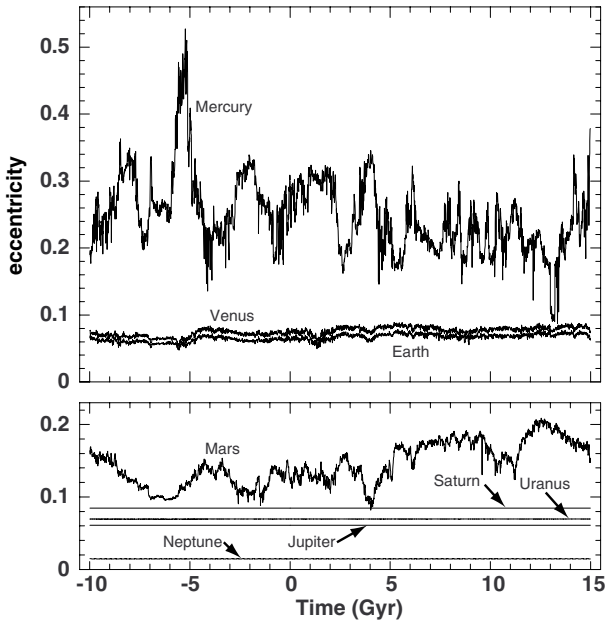

Figure 4. Numerical integration of the averaged equations of motion of the solar system 10 Gyr backward and 15 Gyr forward. For each planet, the maximum value obtained over intervals of 10 Myr for the eccentricity is plotted versus time. For clarity, Mercury, Venus and the Earth are plotted separately from Mars, Jupiter, Saturn, Uranus and Neptune. The large planets' behavior is so regular that all the curves of maximum eccentricity appear as straight lines. On the contrary the corresponding curves of the inner planets show very large and irregular variations, which attest to their diffusion in the chaotic zone (Laskar 1994).

the exponential divergence of the orbits, we know that it will not be possible to obtain precisely the orbital evolution of the solar system after more than 100 Myr.

The computation of the evolution of the solar system over 5 billion years may thus appear illusory, but one does not seek here to predict the precise evolution of the system, but to look only for its possible behavior. With this intention, the integration of the orbits was even pushed over durations going well beyond the age of the solar system (Laskar 1994, 1995). The results (figure 4) provide a very clear vision of the stability of the planetary orbits. In this figure is represented the computed evolution of the eccentricity of the orbits of planets of the solar system over a duration of 25 billion years (from −10 to +15 billion years).

In fact, for better clarity, the plotted curve represents only the variation of the maximum eccentricity reached by the planetary orbits over intervals of 10 million years. Indeed, the oscillations of the eccentricity resulting from the linear coupling of the solutions (figure 3) are removed by this procedure. In doing so, the only variations which appear in figure 4 are thus the variations due to the chaotic diffusion of the orbits.

For all external planets, the maximum eccentricity is almost constant. That reflects the fact that these trajectories are very close to regular and quasiperiodic trajectories; possible instabilities are insensitive with the scale of the the drawing.

For Venus and the Earth, one observes moderated variations, but still significant. The maximum eccentricity of the Earth acquired through chaotic diffusion reaches about 0.08, whereas its current variations are approximately 0.06. This situation is about the same for Venus.

The two curves of the maximum eccentricity of the Earth and Venus are very similar, because of the linear coupling between these two planets. The evolutions of the orbits of Mars and Mercury are very spectacular. The diffusion of the eccentricity of Mars can bring this to 0.2 in a few billion years, whereas the variations of Mercury's orbit can lead its eccentricity to values exceeding 0.5.

In fact, the system is still constrained by angular momentum conservation, which constrains strongly the most massive planets, and it is remarkable to note that, in the system of interior planets, the less massive a planet is, the larger is the possible diffusion of its orbit. The behaviors of the inclinations are very similar to those of the eccentricities.

Because of the chaotic character of the orbits, a very small modification of the initial conditions will lead to a solution different from the preceding one after a few hundreds of million years, but the general aspect of the solutions will undoubtedly remain the same. To evaluate which are the possible maximum variations for the orbits of planets over 5 billion years, one can seek, by very small modifications of the initial conditions, the trajectory which leads to the strongest variations of the orbits.

More systematically, Laskar (1994) calculated five trajectories of very close initial conditions over 500 Myr. The trajectory leading to the strongest Mercury eccentricity is then retained, and, in the vicinity of this maximum, five new trajectories are computed again for a new duration of 500 Myr. For Mercury, this method then makes it possible to obtain in ten such stages an orbit which comes to cut Venus's orbit in less than 3.5 billion years. Let us note that, brought back to the initial position, because of the exponential divergence of the orbits, the displacements of initial conditions correspond to a displacement of the position of the Earth smaller than Planck's length ($\approx 10^{-33}$ cm).

It should, however, be noted that, to arrive at this possible collision between Mercury and Venus, the model was used beyond its rigorous field of validity, which does not includes the vicinity of collisions. In addition, the solution was carefully chosen, so in any case it is surely not a very probable one, and the majority of the solutions of close initial conditions will not lead to this possible collision.

The same method was applied to all other planets, but the chaotic diffusion of their orbits did not allow for a collision in less than 5 billion years. The planet which, with Mercury, has the most unstable orbit is the planet Mars, whose eccentricity can, by this same method, reach approximately 0.25 in less than 5 billion years, while the Earth's eccentricity barely reaches 0.1.

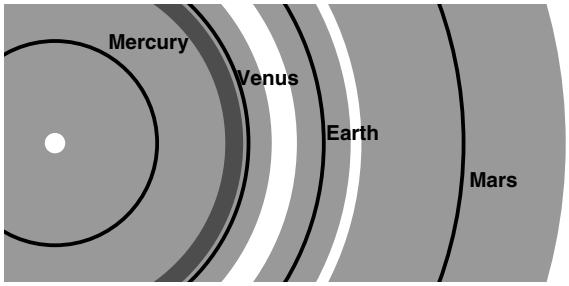

Figure 5. Estimates of the zones possibly occupied by the inner planets of the solar system over 5 Gyr. The circular orbits correspond to the bold curves, and the zones visited by each planet resulting from the possible increase of eccentricity are the shaded zones. In the case of Mercury and Venus, these shaded zones overlap. Mars can go as far as 1.9 AU, which roughly corresponds to the inner limit of the asteroid belt (Laskar 1995).

Marginal stability of the solar system

If one summarizes these results on a plane graph representing the zone swept by the planetary orbits for the maximum values of their eccentricity (figure 5), one notes that the solar system is 'full': there is no place for an additional body. One needs at least 3.5 billion years to allow a collision between Mercury and Venus, but an additional body placed in this system will probably collide more rapidly with one of the already existing planets.

This observation leads then to the concept of marginal stability for the solar system: the solar system is unstable, but catastrophic phenomena leading to the destruction of the system in its current form can take place only in a time comparable with its age, that is to say approximately 5 billion years. The observation of this present state then makes it possible to suppose that the chaotic evolution of the orbits was a determinant process for the structuring of the system after the early stages of its formation (see SOLAR SYSTEM: FORMATION). At that time, some bodies other than the current planets could have remained, but in this case the system would have been much more unstable, and a collision or an ejection could have taken place (an example could be the impactor of the Earth which was at the origin of the formation of the Moon). After this event, the remaining system becomes much more stable. We thus obtain a self-organization of the system towards increasingly stable states. This vision is in agreement with the models of formation of planets by accretion of PLANETESIMALS (Safronov 1969), because it shows how the residual bodies could disappear, in particular in the internal solar system. It is remarkable that the zone swept by the orbit of Mars to its maximum eccentricity reaches the limits of the asteroid belt.

Concerning the system of the outer planets, things are appreciably different, because the direct gravitational short-period perturbations are more significant. The recent numerical simulations show that particles placed among the outer planets do not remain beyond a few hundreds of million years, apart for some particular zones of stability or beyond Neptune, in the Kuiper belt, where objects explicitly were found.

Finally, these observations also make it possible to have an idea of the general aspect of a planetary system around a star (see EXOPLANETS). Indeed, if the process of planetary formation from planetesimals is correct, it becomes possible that, in their final states, planetary systems will always be in a state of marginal stability like our own solar system. At the end of the phase of formation of the system a great number of bodies can remain, but in this case the system is strongly unstable, and is led to a collision or an ejection. After this event, the system becomes more stable. In particular, a system with only one planet, or even with two planets like Jupiter and Saturn, will not be able to exist, because this system would be too stable so that gravitational instabilities could not evacuate all the other bodies initially present. More precisely, if such a system exists, a multitude of small bodies will have to also remain, which will not have been evacuated by these gravitational instabilities.

Solar Telescopes and Instruments: Ground

Solar observations require special telescopes and instruments. They share the basic optical principles with their nighttime companions, but there are also some substantial and characteristic differences between solar and stellar telescopes.

The most obvious distinction is caused by the target of observation: the Sun. It irradiates the Earth's surface with a power of about 1 kW m^{-2}, and a solar telescope has to withstand this heat input while maintaining its optical quality.

The Sun, as an extended object, allows the study of details on its surface. In order to achieve the highest spatial resolution possible, the solar image scale has to be adapted to the pixel size of the detector in the focal plane. This requires a large focal length and a large f-number for a given entrance aperture diameter, and that again distinguishes a high-resolution telescope from any other astronomical instrument. The properties of the telescope site are important for the achievable image quality. In addition to the high-resolution telescopes there are special-purpose solar telescopes which investigate global properties, such as the solar oscillations or the large-scale effects of the Sun's magnetism.

Resolution aspects

The most important characteristics of a telescope are its resolution and light collection power. Since the Sun appears at least 10^{10} times brighter than any star in the sky, one may think that the second parameter is rather irrelevant for a solar telescope, but we will see later that this is indeed not the case.

The image of a point source is completely described by the point spread function (PSF) for a perfect telescope. For a circular clear (unobstructed) aperture we obtain the well-known Airy pattern $\mathrm{PSF} = (1/\pi)[J_1(Br)/Br]^2$, where $B = \pi D/\lambda f$ and J_1 is the Bessel function of order 1; D and f are the aperture and the focal length of the telescope and λ is the wavelength used for the observation. An important quantity derived from the PSF is the resolution angle $a_1 = r_1/f = 1.22\lambda/D$, or $a_s = 2.52 \times 10^5 \lambda/D$, where r_1 is the radius of the first dark Airy ring and a_s expresses the resolution in arcseconds. The imaging of extended objects, such as the Sun, with its low-contrast structures depends strongly on factors in addition to the PSF. These factors include the imperfection of the optical elements of the telescope, atmospheric distortion and image motion, as well as the degradation effects of the detector.

The modulation transfer function (MTF) describes the reduction in contrast between the object and the image, as a function of spatial frequency: $\mathrm{MTF}(k) = C_i(k)/C_o(k)$. The MTF is the modulus of the optical transfer function (OTF), and the OTF and the PSF are Fourier pairs, so the MTF is easily computed from the PSF. For a circular clear aperture the MTF is

$$\mathrm{MTF_T}(k) = \frac{2}{\pi}\left\{\arccos\left(\frac{k}{k_c}\right) - \frac{k}{k_c}\left[1 - \left(\frac{k}{k_c}\right)^2\right]^{1/2}\right\}$$

where k_c is the cutoff wavenumber of the telescope ($\mathrm{MTF}(k_c) = 0$). The resolution angle corresponds to a wavenumber $k_m = 2\pi {r_1}^{-1}$ and the contrast reduction factor at this wavenumber is 0.09 (figure 1). In a complex optical system each component is described with its own transfer function and the total MTF is just the product of the individual functions:

$$\mathrm{MTF_{tot}} = \mathrm{MTF_D} \times \mathrm{MTF_T} \times \mathrm{MTF_S} \times \mathrm{MTF_C}$$

where the indices denote diffraction, telescope aberrations, seeing and detector.

Telescope aberrations

Deviations from a perfect figure of an optical surface are specified as wavefront error, σ, expressed in units of the incident wavelength. The PSF provides a simple criterion for the overall quality of a telescope: if the central intensity is at least 80% of the value for a perfect system, the instrument is called diffraction limited. The ratio $S_R = {I_0}^{\mathrm{real}}/{I_0}^{\mathrm{ideal}}$ is called the Strehl ratio. For small aberrations the relation $S_R = 1 - k^2\sigma^2$ holds and we find the well-known criterion for the acceptable amount of wavefront errors for a diffraction-limited system, $\sigma = 0.0712\lambda = \lambda/14$.

The disturbing Earth's atmosphere

The image degradation caused by the Earth's atmosphere is due to thermal inhomogeneities causing local fluctuations in the index of refraction. The most commonly used parameter to describe this effect is the Fried parameter $r_0 = 0.299D[(k\sigma)^2]^{-5/3}$, where σ^2 is the averaged mean square wavefront error (in rad). The value of r_0 depends on the telescope site, the time of the day and on wavelength. Even under best conditions r_0 does not exceed 20 cm at visible wavelengths. Good sites for solar telescopes are high mountain peaks, sites on islands or places surrounded by a lake. Water surfaces, both nearby and more distant ones, produce a smooth temperature profile of the overlying air—an important ingredient of good seeing. Another important factor is wind, which prevents the buildup of turbulence in the immediate surroundings of a telescope caused by heating of the soil. Qualitatively, seeing conditions corresponding to a certain value of r_0 permit (on average) the same spatial resolution as a telescope with a diameter of r_0. The Fried parameter is a time-averaged value of the statistically varying seeing, and a sequence of many short-time exposures (with exposure times of a few milliseconds) therefore will contain some frames with a quality much better than the limit given by r_0. Frame selection techniques are used to extract these high-quality frames from the sequence. The spatial resolution of solar telescopes is usually seeing-limited for spectroscopic measurements with exposure times longer than some 10 ms, and ADAPTIVE OPTICS is needed to overcome this limitation.

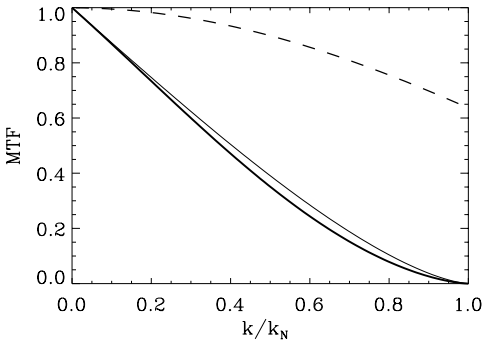

Figure 1. Modulation transfer function of an ideal telescope (thin full curve), a CCD camera (with two pixels per resolution element of the telescope, dashed curve) and their product (thick curve) plotted as a function of normalized spatial wavenumber.

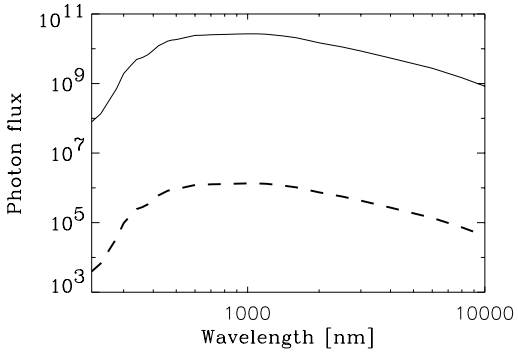

Figure 2. Photons per resolution element of a telescope, for a wavelength interval of 1 nm and perfect telescope transmission. The dashed curve shows the same function for a telescope efficiency of 0.05 and a wavelength band of 1 pm.

Detector transfer function

Solid-state digital detectors nowadays have replaced analog media as recording devices. The commonly used CCD CAMERAS have smaller pixels and a much higher sensitivity (quantum efficiency) compared with photographic film. From sampling theory it is known that correct sampling is required in order to avoid spurious signals in the recorded image. The smallest structure, $x_c = \lambda f D^{-1}$, in a telescope image is given by the diffraction limit of the instrument. Critical sampling requires two pixels per resolution element, $p = 0.5x_c$, where p is the pixel size. The length x_c corresponds to the cutoff wavenumber $k_c = 2\pi/x_c$. The pixel size defines the maximum frequency of the digitized data, $k_N = 2\pi/2p$, so $k_c = k_N$ for critical sampling. In addition to the transfer effects of pixel size, the transfer function of a CCD camera has a second component, which describes diffusion processes in the photosensitive layer: $\mathrm{MTF_C} = \mathrm{MTF_P} \times \mathrm{MTF_D}$. The pixel contribution is $\mathrm{MTF_P} = \sin(kp/2)/(kp/2)$, where p is the pixel pitch, which is assumed to equal the pixel size (modern CCDs have indeed 100% fill factor, i.e. no gaps between pixels). At the Nyquist frequency, k_N, the pixel MTF has dropped to 0.637, so critical sampling leads to a significant contrast reduction at high spatial frequencies (figure 1). The (usually small) diffusion contribution depends on wavelength and on pixel size. For a given image scale, smaller pixels increase the contrast transfer, i.e. the resolution, but this improvement has to be traded against the concomitant decrease in dynamical range, which is inversely proportional to the pixel size.

Correlation tracking

Atmospheric seeing causes image degradation due to blurring and also image motion within the field of view which leads to distortion. The local image motion can be compensated by means of a high-speed correlation tracker. A fast camera records images of the solar granulation at a rate of at least 1000 frames per second. The image displacement is computed with a suitable algorithm, e.g. cross-correlation, and a fast tip-tilt mirror finally corrects the image motion in a servo-loop. Correlation trackers need a closed-loop bandwidth of more than 50 Hz for proper functioning.

How bright is the Sun?

The spectral flux of the Sun measured outside the Earth's atmosphere peaks in the green wavelength region. At a wavelength of 550 nm it is $f_\lambda = 1.96$ J m^{-2} s^{-1}. This corresponds to a photon flux of $f_p = 5.4 \times 10^{18}$ photons m^{-2} nm^{-1} s^{-1}. Compared with the canonical value of 10^8 photons m^{-2} nm^{-1} s^{-1} for a zero-magnitude star, the Sun is indeed a bright source. Very seldom, however, is the Sun observed as a star, and high-resolution measurements are better characterized by the photon flux per resolution element of a telescope:

$$f_{\mathrm{res}} = \frac{\pi}{4} \frac{f_p \lambda^2}{R_\odot^2}$$

where f_p is the photon flux, λ the wavelength and $R_\odot$ the angular radius of the Sun (4.65 mrad). This quantity is a property of the Sun and is independent of the telescope size. Any increase in light-collecting area is exactly compensated by a corresponding decrease of the resolution element. The wavelength dependence of f_{res} is shown in figure 2, together with a curve computed for a realistic telescope efficiency of 0.05 and a wavelength bandwidth of 1 pm, a typical value for narrow-band spectroscopy.

Small-scale objects on the Sun are highly dynamic or transient; typical time-scales range between several minutes to just a few seconds. Obvious examples are the formation or disappearance of a thin magnetic flux tube or a flare event. The temporal and the angular resolution of an observation are coupled: the smaller the feature, the faster is the cadence needed for adequate sampling of the evolution. Figure 2 demonstrates the lack of photons

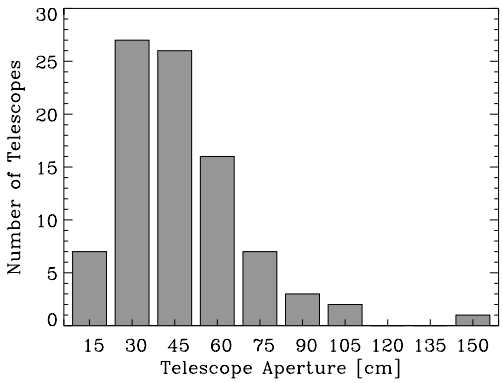

Figure 3. Distribution of telescope apertures, excluding helioseismic instruments.

especially for narrow-band measurements in the blue part of the visible spectrum.

Telescope types

Optical solar telescopes can be divided in three groups, according to their main purpose: high-resolution, synoptic and helioseismic instruments. About 100 such telescopes are installed world-wide. Figure 3 shows the distribution of apertures of the first two groups. Most of these telescopes have diameters of less than 50 cm, and there is only a single one (the 1.5 m McMath–Pierce Telescope at KPNO) with an aperture of more than 1 m. It may be worthwhile to mention that most high-resolution telescopes are older than 15 yr. This is related to the dominating effect of day-time atmospheric SEEING on the achievable spatial resolution. Even at the best sites, narrow-band spectroscopic observations are almost always seeing limited. A Large Earth-based Solar Telescope (LEST) had been thoroughly studied and discussed for many years; its realization has finally been indefinitely postponed owing to lack of sufficient funding.

The breakthrough in solar adaptive optics in 1999 will revolutionize high-resolution solar observations: diffraction-limited observations will become possible in the near future even for large-aperture telescopes and for a significant fraction of the time (whenever the seeing quality exceeds a certain threshold value), and this will eventually lead to the development of a new generation of telescopes with apertures of 2 m and beyond.

High-resolution telescopes

This class of telescopes is designed for diffraction-limited observations and therefore their image scale is adapted to the resolution (pixel size) of the focal plane detectors. In order to image one resolution element onto two pixels, a focal length of $f = 2\Delta x A_u a_s^{-1}$ is needed, where A_u is the astronomical unit, a_s the size of a resolution element and Δx the pixel size. Using the above relation for a_s we obtain

$$\frac{f}{D} = \frac{2\Delta x}{\lambda}$$

for the focal ratio ($\approx$60 for a pixel size of 20 μm). The field of view is only a small fraction of the solar disk, with a diameter of typically just 2 or 3 arcmin.

Tower telescopes have been the classical design of a solar instrument, and the main advantages are (i) simple optics (one mirror with optical power suffices), (ii) large focal length of primary mirror (no hot focal plane, large field of view), (iii) slender, tall building (telescope entrance at large height, above local turbulence layer) and (iv) non-moving telescope and focal plane instrumentation, only few moving parts (feed optics). In order to avoid image degradation caused by internal turbulence, many of these telescopes have been built as evacuated systems, with high-quality entrance and exit windows. Either coelostat systems or alt-azimuthal two-mirror configurations are used as feed optics. The main advantage of the former is the non-rotating solar image, while a turret is much more compact and can be included in the evacuated light path.

The 70 cm Vacuum Tower Telescope on Tenerife is shown as an example in figure 4. Most of the vacuum tube is indeed empty and only needed to accommodate the large focal length of 45 m. The size of the entrance window is one of the limiting factors for the aperture of such vacuum telescopes: at diameters beyond 1 m either the window becomes too thick or bending stress near the circumference, caused by the atmospheric pressure force (8 tons-force for a 1 m window), leads to unwanted polarization effects. Therefore the LEST had been planned as a helium-filled system, with a very thin window to seal the helium from the ambient air. Helium has a smaller index of refraction, (3.6×10^{-5}, compared with 2.93×10^{-4}) than air, higher thermal conductivity and larger kinematic viscosity. These properties result in very small temperature variations and consequently little wavefront disturbance in a helium-filled telescope. However, helium technology is costly and the fabrication of a thin, optical-quality entrance window with a diameter larger than 2 m is a challenging task.

Compact designs with two or more image-forming mirrors are also used for solar telescopes. These telescopes can be installed in much smaller buildings and have much less steelwork. Different optical designs have been used, including Newton-, Gregory- and Ritchey–Chrétien-type configurations. The focal length of the primary mirror is rather short, producing a 'hot' primary image, and therefore all optical elements between the primary and the first image need to be cooled. A modern example is the French THEMIS telescope on Tenerife, a 90 cm Ritchey–Crétien-type telescope, evacuated, and with very low instrumental polarization.

Open-air versus closed telescopes

The evacuation of a telescope completely eliminates internal telescope seeing, and filling such a tube with helium would produce the same effect. Future large telescopes of the 3–4 m class will be neither evacuated nor helium filled, owing to insurmountable problems with the necessary entrance window of any closed system. In

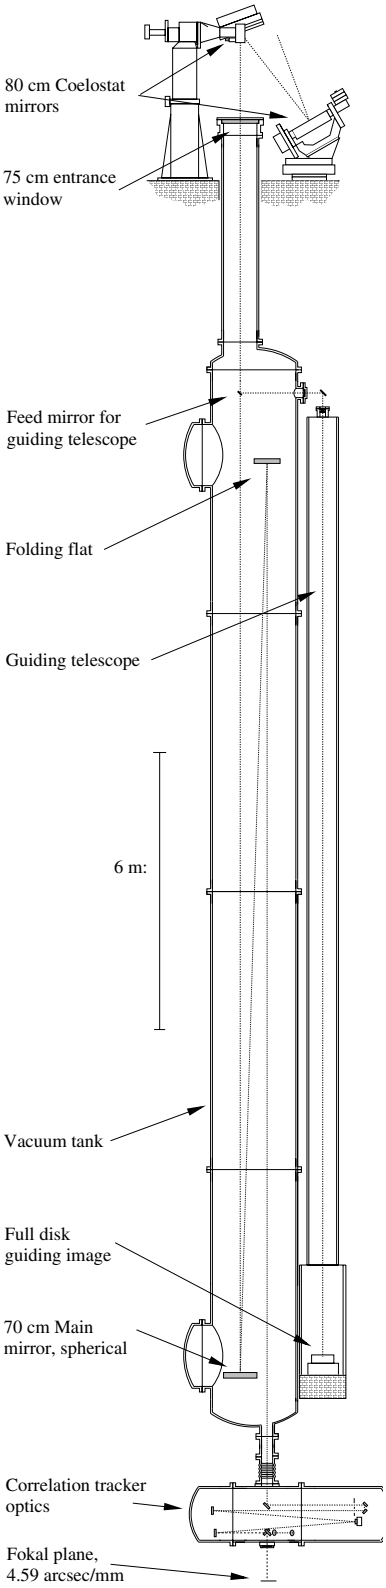

Figure 4. Sectional cut through the 70 cm German Vacuum Tower Telescope on Tenerife. The image shows the main optical components at the correct geometrical scale (T Kentischer, KIS).

addition, closed telescope are limited in spectral range to wavelengths shorter than 2.7 μm, where the window material becomes opaque.

The main source of internal telescope seeing is not the direct heating of the air inside the telescope tube; it is rather caused by the heating of the front side of the primary mirror which in turn heats the air in front of it.

Using a value of 1000 W m^{-2} for the solar irradiance at a high-mountain site, the absorbed heat amounts to about 100 W m^{-2}. From the known properties of Zerodur, the commonly used material for mirror blanks, and of aluminum one can estimate a temperature increase of about 20 K above ambient temperature. The elimination of mirror seeing in an open telescope therefore will require active cooling of the main mirror. The use of mirror materials with high thermal conductivity would make mirror cooling much easier.

Synoptic telescopes

During the first half of this century many solar observatories have been dedicated to routine or patrol observations of the Sun, and a wealth of phenomena have been described. Recently, the variability of the Sun and the possible dependence on the magnetic activity cycle of its luminosity and other quantities have initiated a new generation of synoptic telescopes, both space-borne and ground-based ones.

Synoptic telescopes have a large field of view and most of them observe the full Sun. Their main purpose is the investigation of large-scale properties and the observation of long-term variations of the Sun. For full-disk observations apertures of 10–20 cm are normally sufficient, and the focal lengths f are in the range 1–2 m, producing images of the Sun with diameters of $d = 0.01f$. With an image size of 20 mm, a large-format CCD camera with 2000 pixels $\times$ 2000 pixels and a pixel size of 10 μm, a spatial resolution of 2 arcsec can be achieved (assuming critical sampling). Synoptic observations monitor the solar atmosphere at different layers, from the photosphere through the chromosphere to the transition layer (the corona is not accessible from ground, but synoptic observations are carried out from space, e.g. by SOHO or TRACE; see also SOLAR TELESCOPES AND INSTRUMENTS: SPACE). Medium-bandwidth filtergrams (FWHM $\approx$ 50 pm) are produced using Lyot filters or interferometers, e.g. Fabry–Pérot etalons.

NASA, NOAA and other data centers provide (incomplete) databases of a variety of daily synoptic images from different observatories, including

- photospheric images in 'white light' (sunspots),
- magnetograms (photospheric magnetic field),
- Hα images (chromosphere),
- Ca II K images (chromospheric network),
- He 1083 images (chromosphere, transition region),
- coronographic images (corona).

Daily images are sufficient to study the long-term behavior of the Sun, on the time-scale of months or years, including

variations due to the 11 yr activity cycle. In addition, there are observing programs that study large-scale flows in the photosphere or the emergence of magnetic flux. These measurements require cadences in the order of minutes and high accuracy. Such a program is envisaged e.g. within the SOLIS (Synoptic Optical Long-term Investigations of the Sun) project. SOLIS consists of three telescopes with apertures between 8 mm and 50 cm and it will also observe integrated sunlight ('Sun as a star') and investigate the possible cycle dependence of spectral lines. Figure 5 shows the schematic layout of one of the instruments, the 50 cm vector-spectromagnetograph.

Atmospheric seeing, image quality and photon shortage are normally not an issue for synoptic observations, because diffraction-limited imaging is not required. Photometric accuracy is critical for the measurement of the vector magnetic field, and SOLIS will therefore use an 'oversized' 50 cm telescope for that purpose. Important criteria for the quality of such long-term observations are completeness, time coverage and consistency of the data over the full time interval. Completeness and time coverage could be achieved by organizing networks of similar telescopes across the globe and by automated operation of the instruments.

Helioseismology instruments

Helioseismic experiments are probing the dynamics and structure of the solar interior with very high precision and they allow us to test the standard model of stellar evolution by measuring the global solar oscillations. These consist of a superposition of millions of modes with velocity amplitudes of a few cm s^{-1} per mode, and frequencies between 2 and 4 mHz. Frequency resolution Δf is equivalent to the total duration T of a measurement ($\Delta f = T^{-1}$), and, therefore, long-term observations are necessary. Different observing strategies are possible: (1) repeated observations at a single site, (2) continuous observations from the south pole or (3) network observations from stations around the Earth. The first method is certainly the simplest one and it has been used for years, e.g. at the Observatorio del Teide, where the first station of the BISON (Birmingham Izaña Solar Oscillations Network) NETWORK has been operated since 1975. The obvious disadvantage is a strong contribution to the power spectrum at a frequency of 1 per day (=11.57 μHz) and overtones, which corrupt the spectrum. The south pole measurements have no such effect, but for practical reasons measurement cycles are limited to 3 months and bad weather interruptions may occur at any time. The network approach is the most promising one, since it offers basically unlimited observing time. It is especially important to have virtually identical instruments. At present, three major networks are operated around the Earth. With six stations, more or less equally distributed in longitude, there is sufficient overlap in operating time to compensate for technical failures or bad weather conditions. With improving reliability and increasing degree of automation, duty cycles of more than 90% have been reached.

Different approaches are used to achieve the necessary sensitivity for the velocity measurements: some network telescopes observe integrated sunlight and use atomic resonance spectrometers for the wavelength measurements, reaching an accuracy of a few mm s^{-1}. These experiments measure only the lowermost modes with $l \leq 4$. The GLOBAL OSCILLATION NETWORK GROUP (GONG) instruments use a Michelson interferometer and a Fourier tachometer technique to measure the position of the line of neutral nickel at 676.8 nm. GONG has a spatial resolution of about 8 arcsec (an upgrade to 5 arcsec is planned) and can resolve modes up to $l = 250$. In a 30 day data set, frequencies can be measured with an accuracy of about 50 nHz (about one-seventh of the nominal frequency resolution) and a 1 yr observation will provide an accuracy of 15 nHz. As a result, the frequencies of the solar oscillations are by far the most accurately known parameter of the Sun.

Focal plane instruments

Focal plane equipment can be divided in two major subgroups: (1) broad-band imaging and (2) spectroscopic instruments. In the simplest case, an imaging instrument is just a camera and a filter to select the wavelength band of interest. Imaging instruments play an important role for synoptic observations and morphological studies of the solar atmosphere. With high-speed cameras and suitable *post facto* image reconstruction techniques diffraction-limited images can be obtained. Sequences of images are used to study horizontal flows using a local correlation tracking algorithm. For the measurement of physical parameters of the Sun (e.g. temperature, element abundance, magnetic field strength) spectroscopic instruments are needed. Strictly speaking, an instrument can only collect photons from the Sun, i.e. measure intensity,

$$I = I(x, y, \lambda, t, \boldsymbol{p})$$

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills, Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

and all physical information is derived therefrom (x, y are coordinates on the Sun, λ, t and $\boldsymbol{p}$ denote wavelength, time and polarization state, respectively). Focal plane instruments are distinguished by the corresponding measurement techniques and the range and resolution limit of one or more of the aforementioned variables.

Grating spectrographs measure simultaneously one spatial dimension, defined by length of the entrance slit, and wavelength. The basic characteristics are derived from the grating equation

$$\sin\alpha + \sin\beta = \frac{m\lambda}{g}$$

where α and β are the angles between the grating normal and the incoming and outgoing beam, m is the diffraction order and g the grating constant. For the Littrow configuration the two angles are nearly identical, so the grating equation simplifies to $m\lambda = 2g\sin\beta$. According to the Rayleigh criterion two neighboring spectral lines are 'resolved' if the diffraction maxima of one line coincides with the diffraction minima of the other line. This eventually leads to the equation for the resolving power

$$R := \frac{\lambda}{\Delta\lambda} = \frac{2W\sin\beta}{\lambda}$$

where W denotes the width of the wavefront at the grating. The resolving power is independent of the grating constant. The angular dispersion is derived from the grating equation: $\delta = 2\tan\beta\lambda^{-1}$, and is also independent of the grating constant. The linear dispersion $D(=f\delta$, where f is the focal length of the imaging system) is of high practical importance, since it defines the image scale in the focal plane of a spectrograph and, together with the pixel size of the detector, the actual spectral resolution of a measurement.

From the above equation we conclude that high spectral resolution requires large gratings used at high (and nearly equal) angles of incidence and diffraction. The resolution is sometimes written as $R = nm$, where n denotes the total number of illuminated grooves and m the diffraction order. This is mathematically correct, but it may lead to the erroneous conclusion that the number of grooves or the diffraction order contributes to the resolution power of a grating spectrograph.

The observation of a certain area on the Sun is done by scanning the solar image across the spectrograph slit. The quality of such a measurement depends mainly on the precision of the scanning. This kind of measurement is rather sensitive to image distortion, which in this case is nearly uncorrectable. With successful adaptive optics, this problem will more or less disappear.

In contrast to prisms, gratings produce overlapping spectral orders, so that additional filters are required to select a specific wavelength. Echelle spectrographs make best use of this multi-line capability and are therefore very versatile for diagnostic spectroscopy. A typical echelle grating has 79 grooves mm^{-1} and is used at (or near) an angle β of 63.4° ($\tan\beta = 2$). These gratings are blazed to maximize the grating efficiency at that angle. Visible wavelengths correspond to diffraction orders between 30 and 50 with a free spectral range FSR $= \lambda/m$ (= 13 nm for $m = 40$). The spectral order(s) of interest are chosen via a pre-disperser in front of the main spectrograph or with medium-band interference filters in the focal plane. This allows to simultaneously record several wavelength bands from different parts of the spectrum. In contrast to stellar echelle spectrographs, where a cross-disperser displaces overlapping orders perpendicular to the dispersion axis, the pre-disperser selects short wavelength bands that are imaged in the focal plane along the dispersion axis. This imposes a serious limit on the choice of spectral regions: 'degenerate' wavelengths, with the same value of $m\lambda$, cannot be observed simultaneously.

Filter spectrometers are basically narrow-band imaging devices with wavelength tuning capability. They provide spatial information in two dimensions for a specific wavelength and a complete spectrum is obtained by taking filtergrams at different wavelength positions. The spectral resolution and coverage are determined by the type of filter used. In the past, tuneable Lyot filters (or a universal birefringent filter, UBF) have been used for that purpose. The main disadvantage of this filter type is its low transmission. The spectral resolution ranges between some 10 pm and 50 pm, and the main application has been the spectroscopy of strong chromospheric lines.

The first Fabry–Pérot interferometer (FPI) had been built in 1899, long before the first Lyot filter. The commonly used name for these devices, *étalon* (=standard of measure) reminds to its original purpose. Etalons are characterized by the following (simplified) equations for the free spectral range, FSR, and the resolving power, R, which both depend on the spacing t between the interferometer plates:

$$\mathrm{FSR} = \frac{\lambda^2}{2t} \qquad R := \frac{\lambda}{\Delta\lambda} = \frac{2Ft}{\lambda}.$$

The finesse F is the ratio between the FSR and the width of the instrumental profile. It is independent of the spacing and is a measure of the quality of an FPI (reflectivity, parallelism and smoothness of the interferometer plates). It is obvious from the above relations that for a reasonably high spectral resolution of, say, 250 000 at a wavelength of 550 nm, the FSR is very small, of the order of 0.1 nm and hence a very narrow filter is needed to suppress adjacent passbands. As a consequence, several spectrometers have been built as a combination of a UBF, acting as prefilter, with an FPI. The main drawback of that solution is again the low transmission and difficulties in coherent tuning of the two components.

Another solution is the combination of two or more etalons with different spacings. Coarsely speaking, the largest spacing determines the resolution, while the narrowest etalon increases the FSR. The efficiency of a triple-etalon system is at least one order of magnitude higher compared with a UBF.

Filter spectrometers and grating spectrographs complement each other in many respects: a filter spectrometer observes a fixed field of view and the time needed to obtain a full data set $I(x, y, \lambda)$ depends on the number of wavelength steps, while a grating spectrograph always records a fixed wavelength range and the field of view is coupled to the measurement time through the number of scan positions. Measurements which require a very fast cadence can easily be made with a filter instrument, at the cost of wavelength information, but without loss of spatial field. Grating instruments are especially valuable, when precise wavelength information, e.g. the shape of line profiles, is needed. Filter and grating spectrographs are used for POLARIMETRY by adding the capability to discriminate between the polarization states of the incoming light. SOLAR MAGNETOGRAPHS usually measure the line-of-sight component of the magnetic field on the Sun. The investigation of the strength and orientation of the magnetic field vector requires complicated spectropolarimeters (see POLARIMETRY: SPECTROPOLARIMETRY) and a rather involved inversion technique to deduce the relevant physical quantities from the polarization measurements.

Solar Telescopes and Instruments: Space

The first solar space observations

Fifty years of development in solar space instrumentation have demonstrated the close relation between technical and scientific progress.

Solar physics from space, and indeed space astronomy, started in 1946 in the United States, when captured V-2 rockets, capable of rising 160 km above the ground, became available for use as free-flying, high-altitude laboratories. It was not surprising under these circumstances that a group from the US Naval Research Laboratory (NRL) in Washington, DC under Richard Tousey became the first to make use of the fortunate opportunity.

An initial attempt was made on 28 June 1946 to observe radiation in the hydrogen Lyman alpha line from the Sun. However, the camera was never retrieved from the crater made when the V-2 impacted on the desert floor of the White Sands Missile Range in New Mexico. The next attempt, on 10 October 1946, was a success, giving us the first ultraviolet spectrum of the Sun, 220–340 nm (nm—nanometer, i.e. 10^{-9} m), shown in figure 1. At altitudes above 55 km, rising through the ozone layer, the solar spectrum appeared all the way down to 220 nm. The first observations of solar x-rays followed in 1949 when Herbert Friedman, also of NRL, flew a payload of Geiger counters on a V-2 rocket (see also ROCKETS IN ASTRONOMY).

Further rocket observations in the 1950s established that the Lyman alpha line of hydrogen was emitted from the solar CHROMOSPHERE. The radiation in this line was measured quantitatively in 1949 on the same flight that detected solar x-rays and also measured the Schumann ultraviolet continuum at 142.5–160 nm. The line profile of Lyman alpha was measured later, and the narrow absorption core at its center, detected in 1959, established the presence of an extended geo-corona. The first solar spectrum below Lyman alpha was recorded in 1960. Emission lines at these short wavelengths were classified as lines from high ionization stages, mainly of iron, and shown to come from the hot coronal plasma at 1.5–2.5 MK (MK—megakelvin, i.e. million kelvins). The strong enhancement of x-ray emission during solar flares was detected in 1956. When a rocket was flown during a solar eclipse in 1958, it was determined that solar x-rays originated in the CORONA, particularly above ACTIVE REGIONS. The first image of the Sun in x-rays was recorded in 1960, using a pinhole camera on board a rocket. Finally, it may be mentioned that the first CORONAGRAPH was flown in space in 1963.

Looking back it is amazing that these early days of rocket experiments and our first established, simple knowledge about the ultraviolet and x-ray emission from the Sun are only 40–50 years behind us. The early discoveries are now so familiar that we hardly reflect on how difficult they were to obtain and on the fact that they were not obvious.

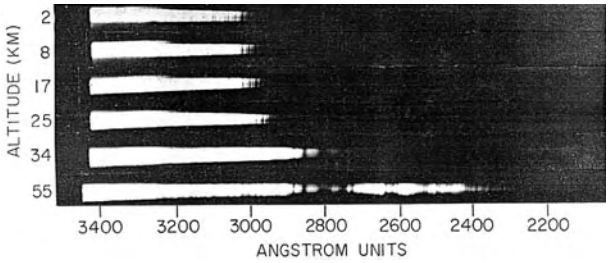

Figure 1. The first ultraviolet spectrum of the Sun. Recorded on a V-2 rocket flight on 10 October 1946.

Early technical developments

Technical developments in many fields conditioned the early progress. Contributions to these developments came from universities and research laboratories in the US, France and the UK.

Magnesium fluoride lenses, transparent to 110 nm, were used in the first rocket observations. Development of mirror coatings with high reflectivity in the far ultraviolet was, however, crucial for progress beyond the first simple experiments. Oxidized aluminum, used on mirrors in the visual wavelength range, does not reflect radiation at far-ultraviolet wavelengths. However, fresh unoxidized aluminum is an efficient reflector down to 100 nm. The solution was to coat the fresh aluminum with a layer of magnesium fluoride. This stopped oxidation and preserved the high reflectivity. Below 110 nm other reflecting materials were found, notably gold, used in instruments on ORBITING SOLAR OBSERVATORIES (OSOs) (see below) and Skylab, but also osmium and silicon carbide. Today, multilayer mirror coatings can be produced with reflectivities up to 30% in narrow ultraviolet and x-ray wavelength bands.

Another important concern is to avoid contamination by stray light. The Sun radiates the overwhelming part of its energy in the visual spectral region. Even a small fraction of this light scattered off the instrument surfaces will completely swamp the ultraviolet signal that we want to study. This problem was solved when an aluminum filter, consisting of a freely suspended aluminum foil of 100 nm thickness, was developed in France and the US. The filter reflected visual light but was transparent to ultraviolet radiation.

Detector development was no less essential. In the 1950s and 1960s Kodak increased the sensitivity of their ultraviolet-sensitive Schumann emulsions, originally developed around 1900. In these emulsions the silver halide grains are sticking out of the gelatin layer to avoid absorption of ultraviolet radiation in the gelatin. This makes it sensitive to mechanical pressure and a roll film camera that could hold large amounts of this film was not made until the 1980s for the High Resolution Telescope and Spectrograph (HRTS), on Spacelab 2. Indeed, since photographic film quickly records vast amounts of image data, it has continued to be used almost until this day.

Photoelectric detectors were used in the near ultraviolet in instruments flown on rockets already in 1952. Channel electronic multipliers came into use with the first satellite instruments. Array detectors in two dimensions proved difficult to make for ultraviolet wavelengths. The first spectral and image scans were therefore made with pinhole devices. This meant slow scans and low time cadence for images and spectra. A modern solution is to convert the ultraviolet radiation to visual light before it is registered with a conventional CCD.

The years of early rocket and satellite experiments also saw the development of increasingly accurate pointing systems. The first rockets flew without pointing and for some time instrument resolution did not put any stringent demands on pointing accuracy. However, it became obvious that much of the extreme ultraviolet and x-ray emission is concentrated in active regions a few arcminutes in extent consisting of even smaller structures. Thus, good instrument resolution and pointing became decisive in order to make any sense of the observations.

A biaxial pointing system, stable in pitch and yaw, was designed by the University of Colorado in 1954 and improved versions were used for all ultraviolet and x-ray observations in the subsequent decade. A triaxial pointing system, developed at the Atomic Energy Research Establishment in England in 1965, prevented variations in roll. Pointing could now be stabilized to 2 arcsec. Today pointing stability is better than 1 arcsec on modern satellite platforms.

In this perspective satellite observatories may be regarded as a final step among the early technical developments. The first decade of satellite observatories saw increased sophistication in satellite platforms as well as in instrumentation. Space solar physics outgrew its beginnings and reached maturity with the instruments on the Apollo Telescope Mount on Skylab in 1973–4.

Satellites, balloons and rockets in the 1960s

The first registration of solar ultraviolet and x-ray radiation using instruments on a satellite came on the Soviet Sputnik 2 in 1957. The first US satellite with solar instruments, Vanguard 3 in 1958, was a failure. However, close observations of its orbit led to the discovery of the expansion and contraction of the Earth's ionosphere caused by diurnal and long-term variations in the solar ultraviolet and x-ray emission.

Solrad 1, launched in 1960, was the first in a series of satellites observing various wavelength bands in ultraviolet and x-rays. These satellites provided long-term coverage of wavelength and intensity changes of the solar radiation until 1976. Solrad demonstrated the strong solar variability in x-rays compared with the much lower variability in the ultraviolet. The satellite instruments did not have imaging capabilities in x-rays, but observations during the solar eclipse in 1966 showed that the solar x-ray emission was concentrated in small regions, less than 1 arcmin in diameter, i.e. the hot cores of active regions.

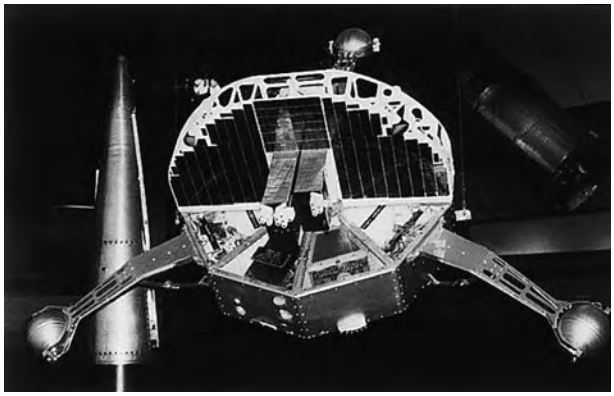

Figure 2. Model of the OSO satellites. OSOs 1–7 all looked similar.

1962 saw the beginning of a new series of solar satellites, the OSO missions (figure 2). The intent was to follow the Sun through an entire 11 year cycle with nearly identical ultraviolet and x-ray instruments. The OSO satellites had three axis-stabilized platforms. Pointing stability exceeded the imaging quality of the scientific instruments, but solar imaging was possible with a resolution of about 1 arcmin for the earliest OSOs. Studies could be made of coarse active region structures and of emission associated with the solar supergranulation in several spectral lines formed at different temperatures. OSO-8 (1975–78), the last in the series, came after Skylab (1973–4), differed from the earlier OSOs and is mentioned below.

Rocket experiments continued after 1960 in the US and in other countries. In France we may note the rocket and balloon flights in the 1960s and early 1970s that carefully measured the solar ultraviolet radiation from ∼200 nm down to Lyman alpha at 121.6 nm and its variation from Sun center to limb. The solar spectrum at these wavelengths comes from the upper photosphere, the lower part of the chromosphere and the temperature minimum layer between them. The strong discrepancy, as much as a factor of 10 at wavelengths of 150–180 nm, between the observed and theoretically calculated intensities inspired improved efforts at modeling these layers in the solar atmosphere. The lowest observed radiation temperature in the ultraviolet continuum at 150 nm was much discussed. Successive experiments found different results. This was not trivial since the value of the minimum temperature on top of the photosphere was considered to be connected to the amount of non-thermal energy passing from the photosphere to the corona and heating the corona.

The UK launched its first satellite for solar research, ARIEL 1, in 1962. Ariel 1 carried instruments that measured the solar spectrum in x-ray wavelengths, 0.4–1.4 nm. The enhancement of the solar x-ray intensity by factors of 10 or more during SOLAR FLARES was recorded on many occasions. This was of great interest at the time for

Dirac House, Temple Back, Bristol, BS1 6BE, UK

understanding the enhanced ionization in the D-layer in the Earth's ionosphere during flares, leading to disruption of radio communications. Groups in the UK also took part with far-ultraviolet and x-ray instruments in the OSO program, i.e. OSO-4, -5 and -6, leading up to their later strong participation in SMM, Yohkoh and the Solar and Heliospheric Observatory (SOHO).

The UK Skylark rockets launched several ultraviolet instruments starting in 1964. In 1968 they obtained for the first time spectra of both the solar limb and the disk in the spectral range 150–220 nm. These observations were aimed at deriving the temperature structure of the outer solar atmosphere at ~100 000 K using a method that did not rely on uncertain instrument calibration, atomic cross sections or element abundances. Grazing incidence observations at shorter wavelengths, 15–80 nm and 1.5–5 nm, were added to study the corona at temperatures of 1 MK or more.

Slitless spectrographs launched into the total solar eclipse on 7 March 1970 by British and US investigators revealed that the emission from spectral lines emitting at temperatures of 10 000–300 000 K was not limited to a range in altitude of a few tens of kilometers as predicted by theoretical models, but extended over more than 1000 km. The true significance of this observation did not, however, make a strong impression at that time.

Finally, one might mention two tests of the NRL ultraviolet spectrometers, SO82A and SO82B, on Skylab. The test rocket for SO82A was launched during a solar flare on 4 November 1969. For the first time the small hot kernel of a flare was revealed. It was only a few arcseconds across and it showed up in highly ionized iron lines emitting at temperatures of several million kelvins. The corresponding test flight for SO82B in August 1970 led to the first published measurement of the large non-thermal widths of lines formed around 100 000 K, pointing to the presence of strong dynamics and waves in the transition region between the solar chromosphere and corona.

Early observations of the spectral region 20–150 nm showed that it contained a number of emission lines. Many of these lines had been identified and absolute intensities had been established. Analysis techniques had been developed in response to the new observations, to determine plasma densities and temperature structure of the emitting layers. In the resulting models the temperature above the chromosphere rose sharply from 10 000 K to 300 000 K in only about 100 km. It was at first not recognized that this result disagreed strongly with the observation that solar plasma in the 100 000 K range extended several thousands of kilometers above the chromosphere.

Skylab

SKYLAB is covered in a separate article in this encyclopedia and will only be described briefly here. The Skylab instruments were much larger than the corresponding OSO instruments. Angular resolutions in x-ray and extreme ultraviolet approached 2–4 arcsec. These high-resolution pictures showed that the solar transition region and corona are built up by magnetic loops containing the hot solar plasma. Solar flares occurred in the loops and the high-temperature components of flares were detected, having temperatures up to 20 MK. Loops and prominences were seen to tear loose from the solar surface to form what have later been termed coronal mass ejections (CMEs). CORONAL HOLES, extended regions where the emission in spectral lines from the corona was strongly depressed, were discovered and the occasional fast solar wind near the Earth, with wind speeds twice as high as the 'normal' solar wind, was found to be coming from the equatorial coronal holes. It was recognized that the Sun might have more permanent polar coronal holes.

Skylab missed out on dynamics and rapid time variability. Observations could be made only on a limited supply of photographic film or the photoelectric scans of wide fields of view took too long a time. Thus, high-cadence observations of loop structures were few. The Skylab spectrometers also lacked combined good spectral and spatial resolution. Thus, they could not detect the high velocities, 40–100 km s^{-1}, commonly occurring in the 100 000–500 000 K temperature range now observed with the ultraviolet spectrometers on the Solar and Heliospheric Observatory (SOHO).

Modern rockets and satellites

Many advanced instruments have flown in the more than 25 years, since Skylab. The Soviet Union had solar instruments on several satellites, an early example being OST-1, on Salyut 4 in 1975. This far-ultraviolet telescope, constructed by the Crimean Astrophysical Observatory, obtained new characteristics of plages and solar flares.

The Japanese Astro A, also known as HINOTORI, was launched in 1981. Its main objective was the detailed study of solar flares. One of its instruments imaged flares in x-rays, at energies of 10–40 keV or around 0.1 nm wavelength. Another instrument performed spectroscopy of x-ray flares in the wavelength range 0.17–0.2 nm, using a Bragg spectrometer. Investigations recorded the time profile and spectrum of x-ray flares and looked for gamma rays from flares at energies from 0.2 to 9.0 MeV. Hinotori was a forerunner for Japan's highly successful solar x-ray satellite, YOHKOH, launched in August 1991 and still in operation.

Orbiting Solar Observatory 8

OSO-8 was launched in June 1975 and operated until September 1978. It was the first solar satellite to attempt observations of the solar atmosphere with simultaneous high spatial and spectral resolution. It was also the first satellite to operate on a near-real-time basis with the science teams on the ground. It had two pointed instruments: an ultraviolet spectrometer, wavelengths 120–200 nm, and a multichannel ultraviolet and visible polychromator with six wavelength channels. These channels registered the strong resonance lines from singly

Brunel Road, Houndmills, Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

ionized calcium and magnesium and the Lyman alpha and beta lines from hydrogen. The wavelength border regions of the channels contained visual and ultraviolet continua and the lines from doubly ionized silicon at 120.6 nm and five-times ionized oxygen at 103.2 nm. Thus, the instruments could study the solar plasma at temperatures from 6000 K to 250 000 K, i.e. the chromosphere and lower transition region. Spectral resolutions ranged from 2 to 10 pm (pm—picometer, i.e. 10^{-12} m). The best possible angular resolution of both instruments was 1–2 arcsec. However, the slit spectrometer took most of its data with a 2 arcsec × 20 arcsec slit and the multichannel instrument was mainly run in a coarse mode with 10 arcsec resolution. These two instruments were built and operated by the University of Colorado and the French National Space Agency, CNRS, respectively.

OSO-8 demonstrated that the energy in the 150–300 s oscillations was several orders of magnitude lower than the radiative losses from the upper solar atmosphere. Thus, the solar corona could not be heated by acoustic waves, the most commonly held view at the time. Persistent redshifts in lines emitted from the transition region, equivalent to down-flow velocities of $\sim$10 km s^{-1}, were also recorded for the first time. Since flows of this magnitude will drain the corona of gas in a few minutes, alternative explanations have been sought. The most promising involve disturbances generated near the top of magnetic loops by processes heating the corona, then progressing downward along the loop legs. Similar redshifts have been noted in stars and may be a general property of stellar atmospheres.

Figure 3. The HRTS, flying on the space shuttle as part of Spacelab 2, July–August 1985. HRTS is the long tube to the right in the figure.

High Resolution Telescope and Spectrograph

The High Resolution Telescope and Spectrograph (HRTS) (figure 3) had the high angular resolution not realized with OSO-8. HRTS was built and operated by the US Naval Research Laboratory and flew on 10 rocket flights between 1975 and 1997 and was a part of Spacelab 2 in 1985. On most flights the spectrograph operated at wavelengths between 117 and 170 nm, covering the full range or registering selectable narrow bands, 1.4 nm wide, centered on strong emission lines. HRTS was the first ultraviolet spectrograph with stigmatic imaging of an extended slit, 1000 arcsec long, at high angular resolution (1 arcsec).

HRTS made several important discoveries. Notable are the detection of explosive events on the first HRTS flight and the investigation into the possibly small filling factors for the emission in the solar atmosphere. Explosive events are small regions, with diameters of $\sim$2 arcsec, with a velocity dispersion amounting to $\pm$100 km s^{-1}. They are seen in the 100 000 K plasma and last typically 1 min. They could be caused by magnetic reconnection in the solar atmosphere and may thus be the observational signature of one of the main mechanisms proposed for heating of the solar corona.

The study of filling factors with HRTS was made possible by the good spatial resolution of the instrument and its spectral coverage that included density sensitive line pairs. From the derived densities, the total emission, and the overall size of the emitting structures it was concluded that only a small fraction of the volume is filled with plasma, i.e. filling factors amount to between 1% and 0.01% of the total volume of the structures.

HRTS also discovered that rapid down-flows of plasma in the transition region over sunspots are common, with in-flow velocities of 50–100 km s^{-1} or more. Another discovery was that transition region line profiles frequently have a multiple structure as if several distinct and different velocities exist inside the 1 arcsec resolution element of HRTS. This could be connected to the low filling factors if dynamic conditions are different in the small substructures that the transition region may consist of. Finally, clear connections were discovered between line intensities, wavelength shifts and line widths, and the underlying photospheric magnetic fields. The relation between fields and line shifts is asymmetric for red- or blueshifted profiles. A probable reason for an asymmetry would be if waves running in one predominant direction are present in the transition region.

Solar Maximum Mission

The SOLAR MAXIMUM MISSION (SMM) satellite (figure 4) was launched in February 1980. The primary goal was to make coordinated studies of solar activity, particularly solar

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

flares and eruptions, at a period of high solar activity. Over less than 10 years SMM observed more than 12 000 flares and over 1200 eruptions, called CMEs. The history of SMM was at times dramatic. The attitude control system of the satellite malfunctioned in January 1981 but was repaired in orbit in April 1984 and SMM continued observing until November 1989.

Four of the instruments on SMM registered the energetic solar radiation from gamma ray energies to soft x-rays. These instruments measured the spectral intensity of flares continuously over several years. A comprehensive set of coordinated data on this phenomenon was collected, throwing new light on all kinds of flare processes and on solar activity in general.

The Gamma Ray Spectrometer (GRS) provided gamma ray flare intensities as a function of time as well as the spectral distribution of the radiation. The Hard X-ray Burst Spectrometer (HXRBS) observed time series of hard x-ray bursts from flares in 15 energy channels between 20 keV and 260 keV (1 keV corresponds to a wavelength of 1.23 nm; higher-energy photons have proportionally shorter wavelengths). Thus spectra of the bursts could be built up. Continuous observations were made with a time resolution of 128 ms, but shorter intervals were possible. The soft X-ray Polychromator (XRP) monitored individual emission lines that are strong in active regions and flares. The selected lines give information on temperature, density, velocity, element abundance and non-equilibrium states in the flare and active region plasma. The Hard X-ray Imaging Spectrometer (HXIS) delivered simultaneous images of solar flares in six energy bands between 3.5 keV and 30 keV. The instrument had a coarse field of view corresponding to the size of an active region, with a spatial pixel of 32 arcsec, and a high-resolution field of view centered in the coarse field, with a spatial pixel of 8 arcsec. Time resolution could be automatically varied from 1.5 s in the early stages of a flare to 7 s in the decaying phase. Except for HXIS, which ended its life in November 1980, the high-energy instruments lasted until the end of the mission.

SMM also had three low-energy instruments that supported the studies of flares and solar activity. The Ultraviolet Spectrometer and Polarimeter (UVSP) produced monochromatic raster images at any wavelength between 115 nm and 360 nm with selectable wavelength bandwidth and angular pixel size down to 1 arcsec × 1 arcsec. Images in four lines could be observed simultaneously, or wavelength bands might be placed in the opposite wings of lines to measure Doppler shifts (i.e. velocities) or make polarization measurements. Time cadence for observations with a single pixel could be a fraction of a second. However, in most practical situations it took several minutes to build up a raster image. In April 1985 the UVSP grating drive failed. Observations were still possible but only at a fixed wavelength around 138 nm.

A main objective of UVSP was to study the flare plasma at temperatures below 200 000 K in the transition region lines available in its spectral range. However, all types of solar features were studied: prominences, solar active regions, sunspots, the quiet Sun. An interesting attempt was made to observe explosive events and relate them to solar magnetic fields. Since they have short lifetimes, explosive events might come and go in less time than it took to record a UVSP raster. Explosive events have a considerable velocity dispersion and could be detected by registering strong intensity variations in the far wings of the 154.8 nm line emitted at 100 000 K. Explosive events and other micro-flaring activity were found to be located in areas where magnetic fields of opposite polarity came close together and could well be caused by magnetic reconnection.

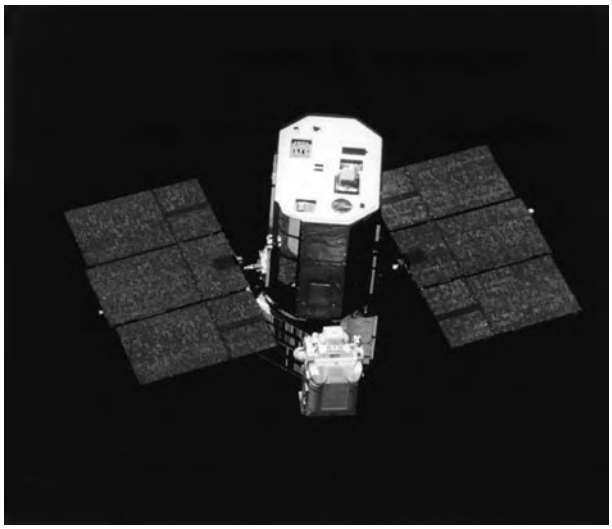

Figure 4. The SMM satellite. The aperture openings for the instruments are visible in the front plate. An astronaut is working on the satellite.

The High Altitude Observatory Coronagraph/Polarimeter on SMM produced images of a selected quadrant of the corona in the range from 1.6 to 6 solar radii with a spatial resolution of 10 arcsec set by the detector pixel size. Observations in seven wavelength bands in the visual spectral range made it possible to distinguish between various features of the solar corona and discriminate between ejected plasma at coronal and chromospheric temperatures. A major outcome of this instrument was a long-term study of CMEs and their relation to solar activity. SOLWIND, operating from March 1979 to September 1985, carried a similar coronagraph, also adding to our knowledge of coronal structure and dynamics.

CMEs were first detected with the coronagraph on OSO-7 and were routinely observed on Skylab. It soon became obvious that CMEs were the cause of strong gusts in the solar wind affecting the Earth's magnetosphere, causing beautiful polar auroras, but also potentially damaging effects to telecommunications and electric power transmissions. The SMM coronagraph had much better time coverage than Skylab, 87% for SMM

against 38% for Skylab. This allowed thorough statistical investigations of the connection between CMEs and solar activity, such as flares and eruptive prominences. Studies found that only half of the CMEs were clearly related to recognized active phenomena. Of the CMEs with such relations 40% were associated with flares, but more than 70% were associated with eruptive prominences. The measured average CME velocities were furthermore considerably lower than those found previously from Skylab. These new results led to a lively discussion on the origins of CMEs and the mechanisms causing them, a discussion that is still going on.

SMM also carried the Active Cavity Radiometer Irradiance Monitor (ACRIM). It measured the solar radiation from the entire solar disk integrated over all wavelengths (total irradiance). For the first time it became possible to measure variations in the solar radiation with time and thus with solar activity. This objective had been pursued from the ground for several decades, without reaching any definitive results (see also SOLAR TELESCOPES AND INSTRUMENTS: GROUND). However, with ACRIM the required accuracy of 0.1% was more than achieved. ACRIM later flew on several space shuttle flights and on the UARS satellite, where it is still in operation. Instruments supplementing ACRIM and giving similar results have been the less accurate ERB on the Nimbus 7 satellite and its successor ERBE.

ACRIM on SMM and in later flights have produced several exciting new results. These include the first unambiguous detection of a decrease in total solar irradiance when a large sunspot crosses the visible solar surface, the so-called 'sunspot deficit'. A corresponding 'excess' effect has also been demonstrated for active regions with large facular areas. Finally, ACRIM has found that the total solar irradiance varies with solar activity, showing a maximum in the period of highest solar activity around year 1990 and minima in 1986 and 1996. Typical rate of change is 0.015% per year. A possible real increase of 0.0036% per year between irradiance minima in 1986 and 1996 is less certain.

The 1990s

The 1990s have seen two extensive and very successful solar space observatories, the Japanese Yohkoh satellite, with US and UK collaboration, and SOHO, a collaboration between the European and US space organizations, ESA and NASA, with ESA as the main partner. The objective of Yohkoh is to study the high-energy radiation from solar flares as well as quiet structures and pre-flare conditions. The instruments on SOHO investigate physical conditions from the innermost core of the Sun to its outer corona and the heliospheric space. Two factors have particularly added to the quality of solar physics from Yohkoh and SOHO data. The first is the open data access and the collaborative spirit of the investigators. Secondly, the real improvement of SOHO and Yohkoh over earlier missions comes more from the high time resolution and continuous coverage than from the modest increase in instrument resolutions.

The Upper Atmosphere Research Satellite (UARS), launched in September 1991 and still in operation, is intended for studies of the Earth's atmosphere but contains relevant solar instruments. ACRIM has been mentioned. SOLSTICE and SUSIM on UARS observe the solar ultraviolet spectrum from 112 nm to 440 nm. The emphasis is on highly accurate absolute calibration that is stable over several years. The record from SOLSTICE and SUSIM constitutes a reference spectrum of the full Sun in ultraviolet and its variation with solar activity.

The main instruments on Spartan 201 are an Ultraviolet Coronal Spectrometer (UVCS) of the type flown on SOHO, and a coronagraph observing in the visual wavelengths. Spartan 201 has flown on five occasions between April 1993 and October 1998, partly supporting observations with Ulysses and SOHO.

Ulysses was launched in October 1990 (see SOLAR WIND: ULYSSES). It is the first satellite to investigate solar and heliospheric conditions at high solar latitudes. It carries no instruments for remote sensing of the Sun, as had been the original plan, but registers heliospheric magnetic fields, plasma waves, dust and solar wind particles, their speed, composition and stage of ionization. The trajectory of Ulysses first took it to Jupiter, where the gravity of the planet accelerated the satellite out of the ecliptic plane and into an orbit at nearly 90° inclination with the ecliptic. Ulysses passed over the south solar pole in June–November 1994 and over the north pole a year later, near solar activity minimum. The measurements showed the well-known slow solar wind, velocity 400 km s^{-1}, at low latitudes. However, at latitudes above 30° this was replaced by the fast solar wind, with a speed of 750 km s^{-1} or more. To the fast winds from equatorial coronal holes had now been added a fast wind streaming out of the coronal holes in the polar caps. Furthermore, this wind fanned out quickly above the solar surface and extended to latitudes much lower than the borderlines of the polar coronal holes, lying near 60° latitude. The magnetic fields from the Sun must similarly fan out in the heliosphere. It will be interesting to see what Ulysses will register on its second pass over the poles in 2000–1 at maximum solar activity when polar coronal holes will be more 'filled in'.

A final mission in the 1990s was the Transition Region and Coronal Explorer (TRACE), launched in April 1998. TRACE observes the solar corona with an unprecedented angular resolution, 1 arcsec in the temperature range from 1 MK to 2.5 MK. The solar emission is observed in EUV wavelength bands centered at 17.1 nm, 19.5 nm and 28.4 nm. Other wavelength channels isolate emission from the chromosphere (10 000–30 000 K) in Lyman alpha from hydrogen, in the resonance lines from three-times ionized carbon at 155 nm (100 000 K) and in the near ultraviolet and white light continuum.

The future

Plans for the future are many and for most part uncertain. The Japanese SOLAR-B satellite is a likely project, scheduled

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

to be launched in 2004. This satellite will contain a visual telescope to measure photospheric magnetic fields with extremely high spatial resolution and ultraviolet and x-ray telescopes to measure and monitor the coronal emission. The mission aims at understanding the detailed relationship between magnetic fields and coronal heating and emission in the Sun.

NASA has sketched an entire 'road-map' of satellites. Only a few of these are likely to fly and at present none is securely financially confirmed. Interesting possibilities include a solar probe, going to 4 solar radii to make *in situ* observation of the acceleration region of the solar wind, and Stereo, which will be a pair of satellites flying in the Earth's orbit around the Sun at a significant distance in front of and behind the Earth. The steroscopic view of solar and heliospheric phenomena will allow a three-dimensional mapping of CMEs.

Europe and ESA are considering a solar orbiter, flying at 45 solar radii from the Sun, and in an inclined orbit to the ecliptic reaching heliographic latitudes of 40°. These plans are still at a preliminary stage, and joining the US in a continuation of SOHO with instruments having super-high resolution should also be considered.

Solar Transition Region

The solar transition region can generally be defined as those plasmas at temperatures between 2×10^4 and 1×10^6 K, a temperature regime bridging the CHROMOSPHERE and CORONA. Prior to the space age, the transition region was unobserved although the existence of the higher-temperature corona was known. Spectral lines formed at transition region temperatures are found primarily below 2000 Å where they are strongly absorbed by the Earth's atmosphere. It was termed the transition region since it was thought to be a thin region of the atmosphere where an abrupt transition from a relatively cool, dense plasma to a hot, highly ionized, tenuous extended plasma occurred. Understanding the solar transition region is an important piece of the great puzzle of determining how the outer solar atmosphere is heated. More recently, interest in the transition region has increased as it is recognized that these plasmas are highly dynamic, displaying such events as jets, explosive events and high-speed flows.

Spectroscopy of the transition region

Observation of the solar transition region requires the use of spectroscopic techniques to isolate spectral lines formed at transition region temperatures. For example, helium has three ionic species: He I, neutral helium, He II, singly ionized helium, and He III, completely ionized helium. In the solar transition region, all three species are present but He II is the dominant species. The ionization state, the relative fractions of the three species, is determined by a balance between the competing processes of ionization and recombination of free electrons with the ions. At 6×10^4 K, He II is the most populous helium ion since at that temperature the free electrons have sufficient energy to ionize neutral helium (He I) but not enough energy to strip away the remaining bound electron to transform He II into completely ionized He III. The emission of He II spectral lines is produced by the collisional excitation of the bound electron to excited levels which then spontaneously decay to lower levels. The Lyman α line (the 1s–2p transition) of He II at 304 Å is a very strong line. It is much stronger than other lines at nearby wavelengths so that it can be fairly easily isolated and observed. Images of the Sun in the light of He II λ304 are shown in figures 1 and 2. These images were obtained with the Extreme-Ultraviolet Imaging Telescope (EIT) instrument on the Solar and Heliospheric Observatory (SOHO) which uses narrow-bandpass coatings on the telescope mirrors to isolate strong spectral lines. Figure 1 was obtained near the minimum of the solar activity cycle and figure 2 was obtained when the Sun was more active.

Temperatures, Densities, Emission Measures, Elemental Abundances

Essentially all of our information about the solar transition region comes from the analysis of spectral lines. Figures 1 and 2 show that much can be learned from images of the intensity of spectral lines. More detailed observations of the transition region are made with spectrographs which can disperse the solar spectrum in order to pick out spectral lines of particular interest.

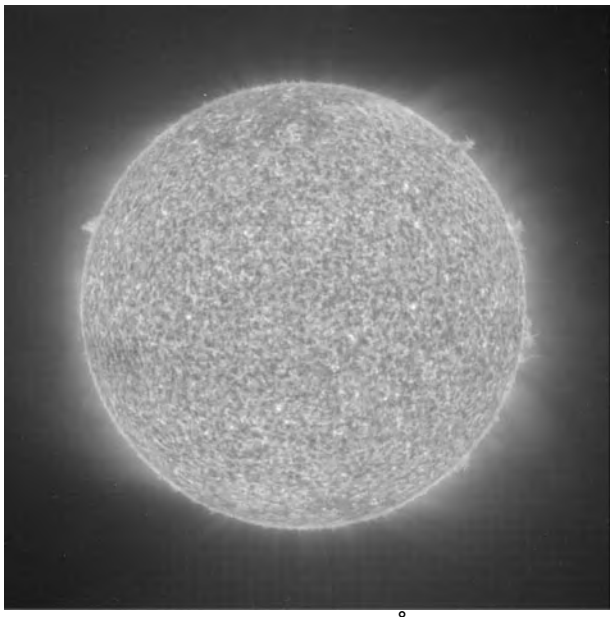

Figure 1. The solar transition region near the minimum of the solar activity cycle seen in He II λ304.

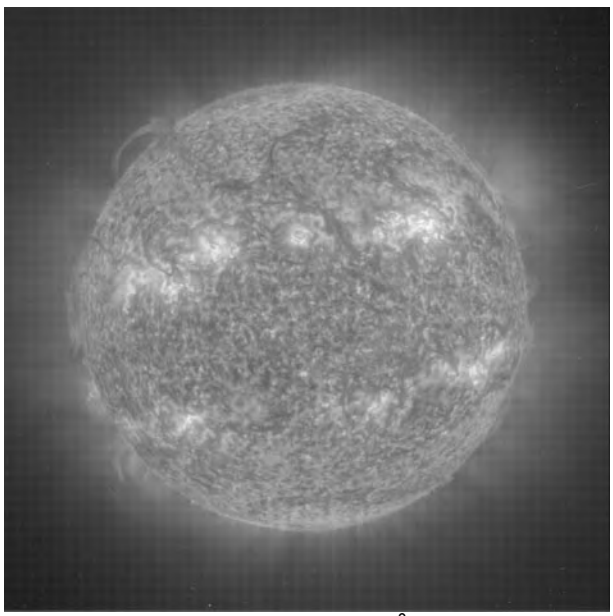

Figure 2. The solar transition region as the Sun approached the maximum of the solar activity cycle seen in He II λ304.

The most direct piece of information that can be obtained about a spectral line is its intensity. The intensity of a line depends on how efficiently the line is produced and how many of the ions that produce the line are in the observed plasma. In the transition region and corona, most lines are produced by collisional excitation of the ion by free electrons. The emission rate is the product of two factors, the electron flux (the electron density multiplied by the electron velocity) and the collision cross section. The cross section is typically large for allowed or resonance transitions and small for forbidden transitions. The number of ions producing the line in the observed plasma is given by the products of the relative population of that ion with respect to all other ions of that element, the density of that element with respect to hydrogen (the elemental abundance) and the density of hydrogen (essentially equal to the electron density) in the observed plasma. Consequently, if we know the temperature, from the calculated ionization balance, the elemental abundance (from other measurements) and the collision cross section, from calculations, we can derive the emission measure ($\int N_e^2 \, dV$) at a given temperature directly from the line intensity. The emission measure provides considerable information about the temperature and density structure of the solar plasma.

A variety of techniques for determining the temperatures and densities of transition region and coronal plasmas are discussed in the article SOLAR SPECTROSCOPY AND DIAGNOSTICS.

Velocity measurements

The spectroscopy of the solar transition region can be taken one further step further to look at spectral line profiles. The object of this is to use the DOPPLER EFFECT to provide information about the velocities in the regions producing the spectral line. If a plasma is moving along the line of sight to the observer, the spectrum of the emitting plasma is shifted in wavelength by the amount $\Delta\lambda = (v/c)\lambda$ where v is the velocity of the observed plasma along the line of sight, and c is the speed of light (in the same units as v) and λ is the rest wavelength of the spectral line (in the same units as $\Delta\lambda$). Plasmas moving toward the observer are shifted to shorter wavelength (blueshift) and plasmas moving away from the observer are shifted to longer wavelength (redshift). If these shifts are observed near disk center, a blue shift corresponds to an outflow and a redshift corresponds to a downflow. At the limb, these shifts indicate horizontal flows.

Figure 3 shows profiles of C IV λ1548 and λ1550 in an active region and sunspot. The profiles are dispersed in wavelength from left to right and position in the quiet Sun runs from top to bottom. Large redshifts can be seen in the sunspot and indicate downflow velocities of 100–150 km s^{-1}. Above the sunspot spectra, one can also see a very small region with exceptionally wide line profiles. These are signatures of explosive events which will be discussed later. These spectra were obtained with the High Resolution Telescope and Spectrograph (HRTS) during a rocket flight.

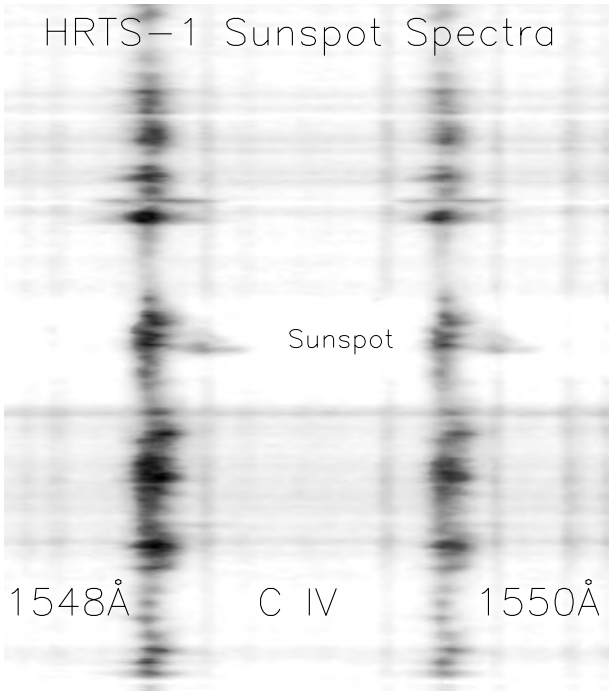

Figure 3. HRTS spectral line profiles of C IV, formed at 1×10^5 K, in an active region and sunspot.

Spectral observations often show that the line has a width that is wider than the spectral resolution of the spectrometer. Part of this excess line width is caused by the motions of the ions which follow a Maxwellian velocity distribution specified by the temperature of the plasma. On examination, one finds that transition region profiles are even broader than would be predicted from the temperature of the ion that emits the line. This excess broadening is called the nonthermal width of the line and is apparently due to motions in the plasmas on spatial scales below the spatial resolution of ultraviolet spectrographs currently in operation. The thermal and nonthermal broadening results in line profiles that have a shape that is nearly Gaussian. Also evident is the net Doppler shift of spectral line profiles of the order of 10 km s^{-1} caused by plasma flows in spicules, loops or other structures. Even more interesting are the occasional line profiles that are non-Gaussian and highly Doppler shifted. These are found in more spectacular events such as jets, ejecta and explosive events.

Elemental abundance variations

For many years, it has been assumed that the relative abundance of elements in solar plasmas does not vary. For example, the standard abundance of iron is about 4×10^{-5} that of hydrogen. The abundances are the result of nuclear processes that ended many years ago. For every parcel of solar plasma, this ratio is now expected

Dirac House, Temple Back, Bristol, BS1 6BE, UK

to be the same. Once the variability of relative elemental abundances was considered a possibility, it was found that relative abundances in the corona were not the same as in the photosphere, that abundances seemed to change during flares and structures with nonstandard abundances were found fairly commonly. The key ingredient in the elemental abundance variations is the first ionization potential (FIP) of the element, or, the energy needed to ionize the neutral species of the element. Elements with low FIP values, such as Mg, Ca, Si and Fe, are enhanced in coronal plasmas relative to photospheric plasmas. The fact that the effect is correlated with the FIP indicates that the separation occurs at fairly low temperatures.

A more detailed discussion of this topic is given in SOLAR TRANSITION REGION.

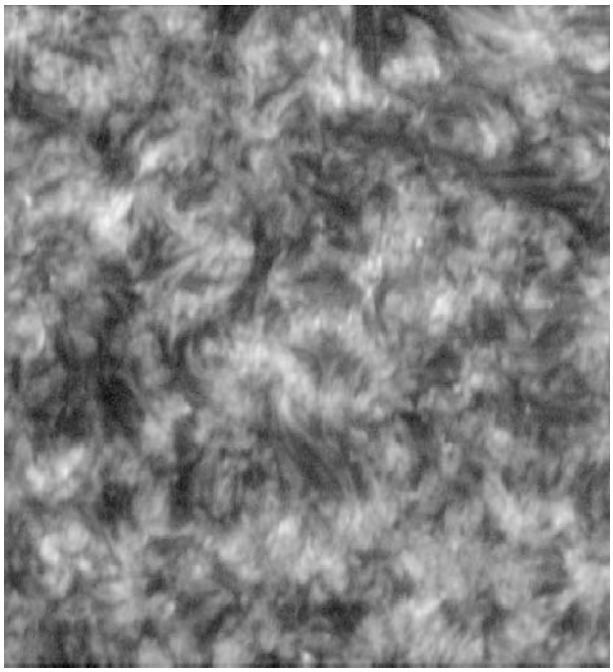
Structure

Large-scale structure of the transition region

Lines formed at transition region temperatures are emitted in most of the large-scale structures that appear on the Sun: the quiet Sun, coronal holes, active regions, prominences, sunspots and solar flares. All of these structures are a result of the interplay between magnetic fields and plasmas.

In the quiet Sun, the magnetic fields are dominated by fields associated with the supergranulation. Here, the supergranular motions in the photosphere sweep the magnetic flux elements from the supergranular cell centers to the cell boundaries. The new magnetic flux that emerges in the cell centers appear to include both positive and negative polarities (upward- and downward-pointed magnetic fields), as if they were the emergence of small kinks in a magnetic flux rope. Consequently, the magnetic fields at the cell boundaries are also bipolar. As a result of the continuous reconnection of magnetic fields, the net result is a complex web of magnetic field lines connecting opposite magnetic field polarities. This magnetic field structure is reflected in the patterns of transition region line emissions. At relatively low temperatures, mostly the base of these short loops is outlined. The corresponding structures in the chromosphere are spicules. At 10^5 K, for example in C IV lines, structures that are the extensions of the cooler chromospheric models are typical. At higher transition region temperature, longer and more complete loops become apparent. A high-resolution image of the quiet transition region obtained with the SUMER instrument on SOHO is shown in figure 4.

The magnetic field in coronal holes is predominantly of one polarity so that the large-scale field extends outward from the Sun and participates in the high-speed solar wind streams. The unipolar nature of coronal hole fields is the result of remnants of active region fields that are swept to the poles during the declining phase of the solar cycle. Nevertheless, the fields in the coronal hole are still pushed around by a supergranular flow pattern that arranges the fields into a supergranular pattern similar to that found in the quiet Sun, except that the fields are mostly of a single polarity. Bipolar fields continue to emerge in the cell centers but, since these have no net polarity, the polarity of the coronal hole fields is unchanged. In transition region lines, the intensity pattern is still that of the supergranular network although it is somewhat less intense than in the quiet Sun. A characteristic structure of the transition region in coronal holes is the macrospicule. These are similar to chromospheric spicules but are about 10 times larger. They typically jet out above the limb and either fade in place or fall back towards the photosphere. Macrospicules can be seen at the top and bottom of the solar images shown in figure 1.



SUMER Image of the Quiet Sun in O VI

Figure 4. The quiet transition region seen in O VI, formed at 3×10^5 K, obtained with the SUMER instrument on SOHO.

SOLAR ACTIVE REGIONS, consisting of sunspots and plage regions, contain the most concentrated large-scale magnetic fields. The strongest fields are in the sunspots but these have no clear signature in transition region lines. Sunspots on average are neither particularly bright nor dark and cannot be located simply from an image of the transition region. Active region plages are often simply regions of relatively bright emission, particularly at low transition region temperatures. For increasing temperatures, the bases of coronal loops and extended portions of loops are outlined. As temperatures approach 1×10^6 K, the loops become more complete as is seen in coronal lines.

SOLAR PROMINENCES are relatively cool plasmas that are typically situated along magnetic 'neutral' lines where the dominant photospheric magnetic polarity reverses. Prominence neutral lines are found in active regions and in the quiet Sun. A number of prominences can be

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

seen in figure 2 in He II. On the disk they are relatively dark and above the limb they are relatively bright. The apparent reason for their darkness on the disk is that they contain cool material with neutral hydrogen and helium with absorbs the emission of extreme-ultraviolet lines. However, this is a matter of current research. Prominences also often erupt from time to time as a component of coronal mass ejections.

Transition region loops and coronal heating

The heating of the transition region and corona is a central, long-standing problem in solar physics. The radiative losses of transition region and coronal plasma occur fast enough that the outer atmosphere of the Sun would collapse in minutes if there was not a constant supply of energy deposited into these plasmas to maintain their high temperatures. The solar transition region is a component of a complex magnetohydrodynamic system. In other words, the temperatures, densities, velocities and magnetic fields of the corona and their evolution are all governed by the equations of magnetohydrodynamics. A complete physical understanding of the solar transition region is only possible if the complete system is understood. The problem of coronal heating encompasses this complete system including the photosphere, chromosphere, transition region and corona (see CORONAL HEATING MECHANISMS). Perhaps the greatest difficulty lies in our inability to measure the Sun's magnetic field above the chromosphere where much of this heating takes place.

The simplest models of the transition region and corona consider the magnetic field as a passive element that constrains plasma flow and heat conduction along the magnetic field lines. The static energy balance models of coronal loops assume that the plasma located along a magnetic field line resembling a coronal loop is uniformly heated along its length by some unspecified mechanism. At the top of the loop where the maximum coronal temperature is reached, the energy input balances the radiative losses and the thermal conduction losses down the field lines to the cooler parts of the atmosphere. In the transition region, the radiative losses are much larger than the local heating rate and are balanced by a dissipation of the thermal conduction flux from the hot corona. These models generally produce an extended corona, resembling the observed CORONAL LOOP structures, and a thin transition that supports the high conductive flux needed. Emission measures of transition region lines, derived from observations, indicate that the volume of the emission measure is small and, in some sense, consistent with a thin transition region.

However there are a number of difficulties with this model. The observed emission measure distribution of the transition region reaches a minimum around 10^5 K with increasing values toward higher and lower temperatures. The static energy balance models are unable to explain the transition region emission measure distribution at temperatures below about 3×10^5 K, in other words, most of the transition region. All of the conductive flux from the corona is radiated away before reaching the middle of the transition region, much less the chromosphere. Further, high-resolution observations of the transition region indicated that it is considerably more extended than predicted by these models. This indicates that it cannot maintain the necessary conductive flux and must itself be locally heated.

Other problems indicate the need for more sophisticated models. For example, the general downflow of transition region plasmas cannot be addressed by the static models but are the basis of steady flow models. These models are capable of reproducing the observed downflows in only the most artificial way and still produce a very thin transition region. The solution to problems of this sort led to models that could include time-dependent flows and heating.

Many of the one-dimensional models continue to predict a very thin transition region. One consequence of this is that hot electrons from the corona are able to penetrate to considerably lower temperatures. In this case, the electron velocity distribution is no longer Maxwellian and greatly complicates the construction of physical models and the spectroscopic diagnostics of these plasmas. The observation that the transition region has a rather shallow temperature gradient indicates that this may not be a real problem but it cannot be totally discounted at this point.

A further discussion of TRANSITION REGION MODELS is presented by V Hansteen.

Very-fine-scale structure and coronal heating

One of the more intriguing properties of the solar transition is the need to invoke the existence of very-fine-scale structures that only sparsely fill the observed transition region structures. In other words, when the transition region is observed at high spatial resolution, it is possible to discern such discrete structures as loops, macrospicules etc. We feel confident that we can measure the volume of such an object. Density-sensitive line ratios are then used to derive electron densities. With the electron density and volume, the emission measure ($\int N_e^2 \, dV$) can be calculated and compared with the emission measure determined simply from line intensities. This comparison generally indicates that the actual volume of emitting material must be much less than what is observed in images of these structures and the actual volume must be only about 1% of the 'observed' volume or less. This can be visualized as the break-up of transition material into thin filamentary strands that follow the magnetic field lines but only fill a fraction of the transition region volume. When a similar analysis is applied to coronal loops, the coronal material seems to completely fill the observed structure. However, the coronal measurements are perhaps not so definitive as in the transition region.

As we will see below, there is evidence for flow patterns in the transition region that are also on very fine spatial scales. These fine-scale structures and flows may be significant in trying to understand how the solar transition region is heated.

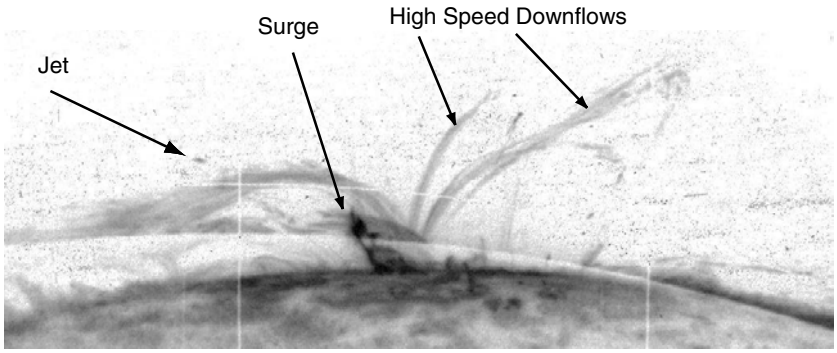

Figure 5. HRTS C IV image of the transition region in an active region at the limb.

Dynamics

As the spectroscopic capabilities of solar ultraviolet instrumentation have improved, it has become clearer that the plasmas at transition region temperatures are highly dynamic. Time sequences of images of transition region structures in the quiet Sun show a continual rearrangement of the network elements and the continual intensity changes in these elements, called 'blinkers'. In the quiet corona, there seems to be a more gradual evolution of the hot structures. Doppler information in transition region spectra also reveals a variety of flows and ejecta, indicating a truly dynamic state.

Flows

Smooth laminar flows of transition region plasmas apparently along magnetic field lines are commonly observed. The speed of sound in solar plasmas varies roughly as the square root of the temperature and has a value of about 40 km s^{-1} at 10^5 K. Flow speeds in the transition are usually subsonic and, in fact, are usually downflows. The typical downflow velocity is about 6 km s^{-1} both in the quiet Sun and in active regions and may approach about 20 km s^{-1}. The net transition region downflow is difficult to understand. There is a net outflow of solar plasma into the solar wind, but the flow velocity associated with this mass loss would be quite small in the transition because of the relatively high densities there. Otherwise we would expect to see a general balance between upflowing and downflowing material but this is not the case.

Persistent supersonic downflows with velocities of 100 km s^{-1} or greater are often seen in and near sunspots, as seen in figure 3. The suspected source for these downflows is the large-scale filamentary transition region structures seen above active regions at the limb. Figure 5 shows filamentary C IV structures above an active region where a surge is in progress.

Further information on TRANSITION REGION FLOWS can be found in the article by P Brekke.

Explosive events

Explosive events have one of the most dramatic signatures in transition region spectra, as seen in figure 6. These

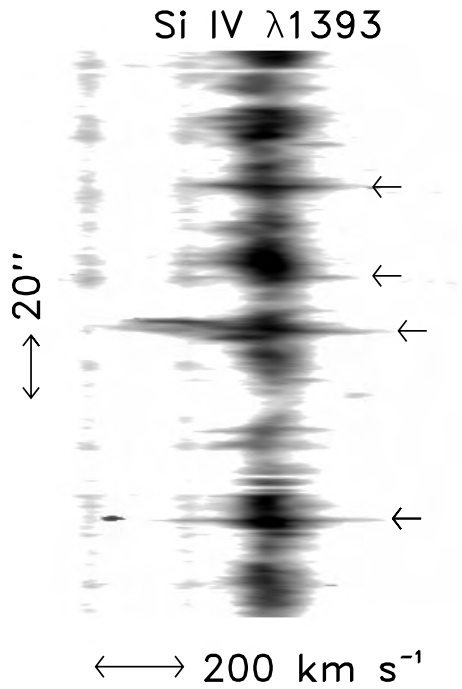

Figure 6. HRTS profiles of Si IV, formed at 7×10^4 K, showing signatures of explosive events in the quiet Sun (arrows).

are most noticeable from their Doppler shifts of about 100 km s^{-1} to the red and/or blue wing of the line in small regions only about 1–2 Mm in extent. Their typical lifetime is about 60 s. The origin of these events can be attributed to magnetic reconnection in a variety of situations. They occur in association with rapidly emerging magnetic flux in active regions, suggesting that the plasma flows are the RECONNECTION jets predicted by the emerging flux flare model. When the positions of explosive events in the quiet Sun are mapped, it is clear that they tend to occur adjacent to magnetic flux elements in the supergranular network boundary. This suggests that explosive events are the result of magnetic reconnection as intranetwork fields are driven by the supergranular flows into the network

boundaries. The details of this scenario are now being examined with the SUMER data from SOHO which has been able to directly observe explosive events in conjuction with magnetic flux reconnection.

Further information on EXPLOSIVE EVENTS can be found in the article TRANSITION REGION: EXPLOSIVE EVENTS by D Innes.

Ejections

One of the more puzzling aspects of explosive events is that the accelerated plasma is not observed to travel very far. Nevertheless, there are many examples of transition region plasmas that are ejected outward into the corona. Doppler shifts of small 7 Mm loops that are repeatedly accelerated to 500 km s^{-1} are observed. Doppler blueshifts (outflows) are commonly found at the top of the supergranular network indicating a continual process of plasma ejection taking place there. Macrospicules, with outward velocities as high as 100 km s^{-1}, are a common feature of coronal holes.

In active regions, SURGES are often observed in chromospheric lines such as Hα as well as in the transition region. These are tongues of plasma that are shot out of active region at velocities as high as 100–200 km s^{-1}. Small plasmoids have been observed to traverse large portions of an active region at velocities of 100 km s^{-1}. Figure 5 shows examples of a surge, a jet and prominence material, all in a single observation. Prominences often erupt and form an essential part of a coronal mass ejection. In some cases, the prominence eruption is the first sign of an incipient mass ejection.

Very-fine-scale dynamics

The nonthermal component of spectral line broadening is a signature of random plasma motions with a characteristic velocity of about 20 km s^{-1}. The typical variations in the velocities of the observed larger-scale flows are only on the order of 6 km s^{-1}. Consequently, the fine-scale motions are not simply the continuation of a distribution of velocities over a wide range of spatial scales, as might be expected for a turbulent plasma. The large-scale velocity variations do have the characteristic velocity spectrum of a turbulent Kolmogorov plasma but the fine-scale velocity variations predicted by this spectrum are much less than the observed value of 20 km s^{-1}.

The evidence for fine-scale motions and structures appears to offer a clue for solving the problem of coronal heating. Where this energy comes from and how it is dissipated is a complex problem with no certain solution at this time. For most coronal heating models the source of the energy is the fluid motions of plasmas in the solar convection zone which contort the magnetic fields in a way that amplifies their field strength and creates magnetic topologies that are at a higher energy level than the minimum energy potential field state. As a result, there are currents and mass motions in the outer atmosphere of the Sun that can be dissipated into thermal energy to replace the losses due to radiation. For example, the currents could be dissipated by Joule (resistive) heating and the mass motions through viscous dissipation. The main problem is that the corona is highly conducting and not very viscous. The electrons are quite free to respond to electric fields so that a potential drop is very difficult to maintain. The main source of resistivity is collisions with the heavier ions but this is not very effective. The induced magnetic field from a current sufficient to maintain the corona would result in magnetic loop structures that are extremely twisted, much more so than observed coronal loops which, at most, display only a mild degree of twist.

One way around this problem is to invoke small-scale currents and flows. One suggestion is that coronal heating occurs in many fine-scale magnetic reconnection events called 'nanoflares'. The small-scale motions deduced from transition region line profiles may be evidence for these nanoflares. The nanoflare theory has also been studied with computer simulations which seem to confirm the idea that motions induced by the large-scale photospheric driving motions result in small-scale stochastic energy release events that resemble nanoflares. The small-scale motions and structures in the solar transition region are probably consistent with the nanoflare theory of coronal heating but, as with many of these issues, this is a topic of current research.

Solar Wind

The continuous outward flow of charged particles (predominantly electrons and protons) from the Sun into interplanetary space. This outflow of plasma 'blows' past the planets at speeds that fluctuate between 200 km s^{-1} and 900 km s^{-1}, and causes the Sun to lose about one million tonnes of mass per second. At a distance of 1 AU from the Sun, the mean density of the solar wind is about 5×10^6 particles per cubic meter and its temperature (a measure of the random kinetic motions of the solar wind particles relative to each other) is about 10^5 K.

Close to the plane of the ecliptic, the average wind speed is about 400 km s^{-1}. The particles that comprise this 'slow' wind emerge predominantly from streamer-like structures in the solar corona that tend to be located relatively close to the solar equator. A fast wind, with a mean speed of about 750 km s^{-1}, flows out of coronal holes that are centered permanently on the solar poles. When coronal holes extend down to, or across, the solar equator, high-speed streams flow out past the Earth and planets. The combination of the Sun's axial rotation and the Earth's orbital motion causes these streams to recur at intervals of 26 to 27 days as viewed from the Earth. Results obtained by the SOHO spacecraft indicate that solar wind particles originate at the boundaries of supergranular cells on the solar surface, where magnetic fields are concentrated.

The solar wind carries with it lines of force of the solar wind, which spread out to form the weak interplanetary field. The Sun's rotation, combined with the radial outward flow of the solar wind, causes the interplanetary field lines to take up a spiral form. The solar wind and interplanetary field interact with the magnetospheres of planets and the tails of comets. The pressure exerted by the solar wind squeezes a planetary magnetosphere inwards, towards the planet, on the Sun-facing side, and drags it out into a tail on the 'downstream' side. The wind drags ions out of the head of a comet to form a long ion tail. Fluctuations in the wind and interplanetary field, caused, for example, by bursts of particles from flares and by coronal mass ejections, distort planetary magnetospheres and sometimes cause ion tails to disconnect from their parent comets.

The solar wind continues to flow outward until it is halted by the weak pressure exerted by the interstellar medium. The boundary of the region within which the solar wind and interplanetary field predominate (the heliosphere) is called the heliopause and is believed to lie at a distance of about 100 AU. The radius of the heliosphere is expected to vary with the solar cycle.

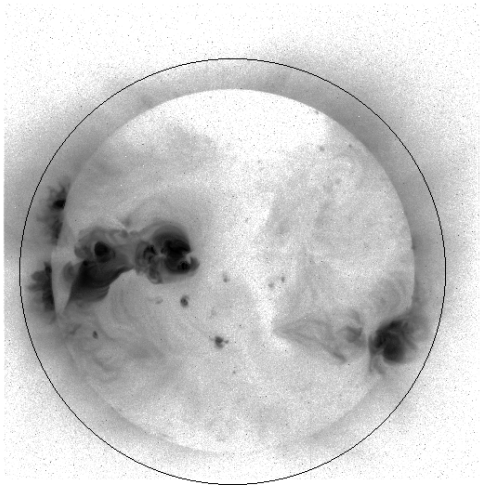

Figure 1. Soft x-ray Yohkoh image from 12 April 1993. The image shows a very distinct low-emissivity coronal hole region (large white area surrounding the north pole and stretching all the way to the equator). There is also a coronal hole present at the south pole, but this is veiled by denser material from surrounding regions and is therefore not visible at the time of the observation (see YOHKOH.)

Solar Wind Acceleration

Solar wind acceleration is the increase of the flow speed of the solar wind plasma from close to zero in the lower SOLAR ATMOSPHERE to the values observed in interplanetary space, which can range from 200 km s^{-1} for the slowest speeds in the ecliptic plane to 750 km s^{-1} for streams originating in the large polar CORONAL HOLES. The exact height in the solar atmosphere at which the plasma starts its outflow is still being debated. Until recently it was thought that the solar atmosphere was more or less static out to distances of 5 to 10 solar radii. With new observations from both ground and space based instruments, it has become clear that at least the fast solar wind streams accelerate at much lower heights in the solar atmosphere than previously thought, starting their outflows probably even below the TRANSITION REGION.

Properties of solar wind streams

Solar wind streams that differ significantly in speed will also differ in other plasma properties such as density and temperature. Different parts of the global solar magnetic field seem to give rise to streams with different properties. The large-scale magnetic field on the Sun can be approximated to first order by a dipole. Near the dipole equator inside of 1.5 to 3 solar radii the magnetic field is strong enough to withstand the outward plasma pressure, the magnetic field lines are therefore closed, and the plasma is confined in these regions called CORONAL STREAMERS. Further away from the Sun the magnetic field becomes weak compared with the plasma pressure, and the plasma forces the field lines to open, permitting a steady outflow of plasma into interplanetary space. These open field lines fill the space between the streamer boundaries and the solar poles. Plasma conditions in the open field regions differ from the conditions in the streamers. Observations show that electron densities and temperatures as well as emission at visible, UV and x-ray wavelengths are lower in the open field regions. Regions of extremely low emission are called coronal holes. The fastest solar wind originates from the large polar coronal holes which, particularly during solar minimum activity, might have extensions all the way to the solar equator (see figure 1, white areas on the solar disk). Measurements in interplanetary space show that this high-speed solar wind has rather constant plasma properties. At the Earth's orbit the flow speed is 750 km s^{-1} (which is 2.7×10^6 km h^{-1}), the proton density is about 2×10^6 m^{-3}, and the electron and proton temperatures are $(1–2.5) \times 10^5$ K respectively. The abundance of alpha particles relative to protons is about 4.5%. The alpha particles are almost six times hotter than the protons and exceed their speed by about 50 km s^{-1}, which is close to the local Alfvén speed. The small traces of other heavy ions, such as O^{6+}, C^{5+} and Mg^{10+}, that are also found in the solar wind, flow with the same speed as the alpha particles. The increase in the flow speed between 0.3 and 1 AU was determined during the HELIOS I and II era to be of the order of 1% in the high-speed wind. Generally plasma properties of the fast solar wind originating from the polar coronal holes vary by less than 10%. (For a more detailed description of the HELIOS I and II solar wind probes see Schwenn and Marsch (1990, 1991).)

In reality the large-scale magnetic field is more complicated than a pure dipole field and several closed field regions can be present at the same time (see SOLAR WIND: MAGNETIC FIELD). The slower solar wind originates from the open magnetic field regions on top of the different streamers, the edges of the streamers and the regions between streamers and coronal holes. These slower streams have plasma properties that are extremely variable. Their speed ranges from 200 to 600 km s^{-1}, their density from 2×10^6 to more than 10×10^6 m^{-3}, the electron and proton temperatures range from $(10–20) \times 10^4$ and $(2.5–15) \times 10^4$ K respectively. Heavy ions in these streams flow either with the same speed as the protons or are slightly slower. The ratio of the alpha to proton temperature is reduced to 3, and the abundance of alpha particles relative to protons ranges from close to 0% to almost 20%. The increase of the flow speed between 0.3 and 1 AU is of the order of 10%, thus larger than in the high-speed wind.

Flow speeds in the near Sun regions

The sound speed in the solar wind plasma is about 40 to 70 km s^{-1} at the Earth's orbit. In solar wind, even the slowest streams are therefore highly supersonic. The transition from sub- to supersonic occurs somewhere close to the Sun, probably between 1.5 to 3.5 solar radii in the high-speed polar wind, and between 3.5 and 8 solar radii in the slower streams. The exact distance from the Sun at which the solar wind speed reaches the

Dirac House, Temple Back, Bristol, BS1 6BE, UK

sound speed is not yet known, partly because we are not sure of the flow speeds in the inner corona, but also because we do not know the particle temperatures (sound speed) very accurately. Given the different properties of streams in interplanetary space one has to assume that their acceleration, as well as other characteristics in the inner corona, are different. The only means to determine these characteristics is by remote observations since no spacecraft has approached the Sun closer than about 60 solar radii. (A spacecraft to probe the solar wind plasma at distances of 5 to 10 solar radii is being planned.) The analysis of remote observations always requires a series of assumptions and approximations, and the results are therefore often a question of interpretation. For example, remote observations of the coronal plasma are always intergrated measurements along a line-of-sight. An example is given in figure 2. This figure shows Thompson scattered polarized white light intensity measured clockwise along the circle shown in figure 1, as a function of position angle, where 0 corresponds to the Sun's north pole. These measurements were carried out daily from day 75 to 135, 1993. The southern polar coronal hole extends roughly from position angle 120° to 220°. It can be seen that the intensity measured inside that region varies significantly both along the time axis and along the position angle, even though the plasma properties measured *in situ* in the high-speed solar wind are rather constant. The intensity changes seen when observing coronal holes remotely are mostly due to changes in the regions surrounding them. At times these surrounding denser regions can veil the coronal holes completely or partially, as in figure 1 at the southern pole. Parameters derived from remote observations represent the plasma properties averaged along the line-of-sight. Thus, particularly measurements carried out in coronal holes will be biased by surrounding regions, and the measurements can only serve as guidelines. Figure 3 shows the electron densities, n_e, derived for a coronal hole region (upper panel) and an equatorial region (lower panel) using polarized white light observations (e.g. Fisher and Guhathakurta 1995).

An estimate of the lower limit on the outflow speed of the electron–proton plasma close to the Sun can be obtained from the mass flux measured *in situ*; these electron densities and the law of mass conservation which states that the flux of protons must be conserved from the solar surface into interplanetary space where *in situ* measurements can be carried out. (The proton flux is defined as the number of protons per m^3 times the proton flow speed times the area expansion of the flow tubes, which is the ratio between the flow tube area on the solar surface, where the stream originates, and the area that this stream covers at a given distance from the Sun.)

The lower limits of the flow speed, v, shown in figure 3, are for the smallest possible flow tube expansion (radial), and the upper limits are for a very large expansion (seven times more than radially). The flow speeds derived from this estimate show that the solar wind accelerates very rapidly in the inner corona, and achieves its almost final flow speeds between 5 and 10 solar radii. This is in agreement with the *in situ* Helios observations which show that there is basically no acceleration of the flow at large distances from the sun. Observations from SOHO indicate that the heavy O^{5+} ions already flow faster than the protons in the inner corona. It seems that, at least in the high-speed wind, the differences between minor ions and protons, seen in the *in situ* measurements, originate in the inner corona with subsequent modification in interplanetary space.

Solar wind speeds of 200 km s^{-1} can be achieved by the pressure gradient force alone. To accelerate the wind to higher speeds, additional energy is needed that has to be deposited in the corona. At present it is not well understood where this additional energy comes from. It is usually assumed that plasma waves play a significant role (see SOLAR WIND: THEORY and CORONAL HEATING MECHANISMS).

Summary

The acceleration of the solar wind plasma to the speeds measured in interplanetary space happens close to the Sun, below 5 solar radii in the fastest streams and at slightly larger distances in the low-speed wind. During this acceleration process the solar wind passes from subsonic to supersonic speeds. The energy source necessary for the acceleration to happen is not yet known but is thought to be high-frequency plasma waves originating either in the lower solar atmosphere or higher up in the corona via a cascade from lower-frequency waves or via locally generated microinstabilities.

Solar Wind Composition

To first order the solar wind composition reflects the composition of the source material, which is photospheric (SOLAR ABUNDANCES). However, there are some important distinctions between the solar wind and solar abundances which will be discussed in the following paragraphs. Since solar wind particles feed the CORONA, and solar energetic particles (*SEPs*; see SOLAR WIND: ENERGETIC PARTICLES) largely originate in the *corona*, elemental and isotopic abundances of matter in the corona, in the solar wind and in solar energetic particles have much in common.

The first solar wind composition measurements were carried out soon after the experimental discovery of the solar wind in the early 1960s. Gradually improved techniques have revealed many details about the acceleration and heating processes operating in the solar atmosphere and corona. With recent improvements of resolution in mass spectrometers carried on the WIND, SOHO and ACE missions, it has also become possible to study abundances of the major isotopic species and hence to gain direct information about the isotopic composition of solar matter. This information is not accessible with optical methods because the natural line widths are much wider than isotopic shifts in spectra. Thus the interest in solar wind composition is twofold and the topics of interest are interrelated. Depending on the viewpoint and the application, studying the solar wind composition and its variability provides on the one hand knowledge about the ways solar matter propagates into the interplanetary space. On the other hand, it provides access to the nuclidic composition of solar matter, information which is relevant for a multitude of astrophysical applications since solar matter is the most important reference point for the isotopic evolution of the solar system. An example of a high-resolution solar wind mass spectrum is shown in figure 1.

An interesting minority within the solar wind population are the so-called 'pick-up ions' which mainly originate from interstellar gas flowing through the inner heliosphere. The elements helium and neon, having the highest first ionization potentials (FIPs), penetrate as neutrals to radial distances of less than 1 AU before they become ionized and can be picked up by the magnetic field which is traveling with the solar wind. Depending on their location of ionization, they relax more or less efficiently to local conditions in the plasma. However, they generally remain in low ionization states which leaves them distinguishable from the rest of the solar wind population. Freshly picked-up particles perform cycloidal motions about the outwards propagating magnetic field; hence their energy distributions reach beyond typical solar wind energies. They are thus particularly susceptible to acceleration in the fields associated with interplanetary shock fronts which are formed e.g. from coronal mass ejections (CMEs) or co-rotating interaction regions (CIRs). In addition to interstellar pick-up ions, other species with low FIPs have been found in the pick-up ion population. These particles originate from evaporating dust grains released from cometary debris and from interstellar dust particles which also can penetrate deep into the inner solar system.

Feeding of the corona with solar matter

Coronal structure and solar wind composition

The corona exhibits a complex spatial and temporally variable structure which becomes visible to the naked eye during solar eclipses. The coronal structure with many details and its dynamic evolution are essentially determined by the configuration of the surface SOLAR MAGNETIC FIELD. Coronal structure and solar wind composition are interrelated in many ways. For a rough characterization two terms are frequently used: '*interstream solar wind*' and '*coronal-hole-associated streams*'. Interstream solar wind is believed to be supplied from the fringes of the equatorial closed loop system. Solar wind particles travelling along open structures on the borderline of magnetic loops exhibit strong variations in composition. This observation has been taken as evidence for multiple sources rapidly connecting and disconnecting thereby producing expanding plasma blobs with complex spatial and magnetic topology which move outwards through the corona. On the other hand, *coronal-hole-associated fast streams* are generally much more stable in their composition.

The balance between the gravitational attraction of the Sun and the Coulomb friction force exerted from outwards travelling protons on minor species seems to play a crucial role in establishing solar wind abundances. In a corona at thermal equilibrium with a temperature of typically 10^6 K, only protons (together with electrons to maintain charge neutrality) reach the escape velocity and move into the interplanetary space. One possibility to visualize the interaction between coronal structures and solar wind composition, which has been extensively studied, uses coronal magnetic flux tubes as elements that guide the solar wind flow. Depending on the flux density or—more precisely—on the phase space density (m^{-6} s^{-3}) in a given flux tube, and depending on the divergence of the flux tube in the solar wind acceleration region, protons couple to minor ions via Coulomb collisions and tend to drag heavy species more or less efficiently according to the individual Coulomb drag factors of each species. An alternative to interplay between coronal structures and the solar wind plasma to populate the solar wind with minor ions involves magnetic fields as carriers of magnetohydrodynamic waves which interact with charged particles. This seems particularly important for coronal-hole-associated solar wind where Coulomb friction seems insufficient to drag minor species. Nevertheless, in this type of solar wind, minor ions are at least as abundant as in the interstream wind, and even helium—although still depleted relative to its solar surface abundance—is better represented in coronal-hole-associated wind than in the typical interstream wind. Hence, momentum added through waves to protons, to

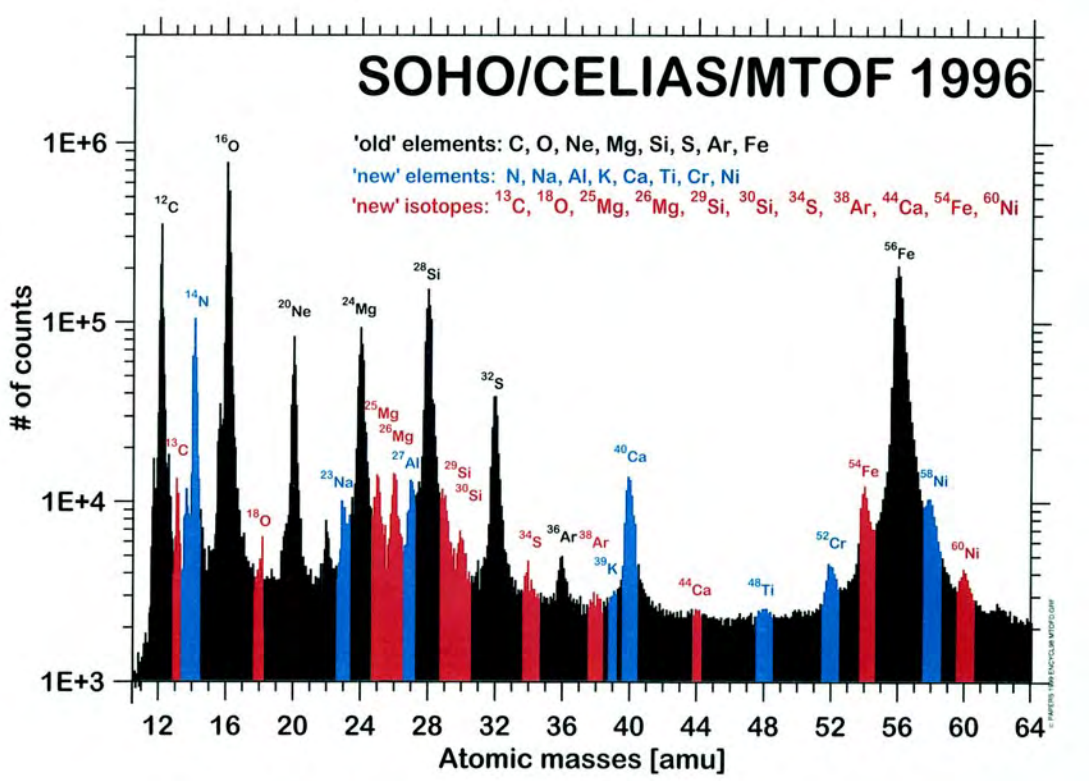

Figure 1. Solar wind elements and isotopes as observed with the MTOF sensor of the CELIAS experiment on SOHO. Elements and isotopes which have been identified for the first time in the solar wind thanks to isochronous mass spectrometry are shown in grey.

helium and to minor species seems crucial to obtain the typical properties of coronal-hole-associated solar wind. This has recently been confirmed with optical observations from the SOHO spacecraft, indicating that ion-cyclotron resonance wave–particle interaction brings minor ions to temperatures as much as a hundred million kelvins, thus exceeding the main gas temperature by one or more orders of magnitude.

Magnetic reconnection is another process to link the magnetic field structures to solar wind abundances. It occurs in the innermost corona and this link to abundances has not yet been extensively explored. Rapidly changing magnetic topologies in reconnection regions around the equatorial streamer belt, which supplies matter to the interstream solar wind, lead to dissipative heating, generation of EUV and soft x-ray radiation, and electric fields which could selectively accelerate particles according to their charge per mass ratio. The EUV radiation originating in the dissipation region and in shock fronts controls the ionization of matter in the underlying chromosphere and thus selectively regulates the replenishment of fresh ions in the corona.

Fractionation effects

Elements

As discussed in more detail elsewhere in this encyclopedia (see TRANSITION REGION: FIRST IONIZATION POTENTIAL EFFECT), the most important elemental fractionation process occurs in the ionization layer situated in the upper chromosphere where species with short ionization times (or low FIPs) are enriched over species with long ionization times typically by factors of 3–5 over photospheric abundances in the interstream solar wind. This effect seems much weaker in coronal-hole-associated wind. Further up in the atmosphere, it appears that wave–particle interaction, which plays a dominant role in the acceleration of coronal-hole-type solar wind, acts in a much more democratic manner than Coulomb drag—including also weakly ionized species—which would otherwise hopelessly remain behind. A summary of solar wind elemental abundances is given in table 1. One conspicuous feature of abundances, in both types of solar wind, is the depletion of helium by typically a factor of 2 relative to hydrogen. Since this feature of helium depletion is also found in the otherwise 'democratically elected' solar abundance representation in coronal holes, it is generally ascribed to the ion–neutral separation process which leaves its imprint on all types of solar wind.

Isotopes

Table 2 is a compilation of recent data on the isotopic composition of the solar wind. The refractory elements which have uniform isotopic composition throughout the

This is a compilation of results obtained with the Apollo/SWC experiment, from lunar soil investigations, from ISEE3/ICI, the SWICS Instrument and the Plasma Ion Spectrometer on Ulysses, and from CELIAS on SOHO (see Bochsler 2000 for more details and a complete list of references). [O] ≡ 8.78 is used as a normalized value for both types of solar wind. It reflects the photospheric abundance of oxygen in dex units as recommended by Holweger (private communication). The standard first ionization times (FITs) are taken from Geiss (1998) and references therein.

solar system and whose solar isotopic composition is presumably well known (e.g. Mg and Si) show no evidence of fractionation between the solar surface and the solar wind to the level of precision which has been achieved to date. In contrast, the volatile elements, i.e. helium, neon and nitrogen, show rather strong variations in the isotopic composition in different solar system samples, such as terrestrial and solar wind. In view of the absence of fractionation effects in the case of the refractories, it can be concluded that the solar wind is generally a faithful representation of the isotopic composition of the solar surface. For the case of the very light element helium with a large relative mass difference between the two stable isotopes, variations of the $^4He/^3He$ ratio of the order of 10% have to be taken into account under normal conditions. Hence, the observed differences between isotopic abundances of *solar wind* volatiles from planetary volatiles are differences which originate at the source; they reflect different histories of *solar* volatiles and volatiles in the rest of the solar system. Isotopic solar wind data represent important benchmarks for models of the early geochemical evolution of the solar system and also put rigid constraints for models describing the acceleration of heavy species in the inner corona.

Since all quantitative models on the FIP effect published heretofore ascribe the depletion of high-FIP elements in the corona essentially to atomic properties, it is no surprise that they predict virtually no isotopic fractionation concomitant with the ion–neutral separation. In view, however, of the sometimes strong variability of the He/H ratio it is possible than an overall isotopic fractionation of the order of 1% per mass unit results for medium-mass elements between the solar surface and the solar wind due to selective acceleration in the corona. This effect is at present, however, still below the detection limit.

Table 2. Isotopic abundances.

Ionic composition

Solar wind particles (as well as SEPs), after passage through the coronal temperature maximum, are usually strongly ionized. Figure 2 is an illustration showing a mass versus mass/charge distribution as obtained with the SWICS instrument of ACE. Protons are suppressed in this instrument to avoid counting overflows; helium appears exclusively as $^4He^{2+}$ together with some traces of $^3He^{2+}$. Carbon and oxygen are almost fully ionized whereas the heavier species usually conserve their innermost electron shells, e.g. Fe is most conspicuous in the mass per charge range from 4.67 to 7.0 (Fe^{12+} through Fe^{8+}). The ionization balance of minor species is predominantly established via electron collisions in the corona at about a distance of $1R_\odot$ from the solar surface. The ionization rates, and to some degree also the recombination rates, depend on the local electron temperatures. In the dense, inner parts of the corona, collisions are sufficiently frequent to establish a quasi-equilibrium distribution of charge states. As the ions move further out, the ambient electron density decreases, collisional reactions are gradually supressed and the result is a relatively wide distribution of charge states which 'freezes' and remains unaltered throughout the heliosphere. Charge states of minor species measured far from the Sun provide a useful means to deduce the electron temperatures in the corona. Another application is reminiscent of hydrological methods: because of their conservative properties, charge states of minor ions are now frequently used as reliable tracers to map distorted solar wind flux tubes back to their source in the solar corona.

Coronal mass ejection related solar wind composition

Only recently has it become possible to reliably determine the rapidly varying composition of minor ions in CME-related solar wind. A long-known feature is the sometimes enhanced He/H ratio which has been taken as evidence for gravitational stratification in the undisturbed corona. Similar effects might be responsible for the sometimes observed mass-dependent fractionation. The most surprising recent discovery, however, is a temporary strong enrichment of ^{3}He, probably due to the same mechanism which produces the even more dramatic enrichments of ^{3}He in impulsive flare particles. With the improved time resolution of modern instrumentation, less surprisingly, extremely unequilibrated charge state distributions, e.g. large amounts of $O^{2+,3+,4+}$ together with otherwise common solar wind species O^{6+} and O^{7+}, have been observed with ACE and WIND.

Historical solar wind

Lunar soil and also the soil in the surface layers of asteroids are constantly exposed to the solar corpuscular irradiation. Particles at solar wind energies penetrate typically to depths of 0.1 μm into dust grains and are stored within these grains for extended periods depending on their diffusive behavior within the mineral and depending on the further history of the grains. Lunar soil undergoes continuous sputtering from solar and cosmic ray particles, combined with erosion from micrometeorite impacts. Because of the occasional covering of soil layers with freshly excavated material from larger impacts, it is possible that some solar particle records are buried within the asteroidal and lunar regolith for billions of years, thus storing an archive of most of the solar wind history in the near-Earth environment and the inner solar system. Some tracers such as ^{40}Ar, which is a decay product from ^{40}K, and volatile fission products from decaying ^{235}U emanating from the lunar interior and re-implanted with the solar wind into surface material make it possible to reliably date the irradiation epochs. The lunar record has been intensively investigated. The results are somewhat controversial. One major problem is the allocation of suprathermal particles and SEPs which exhibit somewhat different isotopic abundances and seem overabundant with respect to the solar wind population. There is general agreement that the isotopic composition of the solar wind has not changed significantly during the last few billion years, except for the case of the ^{15}N/^{14}N abundance ratio which, however, must be attributed to extrasolar contributions. The apparent invariance of the ^{3}He/^{4}He abundance ratio in the solar wind over this extended period bears some significance for the history of the Sun, since it indicates that the outer part of the Sun (from $M_r \geq 0.5M_\odot$ to the base of the outer convective zone) has never undergone mixing since the ignition of the nuclear fuel.

The elemental abundances of the heavy noble gases indicate, however, that there has been a secular modification in solar wind composition over the past few billion years which is possibly related to a change in solar activity (i.e. that the ancient, in-ecliptic solar particle fluence contained significantly more CME-related, transient solar wind than the more recent record). This provides an additional boost to the study of CME-related composition which has only recently become possible owing to the considerably improved time resolution of modern particle instrumentation.

Solar Wind Plasma Waves

Numerous types of waves exist in the SOLAR WIND. Since the solar wind is a plasma (i.e. an ionized gas) these waves are usually called plasma waves. Plasma waves play a fundamental role in determining the physical properties of the solar wind. In an ordinary gas, the gas is maintained in a state of thermal equilibrium by collisions. In thermal equilibrium the particle velocities have a universal isotropic form called a Maxwellian velocity distribution (see Haliday and Resnick 1981). Since the solar wind is very tenuous, collisions are extremely rare. An energetic particle from the Sun can reach the Earth without suffering a single large-angle collision. Under these conditions waves play a role similar to collisions. As the solar wind streams outward from the Sun, various dynamical effects cause the particle velocity distributions to deviate from a Maxwellian, often in the form of beams aligned along the magnetic field or various types of anisotropies. These non-equilibrium features eventually cause the growth of waves via various types of plasma instabilities. As the waves grow to large amplitudes, the waves interact with the particles in such a way as to eliminate the non-equilibrium feature that is responsible for the wave growth, thereby driving the velocity distributions toward thermal equilibrium, i.e. a role very similar to collisions. Waves also carry energy and momentum over long distances, and are believed to play a fundamental role in heating the solar CORONA and accelerating the solar wind. In this article we will describe the various types of waves that occur in the solar wind and discuss the role these waves play in determining the properties of the solar wind (see also SOLAR WIND: GLOBAL PROPERTIES; KINETIC PROPERTIES).

Plasma wave modes

Many types of waves can exist in a plasma. Figure 1 shows a plot of the propagation velocity, v, as a function of frequency, f, for the most commonly observed waves in the solar wind. This plot is representative of conditions at a radial distance of 1 AU (astronomical unit), near the orbit of the Earth. The propagation velocity is determined by a number of parameters, including the speed of light, c, the magnetic field strength, B, the particle number densities, N_s, of the various species in the plasma (s = e for electrons, and s = i for ions) and the temperatures, T_s, of these species. It is convenient to convert these parameters into a series of characteristic frequencies and speeds. The most important characteristic frequencies of a plasma are the electron cyclotron frequency, $f_{ce} = (1/2\pi)eB/m_e$, the ion cyclotron frequency, $f_{ci} = (m_e/m_i)\,f_{ce}$, the electron plasma frequency, $f_{pe} = (1/2\pi)(N_e e^2/\epsilon_0 m_e)^{1/2}$, and the ion plasma frequency, $f_{pi}(m_e/m_i)^{1/2} f_{pe}$. In these formulas e is the electronic charge, ϵ_0 is the permittivity of free space, m_e is the electron mass and m_i is the ion mass. The most important characteristic speeds of a plasma are the Alfvén speed, $V_A = B/(\mu_0\rho_m)^{1/2}$, the electron sound speed $V_e = (\gamma kT_e/m_e)^{1/2}$ and the ion sound speed $V_s = (\gamma kT_e/m_i)^{1/2}$, where μ_0 is the permeability of free space, ρ_m is the mass density and γ is the adiabatic compression factor. For a further discussion of these various quantities, see Stix (1992).

As can be seen in figure 1 the propagation velocity breaks up into a number of clearly defined branches, each of which corresponds to a well-defined mode of propagation. These modes are given specific names. Starting at the lowest frequencies, there are three modes of propagation called the magnetohydrodynamic (MHD) modes. These modes can be ordered according to the propagation velocity and are often called the fast magnetosonic mode, the Alfvén mode and the slow magnetosonic mode. The propagation velocities are given by

$$v_f^2 = \tfrac{1}{2}(V_A^2 + V_S^2) + \tfrac{1}{2}[(V_A^2 - V_S^2)^2 + 4V_A^2 V_S^2 \sin^2\theta]^{1/2} \quad (1)$$

$$v_A^2 = V_A^2 \cos^2\theta \quad (2)$$

$$v_s^2 = \tfrac{1}{2}(V_A^2 + V_S^2) - \tfrac{1}{2}[(V_A^2 - V_S^2)^2 + 4V_A^2 V_S^2 \sin^2\theta]^{1/2} \quad (3)$$

where v_f, v_A and v_s are the propagation velocities of the fast, Alfvén and slow modes. The angle θ, called the wave normal angle, is the angle between the direction of propagation and the magnetic field. As the name MHD implies, these modes involve a mixture of both magnetic and hydrodynamic (fluid) effects. The magnetic effects are represented by the Alfvén speed, V_A, which is proportional to the magnetic field strength, and the hydrodynamic effects are represented by the sound speed, V_s, which is proportional to the square root of the temperature. All three modes have electric and magnetic fields of the type that are usually associated with an electromagnetic wave. The fast and slow magnetosonic modes both have compressional motions of the type normally associated with sound waves (hence the dependence on the sound speed, V_S) and transverse motions of the type usually associated with electromagnetic waves (hence the dependence on V_A). The Alfvén mode on the other hand is a purely transverse mode and has no compressional motions (hence no dependence on the sound speed, V_S). The Alfvén mode was first discovered by Alfvén (1942) and is often called the shear Alfvén mode. For a discussion of MHD WAVES, see also Alfvén and Falthammer (1963). Under normal conditions the propagation velocities of all three MHD modes are substantially less than the solar wind velocity, V_{SW}, which is usually about 400 km s^{-1} (see figure 1).

Proceeding upward in frequency, one can see from figure 1 that as the frequency approaches the ion cyclotron frequency, f_{ci}, the propagation velocities of the fast magnetosonic mode and the Alfvén mode begin to deviate from the constant values given by equations (1) and (2). As the frequency approaches the ion cyclotron frequency the propagation velocity of the Alfvén mode begins to decrease rapidly, and it goes to zero at a frequency slightly below the ion cyclotron frequency. The exact frequency of the propagation cutoff depends on the wave

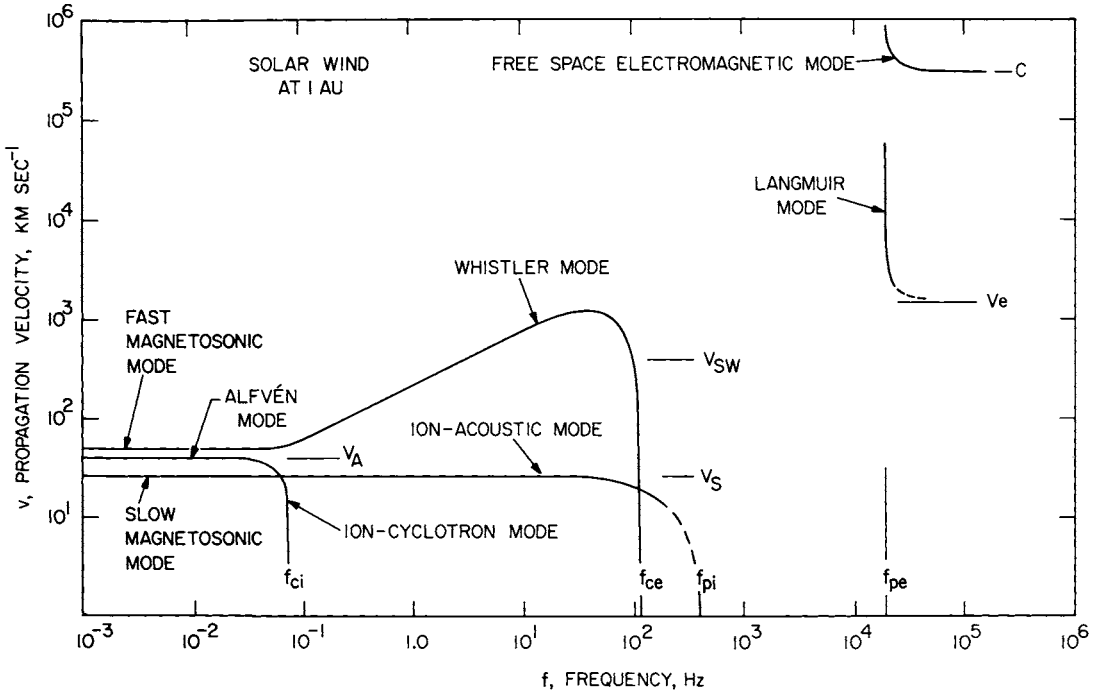

Figure 1. The propagation velocity of various plasma wave modes in the solar wind as a function of frequency for typical conditions at 1 AU.

normal angle. In this frequency range, near the ion cyclotron frequency, the Alfvén mode is usually called the ion cyclotron mode. Above the ion cyclotron frequency the Alfvén mode cannot propagate at any wave normal angle. For the fast magnetosonic mode, the propagation speed increases as the frequency crosses the ion cyclotron frequency, eventually varying as the square root of the frequency. This increase continues until the propagation velocity reaches a peak and then decreases rapidly, going to zero at a frequency slightly below the electron cyclotron frequency, f_{ce}. The exact frequency of this propagation cutoff depends on the wave normal angle. Above the electron cyclotron frequency the whistler mode cannot propagate at any wave normal angle. In the frequency range between the ion cyclotron frequency and the electron cyclotron frequency, the fast magnetosonic mode is usually called the whistler mode, after whistling signals generated by lightning that were discovered by Storey (1953). As the frequency of the slow magnetosonic mode increases the propagation velocity remains essentially unchanged as the frequency crosses the ion cyclotron frequency. Although the slow magnetosonic mode is an electromagnetic wave, at high frequencies, above the ion cyclotron frequency, the wave magnetic field becomes very weak and the wave takes on the properties of an electrostatic wave, with an electric field but no magnetic field. In this high-frequency regime the slow magnetosonic wave has many of the properties of an acoustic wave and is often called an ion acoustic wave. As the frequency approaches the ion plasma frequency, the propagation velocity of the ion acoustic mode goes to zero at the ion plasma frequency. The ion acoustic mode cannot propagate at frequencies above the ion plasma frequency. The ion acoustic mode is strongly damped by a collisionless damping process called Landau damping (Landau 1946). This damping arises because the propagation velocity is comparable with the ion thermal speed, which allows some of the wave energy to be absorbed by resonant interactions with ions moving at approximately the same velocity as the wave. The damping becomes particularly strong when the frequency is near the ion plasma frequency. This region of strong damping is shown by a dashed curve in figure 1. The damping is weak only if the electron temperature is substantially greater than the ion temperature, $T_e \gg T_i$, which raises the propagation speed of the wave well above the ion thermal speed (note that the ion sound speed, V_S, depends on the electron temperature and not on the ion temperature). The condition $T_e \gg T_i$ is only rarely satisfied in the solar wind.

At frequencies above the ion plasma frequency, no waves can propagate until the frequency reaches the electron plasma frequency, f_{pe}. At frequencies near and above the electron plasma frequency two modes of propagation occur, the free space electromagnetic mode and the Langmuir mode. The free space electromagnetic mode is a purely transverse wave with the electric and magnetic fields oriented perpendicular to each other and to the direction of propagation. The free space electromagnetic mode propagates at a speed given by $v = c/[1 - (f_{pe}/f)^2]^{1/2}$. Note that the propagation velocity

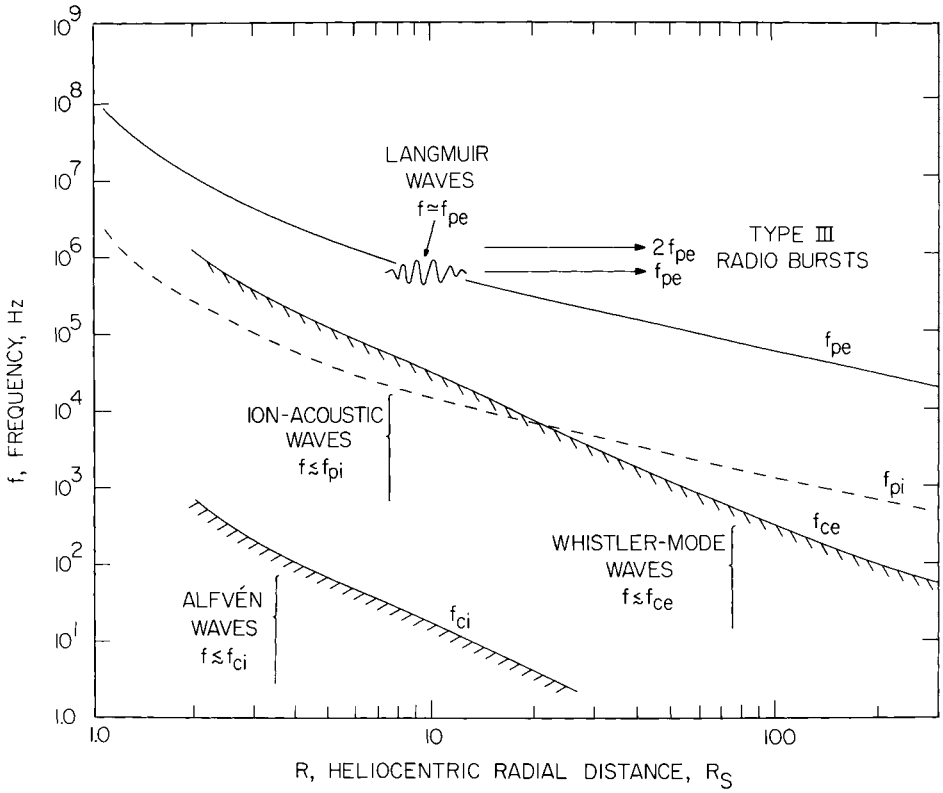

Figure 2. A plot of various characteristic frequencies of the solar wind plasma as a function of the heliocentric radial distance from the Sun in solar radii, R_S. The Earth is at a heliocentric radial distance (1 AU) of about $200R_S$.

of the free space electromagnetic mode goes to infinity at the electron plasma frequency and approaches the speed of light, c, at high frequencies. Since the propagation velocity is always greater than the velocity of any of the particles in the plasma, this mode cannot interact resonantly with the plasma particles and, therefore, does not experience Landau damping. The Langmuir mode is a purely longitudinal electrostatic wave (i.e. it has an electric field, but no magnetic field) and propagates at a speed given by $v = V_e/[1 - (f_{pe}/f)^2]^{1/2}$. Note that the propagation velocity of the Langmuir mode goes to infinity at the electron plasma frequency, and approaches the electron sound speed, V_e, at high frequencies. Since the characteristic propagation speed of this wave is near the electron thermal speed this wave is subject to strong Landau damping. The region of strong damping is indicated by a dashed curve in figure 1. The damping is small only for wave frequencies very close to the electron plasma frequency, $f \approx f_{pe}$, where the propagation speed goes to infinity. Thus, the Langmuir wave propagates with low damping only in a narrow frequency band around the electron plasma frequency, essentially a pure oscillation at the electron plasma frequency. The wave is also sometimes called an electron plasma oscillation.

To develop a complete understanding of the propagation of plasma waves in the solar wind we must consider the radial variation of the various characteristic frequencies of the plasma. Figure 2 shows a plot of the ion cyclotron frequency, the electron cyclotron frequency, the ion plasma frequency and the electron plasma frequency as a function of heliocentric radial distance. As one can see, all of the characteristic frequencies decrease with increasing radial distance from the Sun. To understand the detailed radial dependence we must discuss the radial variation of the magnetic field strength and the electron density. In the radial distance range from about $2R_S$ to $100R_S$, the magnetic field is directed almost radially outward from the Sun (Hundhausen 1972). Under these conditions conservation of magnetic flux shows that the magnetic field strength must vary approximately as $1/R^2$. Therefore, the cyclotron frequencies, f_{ci} and f_{ce}, vary as approximately as $1/R^2$ over this radial distance range. Because of strong multipole magnetic fields near the Sun, inside of about $2R_S$ it is not possible to give a specific prediction for the radial variation, except to say that it is likely to be steeper than $1/R^2$. Beyond about $100R_S$ the magnetic field develops a significant azimuthal component due to solar rotation, eventually varying as $1/R$ at large distances from the Sun. At radial distances beyond about $7R_S$ (Hundhausen 1972), where the solar wind is supersonic, conservation of particle flux shows that the electron density must vary as $1/R^2$. The ion and electron plasma frequencies, f_{pi} and f_{pe}, which

are proportional to the square root of the electron density, must then vary as $1/R$ in this region. Inside of about $7R_S$, where the solar wind flow is subsonic, it is not possible to give a simple prediction for the radial variation of the plasma frequency, except to say that it is likely to be steeper than $1/R$.

Observations

To illustrate the types of plasma waves that are observed in the solar wind, we next show examples of each of the wave modes discussed in the previous section. To be consistent with the previous discussion, we start with the lowest frequencies and proceed to the highest frequencies.

Alfvén waves

Alfvén waves were first discovered in the solar wind by Unti and Neugebauer (1968) and Belcher *et al* (1969) using data from the Mariner 2 and 5 spacecraft. These waves are illustrated in figure 3, which is from Davis (1972). The top three plots shows three orthogonal components of the wave magnetic field, b_R, b_T and b_N. These components were obtained by subtracting the average background magnetic field from the measured field. Superposed on the same plots are the corresponding components of the plasma flow velocity fluctuation, u_R, u_T and u_N. The bottom plot shows the magnitude of the magnetic field, B, and the plasma density, N. The highly irregular variations in the magnetic field and flow velocity, on time scales ranging from a few hours to a few minutes, are Alfvén waves. Note that there is no evidence of corresponding variations in either the magnetic field magnitude or the plasma density. The absence of fluctuations in the magnetic field magnitude and in the plasma density indicates that the waves are non-compressional, thereby uniquely identifying the mode of propagation as the Alfvén mode. Note that the flow velocity variations are in phase (positively correlated) with variations in the corresponding magnetic field components. From the direction of the average background magnetic field during this event (directed inward, toward the Sun) and the positive correlation between the wave magnetic field and the flow velocity fluctuation, one can show that the waves are propagating outward, away from the Sun.

It is now widely believed that the Alfvén waves observed in the solar wind are excited by turbulent fluctuations near the Sun and that the waves propagate outward to great distances from the Sun, probably several AU or more. Although fast and slow magnetosonic waves are sometimes detected, the dominant wave energy is almost always in the shear Alfvén mode. The small amounts of energy in the fast and slow magnetosonic modes are most likely due to the fact that these modes are compressional, which leads to strong damping. In contrast, the Alfvén mode has very little damping, primarily because of the transverse (i.e. non-compressional) nature of this mode.

Ion cyclotron and whistler mode waves

As the Alfvén wave propagates outward from the Sun the ion cyclotron frequency decreases, eventually approaching the frequency of the wave (see figure 2). As the ion cyclotron frequency approaches the wave frequency the propagation velocity begins to decrease (see figure 2), and the wave becomes strongly damped

by a process called ion cyclotron damping. Ion cyclotron damping occurs when the Doppler-shifted wave frequency seen in the frame of reference of an ion moving along the magnetic field matches the cyclotron frequency of the ion. The resulting interaction accelerates the ion and causes a loss of wave energy. The net effect is that the wave energy is absorbed as the ion cyclotron frequency approaches the wave frequency, thereby transferring the wave energy to the solar wind. This cyclotron resonant absorption process is believed to provide a significant heat input into the solar wind.

Evidence of this ion cyclotron absorption process is illustrated in figure 4, which shows a magnetic field spectrum observed by the Helios 2 spacecraft at a radial distance of about 0.3 AU. At the lowest frequencies, below about 10^{-2} Hz, the spectrum is mainly due to Alfvén waves. The intensity can be seen to vary as approximately f^{-1}. Proceeding upward in frequency a noticeable change in the spectral slope, from about f^{-1} to $f^{-1.7}$, can be seen as the frequency approaches the ion cyclotron frequency, f_{ci}, followed by a very abrupt decrease in intensity above the ion cyclotron frequency. The change in slope and the rapid decrease in the intensity near the ion cyclotron frequency are believed to be due to absorption of the Alfvén wave energy by either ion cyclotron damping or possibly Landau damping (Leamon *et al* 1998). Proceeding to higher frequencies, above the ion cyclotron frequency, a weak but persistent level of magnetic noise can be seen at frequencies extending up to about the electron cyclotron frequency. These frequencies are much too high to be caused by MHD waves and are almost certainly due to whistler mode waves (see figure 1). An alternative possibility, that they might be ion acoustic waves, is ruled out by the fact that, at these frequencies, the ion acoustic wave is almost purely electrostatic and would have no magnetic field. The origin of these whistler mode waves is poorly understood. Since whistler mode waves experience a significant level of cyclotron damping due to interactions with the relatively hot electrons ($T_e \simeq 10^5$ K) present in the solar wind, it seems unlikely that the waves could reach the spacecraft from a source near the Sun. The most likely explanation is that they are generated locally by anisotropies in the solar wind electron distribution. Anisotropic velocity distributions are known to be a free energy source for whistler mode waves (Kennel and Petschek 1966).

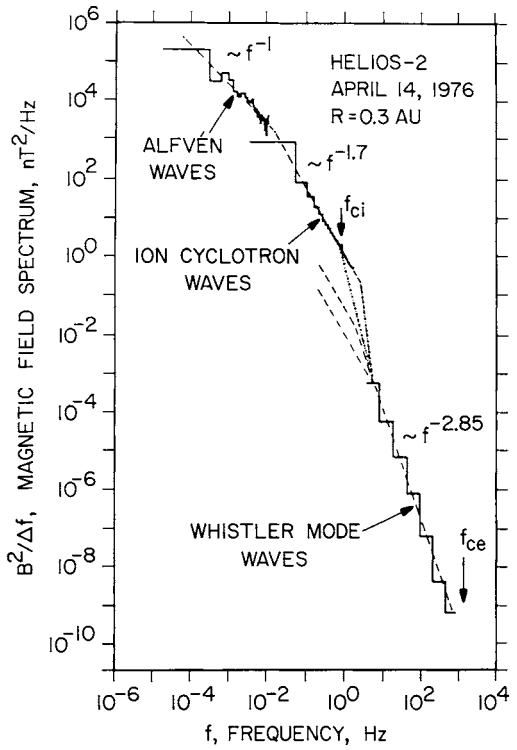

Figure 4. A magnetic field spectrum showing Alfvén waves, ion cyclotron waves and whistler mode waves detected by the Helios 2 spacecraft at a heliocentric radial distance of 0.3 AU. Illustration adapted from Denskat *et al* (1983).

Ion acoustic waves

Since the ion acoustic mode is normally very heavily damped by Landau damping, one would not expect to detect ion acoustic waves in the solar wind. Nevertheless, electrostatic waves have been detected in the solar wind that are believed to be ion acoustic waves. A frequency–time spectrogram showing a series of electrostatic bursts extending up to about 6 kHz that are believed to be ion acoustic waves is shown in figure 5. These waves were detected by the plasma wave electric field antenna on the Voyager 2 spacecraft at a heliocentric radial distance of 1.66 AU. The ion plasma frequency at this time is estimated to be about 300 Hz. Since the ion acoustic mode cannot propagate at frequencies above the ion plasma frequency, one may wonder how the frequencies could extend upward to frequencies as high as 6 kHz. The reason is that ion acoustic waves have very short wavelengths, which cause very large Doppler shifts. Under the conditions present in the solar wind near 1 AU, the frequency is almost entirely determined by Doppler shift, so there is no simple relationship to the ion plasma frequency. The Doppler shift is approximately $\Delta f = V_{SW}/\lambda$, where λ is the wavelength. The minimum wavelength of an ion acoustic wave is $2\pi\lambda_D$, where λ_D is the Debye length (Stix 1992), so the maximum frequency is approximately $f_{Max} = V_{SW}/2\pi\lambda_D$. For typical conditions at 1.66 AU the Debye length is about 10 m, which for a solar wind velocity of 400 km s^{-1} gives a maximum frequency of about 6 kHz, in good agreement with the observed upper frequency limit of the emissions in figure 5. Since the Debye length varies inversely with the square root of the electron density, the maximum frequency is predicted to increase inversely with radial distance from the Sun, in agreement with observations (Gurnett *et al* 1979).

At present the mechanism by which ion acoustic waves are produced in the solar wind is poorly understood. The intensity of these waves has been shown

by Gurnett *et al* (1979) to increase rapidly with decreasing distance from the Sun, which would seem to imply a solar origin. However, since the ion acoustic mode is strongly damped, it is highly unlikely that the waves could have propagated to the spacecraft from a source near the Sun. It is much more likely that they are produced locally. Both laboratory and theoretical studies show that the ion acoustic mode can be driven unstable by a shift between the average electron and ion velocities, such as occurs when a strong electrical current is present. The threshold current for the onset of the current-driven ion acoustic instability is very high when the electrons and ions have comparable temperatures, as it often is in the solar wind, but decreases rapidly as T_e/T_i increases. Although evidence exists that ion acoustic waves are more likely to be observed when T_e/T_i is large, electrical currents sufficiently strong to trigger the ion acoustic instability are usually not present in the solar wind. However, the heat flux carried outward from the Sun by solar wind electrons causes a similar shift between the core electron and ion velocities. Our present view is that the ion acoustic waves are probably driven by the solar wind heat flux. If so, ion acoustic waves could play a significant role in regulating the heat flux carried outward from the Sun. For a further discussion of ion acoustic waves in the solar wind, see Gurnett (1991).

Langmuir waves and type III solar radio bursts

For many years it has been known that a class of solar radio emissions called the type III radio bursts occurs in which the frequency drifts rapidly downward with increasing time (Wild 1950; see also SOLAR FLARES: RADIO

Copyright © Nature Publishing Group 2001

BURSTS). The time scale of the frequency drift varies from a few seconds at frequencies in the hundred MHz range to tens of minutes in the hundred kHz range. In a classic paper, Ginzburg and Zheleznyakov (1958) proposed that these radio bursts are produced by a two-step process in which (1) Langmuir waves are first excited by the energetic electrons emitted by a solar flare and (2) the Langmuir waves are converted to electromagnetic radiation at f_p and $2f_p$ by non-linear mode conversion processes. The downward frequency drift is caused by the decreasing electron plasma frequency encountered by the solar flare electrons as they stream outward from the Sun. The radiation at f_p is believed to be generated by a non-linear interaction between the Langmuir wave and a low-frequency wave such as an ion acoustic wave, and the radiation at $2f_p$ is believed to be generated by a non-linear interaction between two oppositely propagating Langmuir waves. The two-step generation process was confirmed by Gurnett and Anderson (1976) who made the first direct *in situ* observations of the Langmuir waves responsible for a type III radio burst using wave electric field measurements on the Helios 2 spacecraft.

A frequency–time spectrogram of a type III radio burst and its associated Langmuir wave emissions is shown in figure 6. This event was detected by wave electric field measurements on the Galileo spacecraft at a heliocentric radial distance of 0.98 AU. Although several type III radio bursts can be seen, the one of interest starts at 0745 UT (UNIVERSAL TIME). This event is associated with a solar flare that occurred at 0730 UT. As can be seen the type III radio burst associated with this flare was first detected at a frequency of about 6 MHz. The radio emission rapidly sweeps downward in frequency, eventually reaching a frequency of about 40 kHz after about 1 h. The Langmuir waves responsible for this radio emission can be seen from about 0835 to 1010 UT at a frequency of 23 kHz, which is the local electron plasma frequency. This onset time corresponds almost exactly to the arrival time of electrons with energies of about 100 keV from the solar flare, as determined from the energetic particle detector on Galileo; see Gurnett *et al* (1993). For this event the primary emission is believed to be at $2f_p$, which would produce radiation at a frequency of about 46 kHz. Note that the Langmuir waves responsible for radiation at frequencies higher (or lower) than 46 kHz cannot be detected, since these waves must occur closer to (or farther from) the Sun. Other studies have shown that both the intensity of the Langmuir waves and the emissivity of the type III radio events decrease rapidly with increasing radial distance from the Sun (Gurnett *et al* 1980), more or less in agreement with expectation for the $2f_p$ mode conversion process. However, the details of the mode conversion process, and the relative importance of emission at f_p and $2f_p$, remain poorly understood. For a discussion of the dynamics of Langmuir waves and the possible mode conversion processes that could be involved, see Robinson *et al* (1993).

Future research

In the sections above we have reviewed the basic characteristics of plasma waves in the solar wind. Although much is known about these waves at radial distances in the vicinity of the Earth's orbit, very little is known in the near vicinity of the Sun. The intensities of almost all the waves discussed increase rapidly with decreasing distance from Sun. Since many of the waves, such as whistler mode waves, ion acoustic waves and Langmuir waves, are locally generated, it is important that direct *in situ* measurements be made in the region close to the Sun, where the primary heating and acceleration of the solar wind are occurring. At present the closest measurements to the Sun are from the Helios 2 spacecraft, which approached to within 0.29 AU of the Sun. Hopefully, in the not-too-distant future a mission called the SOLAR PROBE will be sent much closer to the Sun, possibly to as close as $4R_S$, and will be instrumented to study plasma waves.

Solar Wind Shock Waves and Discontinuities

Shock waves in a fluid are observed as abrupt changes in all physical parameters of the fluid, such as flow speed, density, pressure and magnetic field, but, most important, in temperature, which ensures that entropy increases from the upstream to downstream side of the shock ramp. For an ordinary shock wave to exist in a fluid, its speed through the fluid must be faster than the speed of sound in the fluid. However, when a magnetic field is present, other characteristic signal speeds, which depend on the magnetic field's strength and direction, are also important in characterizing the shock. Shock waves in the solar wind, which is an ionized and magnetized fluid or PLASMA, are often referred to as interplanetary shocks. These rich events are of interest in themselves, for example, in studying steepened nonlinear waves in a so-called collisionless plasma, and as solar wind consequences of solar events, such as ejected solar mass or strong magnetic fields ramming into the upstream solar wind (see COLLISIONLESS PROCESSES IN ASTROPHYSICAL PLASMAS). They are also important as accelerators of energetic particles, as generators of radio waves and plasma waves and as triggers of geomagnetic phenomena.

In general, relatively abrupt changes in the intensity and/or direction of the magnetic field of the solar wind, i.e. in the interplanetary magnetic field (IMF), are called directional discontinuities, or simply discontinuities. In a sense shock ramps are a special class of discontinuities but will be treated separately here. Non-shock discontinuities are also important in the solar wind and are of interest in understanding its characteristics as a whole, especially in defining the boundaries of its various specific internal structures. The boundary of the Earth's magnetosphere is a directional discontinuity (see MAGNETOSPHERE OF EARTH).

The observations of interplanetary shocks and discontinuities have been the source of special interest to the space science community for over three decades, starting with their first observations by MARINER MISSION 2 and the early IMP spacecraft in the middle 1960s. In particular, it has been shown that generally these structures obey MAGNETOHYDRODYNAMIC (MHD) theory, but their very fine-scale features, which lie outside of the range of applicability for MHD theory, are not as well understood. The ability to make rapid measurements of magnetic field and plasma quantities by state of the art instruments on spacecraft provides an opportunity to investigate interplanetary shock waves and discontinuities on a fine scale for a broad variety of types of events and conditions. By contrast, widely separated multiple spacecraft allow study of the poorly known large-scale shape, evolution and coherence of these structures. The latter studies can be done even for distances encompassing the outer reaches of the solar system by observations from the Voyager 1 and 2 spacecraft, which are now (1999) farther than 70 AU from the Sun. We know, for example, that a shock wave may travel from the Sun past Earth's orbit for many 10s of AU. Hence, a very broad range of spatial scales are being investigated, i.e. from ~40 km to ~80 AU (12×10^9 km).

Shock waves in the solar wind

Definition and types of shocks

To qualify as a shock wave in a magnetized fluid, the changes in the fluid quantities (i.e. N, density; T, temperature; $\boldsymbol{B}$, magnetic field; $\boldsymbol{V}$, flow velocity) across its typically abrupt ramp must satisfy special equations of MHD, called the Rankine–Hugoniot equations, which are expressions for the conservation of energy, mass flux, and momentum flux, and Maxwell's equations of electricity and magnetism, including magnetic flux conservation. The shock parameters of general interest that help to characterize the shock include the following: upstream Mach number (which is proportional to the shock's speed relative to that of the upstream fluid and is also a measure of its 'strength'), mode or type (signifying its wave nature: fast, slow, or intermediate), obliquity (parallel, perpendicular, oblique, depending on the angle between the upstream magnetic field direction and the shock surface normal), sense of travel (forward or reverse, i.e. moving generally 'along with' or 'against' the solar wind flow direction, respectively), and sometimes shocks are separated according to their cause.

What separates the nature of solar wind shocks from those we experience on Earth (that are caused, say, by a fast-moving jet airplane) is the very low density of the solar wind and the existence of a magnetic field 'frozen into' the ionized solar wind's gas. The magnetic field's presence complicates the study of shocks in space. For example, for ordinary gasdynamic shocks in our atmosphere there is only one 'type', the sound wave mode, and obliquity has no meaning. The magnetic field, however, plays a crucial role in the solar wind by coupling its constituent particles, so that this otherwise low-density collisionless plasma acts as if it were a collisional ionized gas. Both ordinary gasdynamic shocks and solar wind shocks are characterized by Mach numbers. The ordinary one is defined as the ratio of the relative speed of the shock (i.e. with respect to the fluid's upstream flow speed) to the speed of sound, and is called the sonic Mach number. The relative speed is the speed of the fast 'piston' that is responsible for causing the shock, such as the speed of the fast jet plane. This Mach number must be greater than 1.0. Hence, high Mach number shocks are 'strong' ones that move fast. However, for a magnetized fluid several Mach numbers can be defined. These are characterized by the strength and direction of the magnetic field, as well as depending on the speed of sound as ordinary shocks do. An example of such an MHD Mach number is the Alfvén Mach number, which is the ratio of the shock speed (relative to the fluid) to the ALFVÉN SPEED, a characteristic signal speed in a plasma. The Alfvén speed depends directly on the magnetic field strength and inversely on the square root of the solar wind density. Other MHD wave speeds are called the slow- and fast-mode speeds

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

and the related Mach numbers depend on combinations of the Alfvén and sound speeds.

The most common types of shocks in the solar wind at 1 AU are fast forward shocks. In the case of fast shocks generally both the upstream sonic and Alfvén Mach numbers must be greater than 1.0. Modern spacecraft observations are revealing many slow shocks, apparently because of the increased sensitivity of the advanced measuring instruments; for these the upstream Alfvén Mach numbers are less than 1.0, but the upstream sonic Mach numbers must be greater than 1.0. So-called intermediate shocks are very rare and, in fact, are believed by some not to be stable enough to be observed at all. However, a team of scientists in 1993 using Voyager data are believed to have identified such a shock. Of further interest is whether the shock is traveling in a forward or reverse sense with respect to the Sun in a solar wind frame of reference. Hence, four categories of shocks are generally of interest in solar wind studies: fast forward, fast reverse, slow forward and slow reverse, each having its unique signature. Figure 1 shows the sense of change of physical quantities for these four types of shocks. The Earth's bow shock is a fast reverse shock, for example, because the shock travels against the solar wind flow direction, and it is of a 'fast-mode wave' nature. Even though a bow shock of a planet occurs in the solar wind, and is therefore an interplanetary shock, it is not always classified as one, because it is viewed as a standing shock associated with a planet. All solar system planets that have been visited by spacecraft (i.e. all but Pluto) have been observed to have bow shocks. Figure 2 shows how the magnetic field ($\boldsymbol{B}$) and solar wind velocity ($\boldsymbol{V}$) change in strength and direction across the ramp for various kinds of interplanetary shocks, as denoted. A perpendicular shock signature (in N, T, B, V) appears to be very abrupt and squared-off like those shown in figure 1. However, a parallel shock, often referred to as a pulsation shock, has an oscillatory field nature, and the average change in B across it is ideally zero, but N, T and V all change across it.

Shock ramp thickness can vary considerably depending on the upstream conditions and on the shock type and obliquity; the abrupt vertical change of the physical quantities in figure 1 denotes the ramp. In actuality there is often a shock 'foot' before the ramp and an 'overshoot' region after the ramp whose specific signatures depend on the surrounding plasma's properties, specifically the values of N, T and B. A typical oblique shock ramp thickness is about 100 km–150 km at 1 AU from the Sun, i.e. at most about the distance between Baltimore, MD, and Philadelphia, PA. Very rapid sampling magnetometers in space allow the field measurements of such a thin ramp. Parallel shocks are much thicker.

Sources of shocks

Blast waves at the Sun, solar wind corotating stream interactions, caused by fast streams ramming into slow ones, rapid gas clouds (called driver gas or coronal mass ejections) from the Sun and/or fast-moving, strong, twisted magnetic field structures in the solar wind acting like huge driving magnetospheres (called magnetic clouds or magnetic flux ropes), plowing into the upstream solar wind, are all possible causes of interplanetary shock waves (see CORONAL MASS EJECTIONS: OBSERVATIONS, CORONAL MASS EJECTIONS: THEORY). Most of the interplanetary shocks seen in the solar wind near Earth, especially during the active part of the SOLAR CYCLE, arise near the Sun and travel to the Earth, usually driven by some fast-moving interplanetary structure. Bow shocks are a separate type again. These are standing shocks which arise from the solar wind ramming, at a fast enough speed, into a planet's outer environment, which is the magnetic field in Earth's case and the ionosphere in Venus' case (see MAGNETOSPHERE OF EARTH: BOW SHOCK, VENUS: INTERACTION WITH SOLAR WIND). The large-scale shapes of interplanetary shock surfaces are only approximately known, mainly from models, because there have not been many spacecraft mission opportunities to provide vastly separated and properly positioned observing points in the solar wind. However, some studies have shown that the radius of curvature of an interplanetary shock surface, at the Earth's distance from the Sun, is close to, but probably smaller than, 1 AU. Hence, these surfaces appear to move out almost uniformly from the Sun on a large scale. Undoubtedly on smaller scales these shocks have surface wrinkles, and other physical variations, that are caused by irregularities

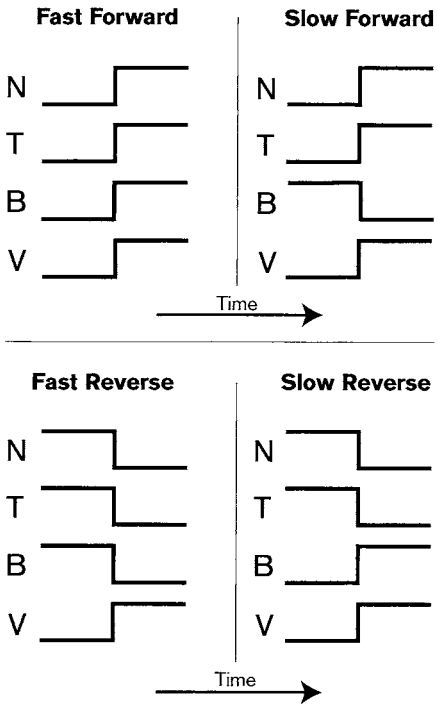

Figure 1. Profiles of solar wind density (N), temperature (T), magnetic field intensity (B) and flow speed (V) across an interplanetary shock ramp, as seen in a spacecraft frame of reference.

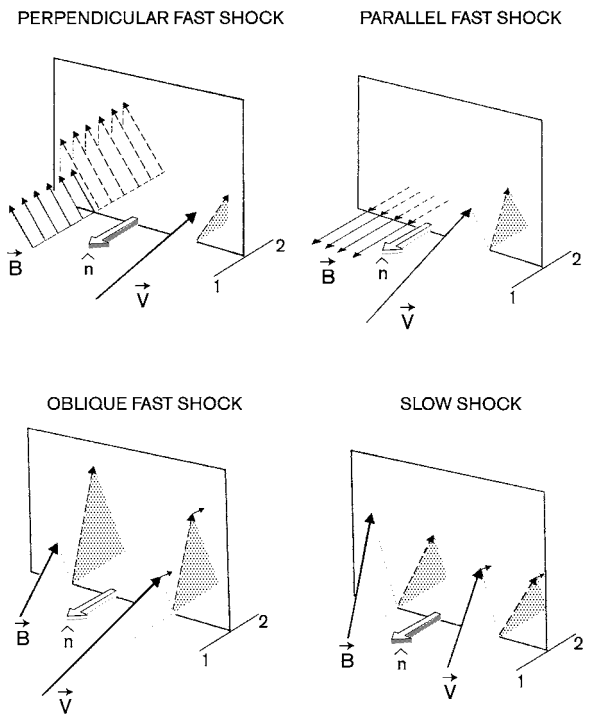

Figure 2. A vector representation of how the magnetic field ($\boldsymbol{B}$) and velocity ($\boldsymbol{V}$) change in strength and direction across a shock ramp for four various kinds of shocks, as denoted. The numbers '1' and '2' represent the up- and downstream states around the shock ramp, respectively, and $\boldsymbol{n}$ is the vector normal to the shock surface. When $\boldsymbol{n}$ is perpendicular (parallel) to the upstream IMF, the shock is referred to as a perpendicular (parallel) shock, otherwise it is called oblique.

in the solar wind as the shocks travel through it. Some of these variations are due to waves and discontinuities that the shock wave encounters, causing new discontinuous features to be generated, in turn.

Discontinuities in the solar wind

Definition and types of discontinuities

An interplanetary directional discontinuity is a relatively abrupt change in direction of the magnetic field 'carried' by the solar wind and sometimes accompanied by a change in magnitude (or intensity) of the field. Even though, by definition, a discontinuity requires a relatively rapid change in magnetic field, there is almost always a measurable thickness to the transition region in which the field's direction and other physical parameters change. This usually thin region is often called the 'discontinuity plane or sheet'. Within this sheet flows an electrical current composed of moving electrons, protons and to a lesser extent other positive ions. The state of the solar wind plasma on each side of the discontinuity plane must satisfy the fundamental MHD conservation conditions listed above for shock waves.

There are various kinds of directional discontinuities in the solar wind. They are usually classified according to the solar wind states on either side of its transition plane. In particular, there are tangential discontinuities in which ideally the component of the field perpendicular to the discontinuity plane, i.e. the 'normal component', is of zero magnitude, but the field's total magnitude does change from one side to the other. This kind of discontinuity is 'frozen into' the solar wind and travels along with it, because of its very high electrical conductivity. Such a discontinuity can have any size angle change of the field across its plane, including the special case of zero. A rotational discontinuity, on the other hand, under typical conditions, has no change in field intensity across the discontinuity plane but has a non-zero normal magnetic field component to that plane, and it propagates with respect to the solar wind. The magnitude of the normal component of the field is directly proportional to the propagation speed, which also depends on the local density of the solar wind, which is constant across the discontinuity. The propagation speed is the normal Alfvén speed. This kind of discontinuity is sometimes referred to as an Alfvén 'shock', but is not a real shock across which entropy always changes. Marked thermal anisotropy of the plasma on either side of a rotational discontinuity will cause a magnitude change of the field across it. A contact discontinuity is one in which there is a nonzero normal component of the field across the discontinuity surface (like a rotational discontinuity), is frozen into the solar wind and travels with it (like a tangential discontinuity), and has a constant field intensity across it. Both tangential and contact discontinuities have a density change across the discontinuity surface. Contact discontinuities are not as commonly observed in the solar wind as tangential or rotational discontinuities. Figure 3 provides a representation of how $\boldsymbol{B}$ and $\boldsymbol{V}$ change across various kinds of directional discontinuities.

The newly discovered Whang double discontinuity (1998) is a combination of an abrupt slow shock intimately accompanied by a much broader rotational discontinuity; such compound structures are not observed very often. Another structure in the solar wind, sometimes empirically referred to as a discontinuity, is a usually abrupt change in the magnetic field's magnitude, appearing as a sharp dip in intensity with rapid recovery reaching a minimum value only a small fraction of the intensities on either side; these are called magnetic holes and may or may not possess accompanying field directional changes.

Discontinuity thickness and rate of occurrence

The thickness of a tangential discontinuity plane in the solar wind, i.e. the thickness of its electrical current layer, depends primarily on the gyroradius (r_P) of the ions in the layer, mainly the protons. Hence, its thickness depends mainly on the ions' temperature and the ambient magnetic field. The temperature is important because it provides the ions' random (or thermal) speeds with which they revolve around the field lines penetrating from one side of the discontinuity plane to the other according to some

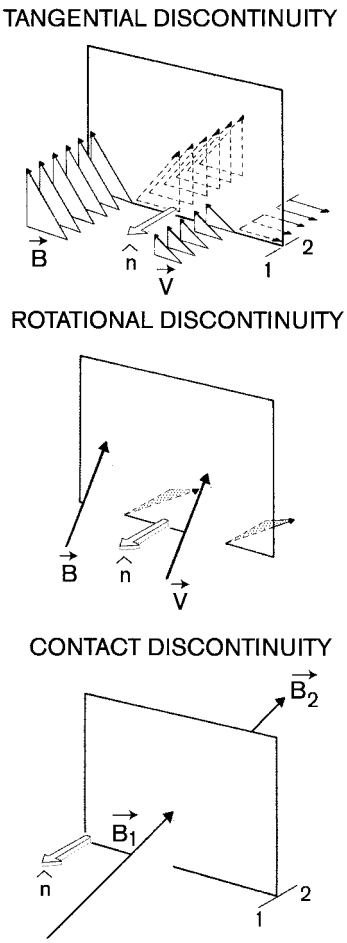

Figure 3. A vector representation of $\boldsymbol{B}$ and $\boldsymbol{V}$ changes across three different kinds of discontinuities, tangential, rotational, and contact, in the same format as figure 2.

measure of r_P. It has been shown that it usually takes many times a single gyroradius to account for the full thickness of a tangential discontinuity, about $30r_P$, which is not fully understood. Hence, on average, a discontinuity thickness at 1 AU from the Sun is about 3000 km. Data from the Mariner 10, HELIOS and VOYAGER spacecraft show that discontinuities generally become thinner as regions closer to the Sun are considered, because the IMF becomes stronger, causing r_P to become smaller. Observations of rotational discontinuity thicknesses are quite comparable with those of the tangential discontinuities on average. Hence, at 1 AU either kind of discontinuity is much thicker, and usually by more than an order of magnitude, than almost all observed interplanetary shock ramps. The estimate of the rate of occurrence of discontinuities in the solar wind depends on how strictly they are defined, i.e. on how large an angle is required across the discontinuity in some unit of time. Generally, however, the rate decreases with distance from the Sun.

Examples of discontinuities

The very large-scale structure in the solar wind called the heliospheric current sheet which separates the solar magnetic sectors is observed locally by spacecraft to be either a rotational or tangential discontinuity. Similarly, large magnetic flux rope structures from the Sun, apparently caused by erupting SOLAR PROMINENCES, called magnetic clouds, as seen at 1 AU very often have a sharp front boundary that is a directional discontinuity. However, numerous discontinuities exist all throughout the solar wind that are not associated with any other obvious solar wind structures.

Effects of shocks and discontinuities on Earth's magnetosphere

A forward interplanetary shock wave may cause a sudden commencement of a magnetic storm at the Earth, because it causes a dramatic increase in the solar wind's dynamic pressure, which depends on the wind's speed and density, exerted on the boundary of the Earth's magnetosphere. On the other hand, a magnetic field directional discontinuity in the solar wind may rapidly alter the solar wind's electric and magnetic connection to the Earth's magnetosphere by allowing (or disallowing) the IMF, depending on its direction, to interact with the Earth's magnetic field. When the dramatic process called MAGNETIC RECONNECTION (between the IMF and the Earth's field) occurs, the related discontinuity at the interface is of a rotational type. This interaction may lead to a magnetic substorm or major magnetic storm depending on the strength and duration of the magnetic field reconnection process (see MAGNETOSPHERE OF EARTH: GEOMAGNETIC STORMS AND SOLAR WIND ORIGINS, MAGNETOSPHERE OF EARTH: SUBSTORMS). These processes of magnetic reconnection and shock wave impingement at the Earth's magnetosphere's boundary are prominent components in the study of space weather (see SOLAR–TERRESTRIAL CONNECTION: SPACE WEATHER PREDICTIONS).

Solar Wind Turbulence

There are fluctuations in all quantities that describe the local plasma state of the solar wind. For example, fluctuations in plasma velocity, magnetic field and plasma density are superposed upon the large-scale relatively smooth flow of the wind at speed $\boldsymbol{V}$, the relatively organized large-scale interplanetary magnetic field $\boldsymbol{B}_0$, and slow radial variation of the density ρ. These fluctuations, known as solar wind turbulence in anticipation of their likely connection to complex nonlinear dynamical activity, have been routinely observed by instruments aboard spacecraft for several decades, starting with early observations by spacecraft such as Mariner 2 in 1962 and Pioneer 6 in 1965 (see MARINER MISSIONS, PIONEER MISSIONS). Because of the large amount of *in situ* data that have been accumulated from spacecraft, solar wind turbulence may be the most extensively probed of all turbulent plasmas in nature or in the laboratory. Certain spacecraft missions stand out in terms of their contribution to knowledge of interplanetary turbulence, notably Mariner 10 and HELIOS (exploration of the inner heliosphere), ISEE-3 and IMP (near-Earth orbit), Pioneer 10 and 11 and Voyager 1 and 2 (outer heliosphere) and Ulysses (high solar latitude (see SOLAR WIND: ULYSSES, VOYAGER MISSION)). Advances are continuing through recent missions such as ACE and WIND. Missions that are currently in the planning stages, such as SOLAR PROBE, may answer fundamental questions regarding the origin of solar wind turbulence and its many influences in the heliosphere.

Scales of turbulence

Solar wind turbulence occurs over a wide range of length and time scales, but most of the energy resides in fluctuations for which time and length scales are long compared with the gyromotions of thermal particles about the magnetic field. In this regime, the solar wind plasma can be reasonably well approximated by the equations of MAGNETOHYDRODYNAMICS (MHD). The complex dynamical activity of such a magnetofluid, MHD turbulence, is closely related to hydrodynamic turbulence, which is well studied in a variety of terrestrial contexts (see MAGNETOHYDRODYNAMICS: MAGNETIC RECONNECTION AND TURBULENCE). It is in this perspective that low-frequency solar wind turbulence, as well as the large-scale solar wind flow itself, is most often studied.

A convenient approximation, called frozen in flow, is often invoked to interpret the time series of observations at a single spacecraft as a snapshot of the plasma fluctuations at nearby spatial locations. The mean solar wind flows at speeds ranging from 250 km s^{-1} to 750 km s^{-1}, but the characteristic speeds associated with dynamical activity of MHD fluctuations (sound speed, Alfvén speed, typical fluctuation speed) are much less (10 to 50 km s^{-1}). Therefore structures described by MHD cannot significantly distort during their time of transit past the spacecraft instruments. This frozen-in property allows the structure and the statistical properties of MHD turbulence to be probed in the solar wind for scales ranging from tenths of an astronomical unit (1 AU $= 1.5 \times 10^{13}$ cm) or more down to scales associated with the thermal proton gyroradius (about 50 km). Discussion of the distribution of energy over scales usually refers to the fluctuation energy spectrum, defined in terms of a Fourier transform of the two-point correlation function. For example, the magnetic energy spectrum is $E_B(\boldsymbol{k}) = (2\pi)^{-3} \int \mathrm{d}^3 r \langle \boldsymbol{b}(\boldsymbol{x}) \cdot \boldsymbol{b}(\boldsymbol{x} + \boldsymbol{r}) \rangle \, \mathrm{e}^{\mathrm{i}\boldsymbol{k}\cdot\boldsymbol{r}}$. Single-spacecraft data give information only about the reduced spectrum, a function of radial wavenumber k_r, obtained from the spectrum by integrating over the components of $\boldsymbol{k}$ transverse to the radial direction.

Energy cascade

Observed near Earth orbit at 1 AU, solar wind turbulence exhibits features that are suggestive of fully developed MHD turbulence, and also properties that are reminiscent of MHD waves. The power spectra of MHD fluctuations exhibit a characteristic appearance. Due to the frozen-in flow property, the frequency (f) spectra correspond to reduced wavenumber spectra through the relation $f = V_{\mathrm{sw}} k_r / 2\pi$ for solar wind speed V_{sw}. Magnetic energy spectra, for example, typically display a power law, $E_B(k_r) \sim k_r^{-\alpha}$, for a range of frequencies (f) and wavenumbers k_r corresponding to spacecraft frame periods from about 10 s up to several hours. The spectral index α frequently has a value near $\alpha = 5/3$ corresponding to an inertial range or Kolmogoroff spectrum in hydrodynamic turbulence, and can be understood by an analogous argument: beginning with a reservoir of MHD energy at large energy-containing scales, turbulent interactions produce a cascade of energy through eddies (vortices), or magnetic structures of progressively smaller size. At sufficiently small scale, the dissipative effects become significant and this direct cascade terminates by damping of fluctuation energy and a corresponding production of heat. For scales that are much smaller than the energy-containing size, and much larger than the dissipative scales, the dynamics of the cascade may be self-similar, that is, invariant under a multiplicative transformation of length scale, thus producing a distinctive power-law distribution. The occurrence of the inertial range in a typical solar wind magnetic field spectrum near 1 AU is illustrated in figure 1.

There continues to be some debate concerning whether there is an active energy cascade involving solar wind fluctuations. However, there are features that seem to require its presence. The proton temperature at 1 AU is difficult to explain unless heat is added in transit from the solar wind source region. The temperature profile in the solar wind from the inner Helios orbit (0.29 AU) to several tens of AU exhibits a non-adiabatic profile, again suggesting deposition of heat. Turbulent energy can be injected by instabilities (e.g. Kelvin–Helmholtz instability) associated with regions of large velocity shear near edges of high-speed streams (velocity change $\Delta V \approx 200$ km s^{-1}),

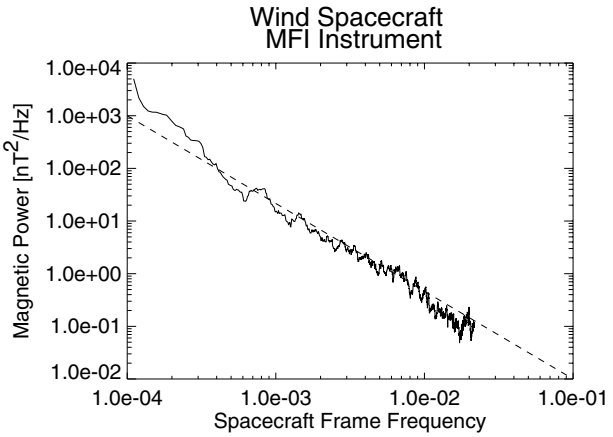

Figure 1. Reduced magnetic energy spectrum from several days of wind data at 1 AU, beginning on 13th October 1997, showing power-law inertial range with index close to the 'Kolmogoroff' value of $-5/3$ (broken line). (Wind data courtesy of Wind/MFI team.)

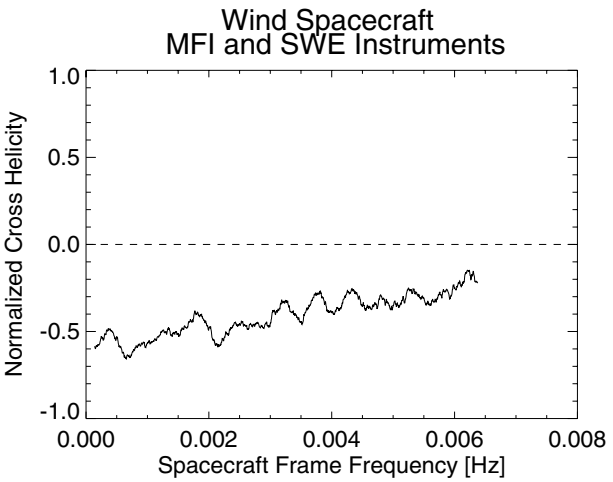

Figure 2. Normalized cross-helicity spectrum $\sigma_c(k_r) = 2\,\mathrm{Re}\langle \boldsymbol{v}_A(k_r) \cdot \boldsymbol{v}(k_r)\rangle / \langle v_A^2(k_r) + v^2(k_r)\rangle$. Values near -1 indicate outward traveling Alfvénic fluctuations. (Wind data courtesy Wind MFI and SWE teams.)

or near microstreams observed at higher latitudes ($\Delta V \approx$ 40 km s^{-1}). In the outer heliosphere, turbulence may be driven by injection of energy due to the 'pick-up' process that occurs in connection with freshly ionized hydrogen or helium of interstellar origin. Taking these sources into account, a cascade and subsequent dissipative heating would be required to prevent build-up of fluctuation energy to levels higher than what is observed.

Alfvénic fluctuations and turbulence

Wave-like properties are also evident in typical observations of solar wind fluctuations. The so-called Alfvénic correlation between the fluctuating components of velocity and magnetic fields are often seen in data at 1 AU. When the correlation is strong, a near proportionality is seen involving the fluctuating magnetic field $\boldsymbol{b}$ and the fluctuating velocity field $\boldsymbol{v}$, in the sense that $\boldsymbol{v}_A \equiv \boldsymbol{b}/\sqrt{4\pi\rho} \approx \pm\boldsymbol{v}$ where ρ is the local plasma mass density. This relation corresponds to an MHD Alfvén wave and the sign of the correlation usually indicates a direction of propagation away from the Sun. It is frequently possible to identify intervals of data that possess a substantial broad band correlation of this type by visually inspecting the $\boldsymbol{v}_A$ and $\boldsymbol{v}$ time series. Figure 2 shows evidence of the presence of these large-amplitude Alfvénic fluctuations in spacecraft data, using a more sensitive technique that extracts the degree of correlation at various scales. In MHD turbulence theory, the quantity $\langle \boldsymbol{v}_A \cdot \boldsymbol{v}\rangle$, called the cross helicity, provides a quantitative measure of the Alfvénic correlation, where $\langle \ldots \rangle$ denotes an appropriate ensemble average. For pure Alfvénic correlation, the cross helicity takes on the maximum value compatible with the fluctuation energy per unit mass, so that $\sigma_c = 2\langle \boldsymbol{v}_A \cdot \boldsymbol{v}\rangle / \langle v_A^2 + v^2\rangle = \pm 1$. Figure 2 shows, for a particular data interval, the Alfvénic correlation over a broad range of frequencies.

High cross helicity intervals are most frequently seen closer to the Sun (Helios) and at higher latitudes (Ulysses). Voyager observations suggest a decrease in Alfvénic correlation in the more distant solar wind. The most obvious interpretation of the Alfvénic fluctuations is that they represent outward propagating waves that escape from the inner corona at the Alfvénic critical point (see SOLAR WIND: CORONAL ORIGINS). In a purely wave picture, the wave spectrum is determined at this inner source surface (at about 10–15 R_s) and propagates outwards as 'fossil' turbulence in accordance with geometrical optics (also called WKB theory). However, in this view, since there is no active turbulence in the super-Alfvénic wind, it is difficult to explain the proton temperature at 1 AU, and the non-adiabatic temperature radial profile. Several effects are routinely observed that are in apparent violation of WKB transport theory, such as systematic radial decrease of cross helicity and decrease of the ratio of turbulent velocity and magnetic field energies. For these reasons the Alfvénic property has also been studied as a property of active MHD turbulence. Theoretical studies have shown, for example, that the normalized cross helicity tends to increase in time for undisturbed freely evolving homogeneous dissipative turbulence. Therefore the decrease of the cross helicity with increasing heliocentric distance points to the existence of some additional process or disturbance. Two such effects have been identified, associated with either non-WKB transport effects, or the injection of turbulent energy near regions of large shear near the boundaries of high-speed streams. Solar wind Alfvénic fluctuations are actively studied using nonlinear models that appear to be able to explain a variety of other features including the presence of discontinuities and distinctive 'arc-polarization,' in which over time the field vector traces a section of a sphere.

Density fluctuations

Averaged over a suitably large, statistically stationary, data interval, interplanetary density fluctuations are relatively small. Typically the root mean square fluctuation normalized by the local mean density is $\delta\rho/\rho \sim 1/10$. Wavenumber spectra of density fluctuations frequently have a 'Kolmogoroff' $k^{-5/3}$ form. This can be explained if the medium is weakly compressible, and the density fluctuations are a linear response to pressure fluctuations associated with the energy cascade. In this perspective, solar wind turbulence is a form of 'nearly incompressible' (NI) MHD turbulence, which requires low turbulent Mach number M, and that the flow not be dominated by longitudinal compressive magnetosonic waves. Such compressive waves are expected to be heavily damped in the inner heliosphere, while one typically finds that $M \approx 1/3$ for stationary samples. Other features, including the frequent appearance of anti-correlated magnetic pressure fluctuations and density fluctuations, sometimes called pressure balanced structures, emerge naturally from this picture. While some of the same features can be interpreted in terms of magnetosonic waves, the NI picture provides a conceptual link between the statistical properties of the density and other MHD turbulence parameters.

Anisotropic turbulence

In contrast to classical hydrodynamic turbulence which is usually assumed to be statistically isotropic, solar wind turbulence is typically anisotropic. Since early observations, it has been known that the variances of the Cartesian components of magnetic and velocity fields are not rotationally symmetric. Various studies also have concluded that the spectral distribution of fluctuation over wavevectors is also anisotropic. Radio scintillation studies, analysis of *in situ* spectral data, as well as inferential studies based upon analysis of cosmic ray scattering, have all concluded that the spectrum of fluctuations (velocity, magnetic field or density) might contain a spectral ingredient in which a significant fraction of the energy is localized in wavevectors that are nearly perpendicular to the local mean magnetic field. An apparently useful model is one in which the fluctuations consist of two components: a 'slab' ingredient with variations essentially only along the mean field $\boldsymbol{B}_0$ and a 'quasi-two-dimensional' component that varies mainly in the two directions transverse to $\boldsymbol{B}_0$. This model is useful in cosmic ray scattering theory, transport theories and heating theories, in which the rotational asymmetry of the fluctuations has substantial influence. In addition to the mean field direction, another important preferred direction for solar wind turbulence is the radial direction, which can also induce anisotropy, especially through expansion and transport effects.

Dissipation, magnetic helicity and scattering of charged particles

Many features of MHD turbulence in the solar wind, notably in the energy-containing range and inertial range, can be understood principally in terms of MHD theory. At shorter scales, however, kinetic processes must come to dominate the dynamical interactions and ultimately must be responsible for converting fluid-scale energy to heat (see SOLAR WIND: KINETIC PROPERTIES). The standard view is that fluctuations that have the character of magnetosonic wave modes are damped rapidly by Landau damping. At scales approaching the gyroradius of thermal protons, significant damping of incompressive MHD fluctuations must occur, presumably through cyclotron resonance damping, which depends upon the polarization or MAGNETIC HELICITY of the fluctuations, along with mechanisms akin to Landau damping, which are of the non-resonant type, and which are therefore insensitive to helicity. These crucial links of fluid-scale processes to kinetic processes are incompletely understood at present.

It is noteworthy that couplings of interplanetary MHD turbulence to non-thermal particle populations (cosmic rays, and suprathermal particles such as pick-up ions) can also be classified as either resonant interactions, such as pitch angle scattering, or non-resonant interactions, such as stochastic acceleration by induced turbulent electric fields (see COSMIC RAYS, DYNAMO THEORY). Resonant interaction of turbulence with charged particles is also sensitive to the spectrum of magnetic helicity, i.e. the spectrum of $\langle \boldsymbol{b} \cdot \boldsymbol{a} \rangle$ where $\boldsymbol{b} = \nabla \times \boldsymbol{a}$ for vector potential $\boldsymbol{a}$. Of the spectral quantities typically extracted from solar wind data, the helicity spectrum is least well understood, and is characterized by random helicity fluctuations, of both right- and left-handed types throughout the inertial range.

Solar Wind: Coronal Origins

To establish the coronal origins of the solar wind is to find its source regions at the Sun. Dominated by electrons and protons, this outflow of fully ionized atoms also carries traces of neutral hydrogen and heavier elements, such as alpha particles, oxygen and iron ions. There are two types of winds detected so far: the fast and the slow (see SOLAR WIND: GLOBAL PROPERTIES). Since they are distinguishable not only by their associated speeds but more importantly by their thermodynamic and compositional properties, their corresponding sources at the Sun must have different characteristics.

The complex magnetic structure of the solar atmosphere is revealed by the electromagnetic spectrum (see SOLAR SPECTROSCOPY AND DIAGNOSTICS) of the solar corona (see CORONA). This complexity contributes to the ambiguity in establishing the source regions of the fast and the slow solar wind. For the PLASMA to escape from the solar surface, it must be connected to magnetic field lines (see SOLAR MAGNETIC FIELD) that stretch out into interplanetary space. How to identify these 'open' field lines is the key to finding the coronal origins of the solar wind.

At present, two distinct and complementary observational techniques have been used to characterize the properties of the solar wind: remote sensing observations and *in situ* measurements. In remote sensing observations, the characteristics are inferred from the electromagnetic spectrum originating from the solar disk and its outer atmosphere to within $30R_s$ (where R_s represents a solar radius) from the solar surface. The field of view is two dimensional, and the information gathered from an extended region of space along the line of sight is heavily weighted by the contributions in the plane of the sky. *In situ* measurements, on the other hand, are local or point measurements made by spacecraft typically beyond $60R_s$. They pertain to the parcel of plasma that intercepts the detector, and hence are limited to a very small volume of space. To establish the coronal origins of the solar wind, the connection between these two types of measurements is essential.

Coronal observations

The corona is revealed in a broad range of wavelengths, and its complex magnetic and density structure is best apparent in the ultraviolet, extreme ultraviolet and x-ray emission which can be achieved from space observations. Because of the intense disk emission in the visible wavelength range, the visible corona can be seen only when the disk radiation is blocked. The invention of the coronagraph (see CORONAGRAPHS) by Lyot in 1930 enabled daily observations of the broad band coronal white light emission, which for centuries was limited to total solar ECLIPSES. Since the solar wind has no detectable emission, simultaneous density and velocity measurements are necessary to establish its coronal sources.

Spectral line observations are weighted by the temperature at which the line is optimally formed. Space observations in the ultraviolet, extreme ultraviolet and x-rays, characteristic of plasmas over one million kelvins in temperature, reveal a complex magnetic structure, with three distinct regions. The most evident are arch-like structures or active regions characterized by intense emission. The other extreme are the polar caps, dubbed CORONAL HOLES, where the emission is practically absent. Coronal holes can also appear on the solar disk at low latitudes. The fraction of the solar surface that is neither coronal holes nor active regions, and appears as diffuse emission with faint large-scale arches, is called the quiet Sun or quiet regions (although far from being quiescent). The intensity of emission from spectral lines varies typically with the square of the density. As the density decreases rapidly as a function of distance away from the Sun, spectral line observations are of value only in the inner corona, within approximately half a solar radius from the solar surface.

The white light or broad band visible emission whose dominant component below $2R_s$ is the polarized K-corona is produced by the photospheric radiation scattered by free electrons traveling along magnetic field lines threading and shaping the corona. Since the K-corona is due to electron-scattered radiation it varies linearly with density as a function of distance. Consequently, polarized brightness (pB) measurements trace the coronal magnetic field to much larger distances than spectral line observations and have currently reached $30R_s$ with space-borne coronagraphs such as the Large Angle Spectroscopic Coronagraph (LASCO) onboard the Solar and Heliospheric Observatory (SOHO) (see SOLAR TELESCOPES AND INSTRUMENTS: SPACE).

The broad band white light emission has proven to be critical in establishing the coronal source of the solar wind. Shown in figure 1 is a sketch of the large-scale coronal magnetic field configuration based on coronagraph images of the Sun and the assumption that the field is basically that of a dipole. The magnetic field lines shown stretching outwards are those forming an envelope around the large-scale arches, also known as streamers (see CORONAL STREAMERS) with the exception of the example of figure 1(*a*) where a few radially extending field lines originate at low latitudes. Coronal holes shown as dark areas are assumed to have only open field lines (not drawn here) and to be the source of the fast solar wind. If coronal holes are the only source of the fast solar wind then this wind can reach spacecraft in the ecliptic plane along the field lines drawn stretching outwards, either from an equatorial extension of the coronal hole, such as in figure 1(*b*), or from a tilt in the dipole, such as in figure 1(*c*). Recent observations, however, have modified this picture.

Comparable with the broad band white light emission, remote sensing radio occultation measurements have played a pivotal role in establishing the coronal density structures associated with the fast and the slow solar wind. Such measurements are made when the radio signal from either a natural source or a spacecraft intercepts coronal density structures and produces a characteristic scintillation pattern such as shown in

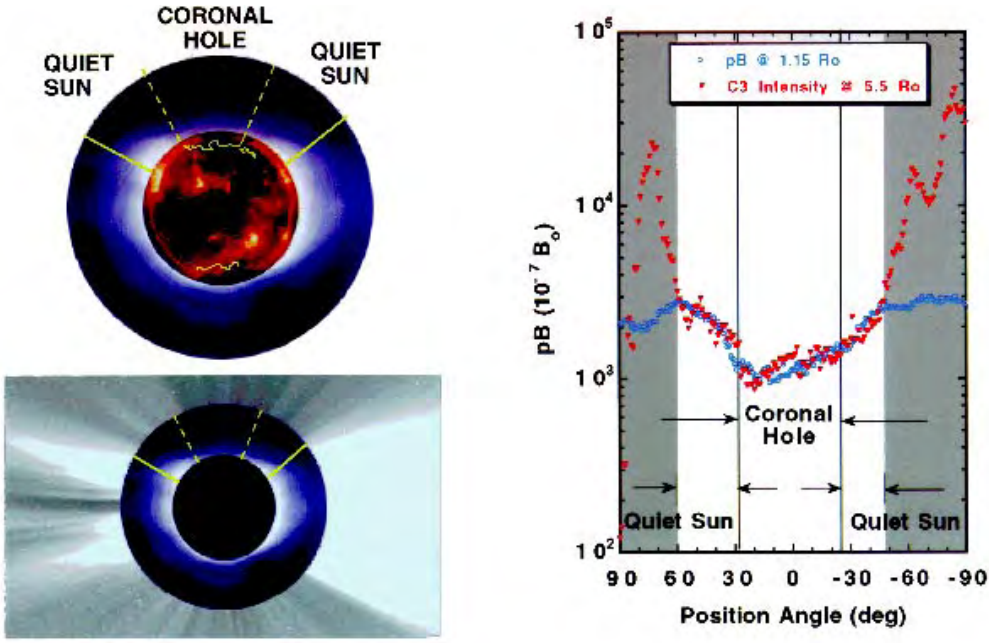

Figure 3. Extension of the coronal hole and the quiet Sun outwards from the solar surface. Top left: composite soft x-ray and pB image, with the coronal hole boundaries shown as derived from He I 18 030 Å disk observations. The dashed lines trace the radial boundaries of the northern coronal hole. The solid line gives the radial boundaries of the quiet Sun. Lower left: composite pB and C2 white light intensity images. The dashed and solid lines are the same as in the top panel. Right: profiles of the pB intensity at $1.15R_s$ (circles) and LASCO C3 white light intensities at $5.5R_s$ (triangles) as a function of position angle.

figure 2. The Doppler scintillation is directly proportional to the electron density fluctuation along the line of sight. While these measurements lack the two-dimensional imaging characteristics of the broad band white light emission, they are more like point measurements. Because of their high sensitivity to changes in electron density over small distances they provide high spatial resolution measurements.

Using Doppler scintillation measurements together with *in situ* velocity measurements, Woo and Martin showed that the slowest wind coincided with conspicuously high levels of density fluctuation associated with coronal streamer stalks. (Streamer stalks are the narrowing of the streamers that extend into interplanetary space.) On the other hand, low levels of density fluctuations were found to be characteristic of the fast solar wind (see figure 2). By comparing radio ranging measurements with simultaneous broad band white light observations, Woo and Habbal found that low levels of density fluctuations could be traced back not only to coronal holes but also to quiet Sun regions.

Further evidence for the origination of the fast solar wind from the quiet Sun as well as from coronal holes emerged from the comparison of density profiles in the corona measured at different radial distances, as shown in the right panel of figure 3. A density profile is obtained by measuring the pB or white light intensity as a function of latitude, or position angle (PA) (measured counterclockwise from 0° north) for a given radial distance. As seen in figure 3, the two profiles at $1.15R_s$ and $5.5R_s$ match over a wide angular extent. The separation of the two profiles occurs at the stalks of the streamers. The angular extent of the coronal hole was established from the radial extension of the boundaries of the coronal hole from disk observations in the He I 10 830 Å line which is commonly used to determine coronal hole boundaries on the solar disk. Beyond the radial boundaries of the coronal hole lies the quiet Sun. The outer radial boundaries of the quiet Sun are determined at the position angle where the two profiles no longer match. That the coronal density profile can be preserved out to several solar radii implies that magnetic field lines tied to the solar wind plasma extend radially outwards from both coronal holes and the quiet Sun.

Velocity measurements provide further support for this view. The only outflow velocity measurements in the corona that are spatially resolved are those recently obtained by the Ultraviolet Coronagraph Spectrometer (UVCS) on SOHO. (Doppler shifts of spectral lines observed on the solar disk do not yield unambiguous results, since the derived downflows or upflows can be connected with closed as well as open magnetic structures.) These measurements extend to $3.5R_s$ in the tenuous polar regions and to $10R_s$ in denser coronal plasmas. One of the unique advantages of this instrument is the measurement of coronal spectral lines, in particular doublets, such as the O VI 1032 Å and 1037.6 Å lines, formed primarily by the resonance scattering of

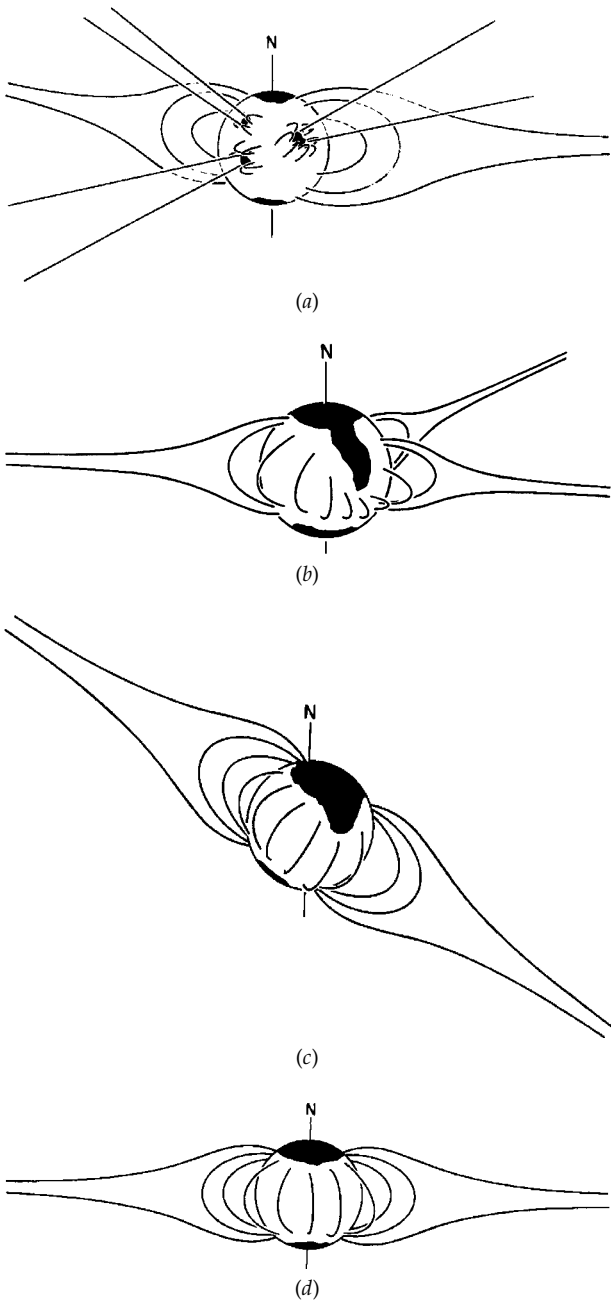

Figure 1. A sketch by Hundhausen of the boundaries between closed and open magnetic field lines, and large-scale closed magnetic field lines, at different times of the solar activity cycle. The sketch is based on visual impressions from the white light emission of the corona. The black shaded areas represent coronal holes. In (*a*) the smaller polar caps and small isolated coronal holes are representative of the magnetic field configuration around the peak of the activity cycle. Panels (*b*) and (*c*) are likely to mimic the configuration between minimum (*d*) and maximum (*a*). The case of a tilted dipole is sketched in (*c*). N points to heliographic north.

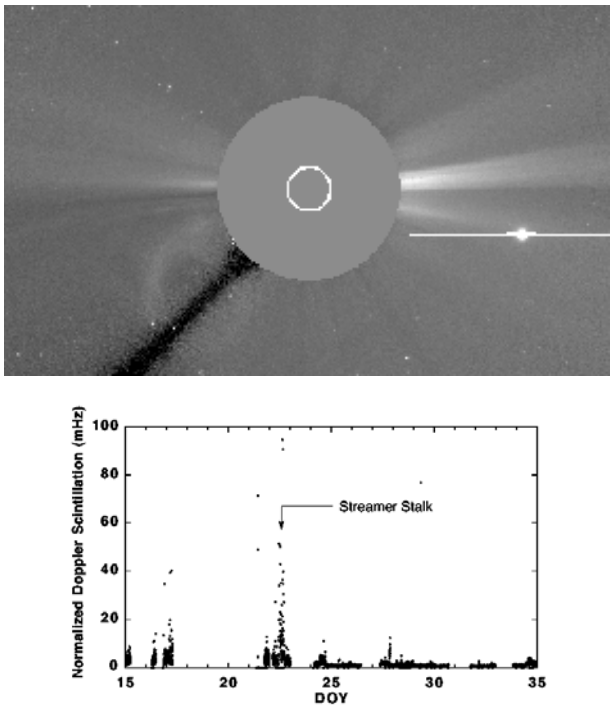

Figure 2. Top: white light image from the LASCO C3 coronagraph taken on 22 January 1997. The innermost circle traces the solar disk. The next circle is the occulter of the C3 coronagraph. The field of view extends from $3.7R_S$ to $30R_S$. The dark region in the lower left quadrant is the support arm of the coronagraph. Jupiter, the bright saturated object on the right, is at the point of closest approach of the line-of-sight radio path from the GALILEO SPACECRAFT which was orbiting Jupiter. North is up. Bottom: radio Doppler scintillation measurements by Galileo during its solar conjunction from 15 January to 4 February 1997, or day of year (DOY) 15–35, when it traversed the plane of the sky from east to west, almost parallel to the equator. The enhanced scintillation from Galileo coincides with the location of Jupiter shown in the top panel, when the radio path intercepted a streamer stalk.

chromospheric (see CHROMOSPHERE) or transition region (see SOLAR TRANSITION REGION) radiation by ions flowing in the corona. The diagnostic which places limits on solar wind velocities is based on the Doppler dimming effect first described by Hyder and Lytes in 1970. As ions flow outwards in the corona, the fraction of the spectral line formed by resonance scattering becomes Doppler shifted out of resonance with the disk emission. Subsequently, the relative ratio between the intensity of the lines forming a doublet changes drastically. In the case of the O VI lines, the intensity ratio of 1032 to 1037 times equals 4 when resonant scattering is dominant and reduces to 2 when only the collisional components are left. The intensity ratio of 1032 to 1037 lines of 2 occurs for an outflow velocity of 94 km s^{-1} and depends only on the velocity distribution along the flow direction.

Shown in figure 4 is an example of UVCS observations taken during the Galileo solar conjunction shown in

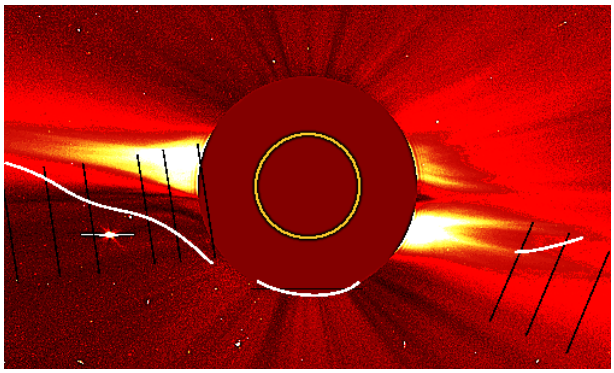

Figure 4. White light image of the corona taken with LASCO C2 on 17 January 1997. The bright object in the east below the equator is Jupiter and indicates the approximate location of the Galileo spacecraft. The field of view spans (2–6)R_S. Shown as black vertical lines are the slit positions of the UVCS detector which is approximately $2R_S$ wide. They are located at 1.9, 2.5, 3, 4, 4.7 and 5.5 solar radii on the east limb at PA= 97°, at $1.9R_S$ in the south polar coronal hole at PA= 180°, and at 4, 4.7 and 5.5 solar radii at the west limb at PA= 247°. The white contours mark the velocity contour value of 94 km s^{-1}.

figure 2. The slit positions of the UVCS detector were chosen to coincide with the passage of the radio signal from Galileo through the corona. By measuring the intensity of the two oxygen lines and their ratio along the slits for different heliocentric distances, contours of the intensity ratio equal 2, shown as white lines in figure 4, were obtained. This contour showed a sharp latitudinal gradient in wind speed close to the stalk of the streamers and a more uniform distribution as a function of heliocentric distance over a large fraction of the inner corona.

The inverse distance of this contour is shown in figure 5(*a*) together with the corresponding latitudinal profile of density from the same time. The density or pB profile again carries the distinct imprint of the coronal hole and the quiet Sun. The corresponding latitudinal velocity profile clearly indicates how the fast wind coincides with the angular extent of the coronal hole and the quiet Sun as determined from the coronal density profile.

Connection between coronal and interplanetary measurements

The connection between coronal velocity and density measurements and their interplanetary counterparts is the only approach currently available to establish the source regions of the different solar wind streams without ambiguity. The advent of Ulysses (see SOLAR WIND: ULYSSES), the first spacecraft to orbit the Sun in a plane perpendicular to the ecliptic and to reach 80° latitude, has made possible the comparison of observations from the same latitudes in the corona and the heliosphere.

Shown in figure 5(*b*) are the Ulysses density and velocity measurements of the south polar region above −30° latitude when the wind speed was consistently

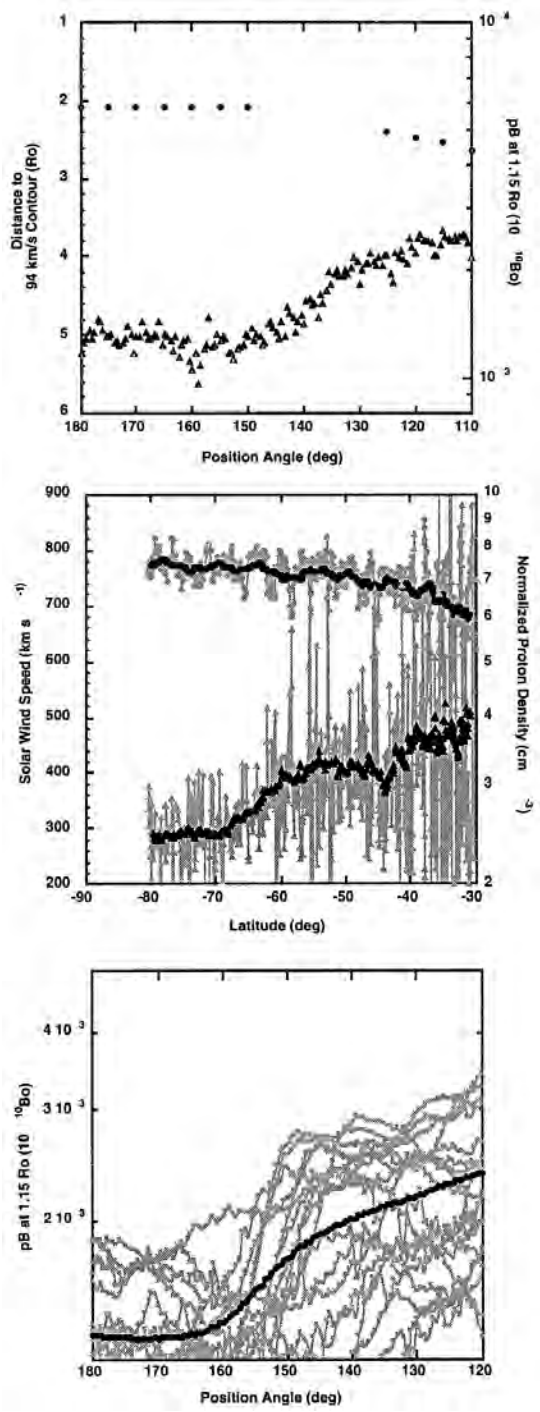

Figure 5. (*a*) pB at $1.15R_S$ and the inverse heliocentric distance of the 94 km s^{-1} velocity contour level versus PA from data corresponding to figure 4. (*b*) Daily averages of Ulysses velocity and normalized density measurements during the slow scans of the south polar region. The larger symbols represent 27-day sliding window averages. (*c*) 19 representative pB profiles at $1.15R_S$ for PA= −30 to −90° latitude for the same time period of the data in (*b*). The black solid line is the average of 253 profiles covering the whole time period.

higher than 650 km s^{-1} characteristic of the fast solar wind. The data were collected during the slow scans of the south polar region for latitudes from -30° to -80.2° from 3 May 1993 to 15 September 1994. The daily averaged data are shown in grey and the 27-day averages are given as bold symbols. The corresponding averaged coronal pB profile from the same time period is shown in figure 5(*c*). Representative individual pB profiles from which the average was made are shown in grey.

Comparison of the coronal and interplanetary density profiles shows a remarkable resemblance indicating a preservation of the density profile from the corona out to interplanetary space. While the density is minimal between -68° and -80°, and from the corresponding PA= 158°–180°, the subsequent gradients also match in both measurements. X-ray and He I 10 830 Å observations of the solar disk indicate that the latitude at which this rise occurs corresponds to the coronal hole–quiet Sun boundary at the Sun. Its appearance in the Ulysses measurements indicates that this boundary too is preserved. Given that the corresponding velocity measured in interplanetary space is typical of the fast wind, this provides direct evidence that the fast wind originates from both coronal holes and the quiet Sun.

The anticorrelation between density and velocity in the Ulysses measurements and the slow decline of the solar wind speed at the boundaries of the polar coronal holes are also remarkably similar to the pattern observed in the inner corona which is shown in figure 5(*a*). The remarkable resemblance of the density and velocity profiles in the corona (figure 5(*a*)) and in interplanetary space (figure 5(*b*)) indicates not only that the density is anticorrelated with velocity in both regions but that the fast solar wind can be traced back to both coronal holes and the quiet Sun. In particular, a clearly defined transition between the radial extension of the polar coronal holes, where the density is lowest, and the surrounding quiet Sun is detected in both measurements, with the angular extent of both regions being preserved from the Sun out into interplanetary space. The distinction between coronal holes and quiet Sun is also evident in the latitudinal profiles of velocity. Anticorrelated with density, the solar wind speed is highest within the angular extent of the polar coronal holes and decreases gradually beyond their boundaries. The connection between coronal and interplanetary measurements provides unambiguous evidence that the fast solar wind detected at mid latitudes by Ulysses around solar minimum originates from the quiet Sun, while the faster wind at latitudes above 60° has its origin in the polar coronal holes.

That the fast solar wind can be traced back to the quiet Sun as well as polar coronal holes implies that it originates from a large fraction of the solar surface. The coronal source regions of the slow solar wind remain more elusive. Radio occultation measurements clearly identify streamer stalks with the slow wind and with magnetic field polarity reversal, while the slowest wind is systematically connected to the heliospheric current sheet in interplanetary space. The heliospheric current sheet is then undoubtedly identified with the extension of these stalks. At present, the coronal source of the slow solar wind is not established. Given that the composition of the slow solar wind is different from that of the fast, it is likely to be associated with the interaction of the closed arch-like magnetic structures and the magnetic field lines that extend into interplanetary space.

Future prospects

Despite the wealth of space- and ground-based observations, the coronal origins at the Sun of both the slow and fast wind remain a puzzle. While present-day observations indicate that the fastest winds measured so far originate from polar coronal holes, and that the quiet Sun is also a source of the fast wind, the exact origin at the Sun is unknown. In particular, what defines an open versus a closed magnetic field line is still a mystery since both coronal holes and quiet regions have a very intricate magnetic field pattern and are indistinguishable when observed in photospheric or chromospheric spectral lines. Future space missions which can reach to within $30R_s$ of the Sun and which combine remote sensing and *in situ* observations, such as the proposed SOLAR PROBE, are the key to unraveling some of these mysteries.

Solar Wind: Corotating Interaction Regions

For several years around each solar activity minimum corotating interaction regions are the dominant and most extensive feature in the heliosphere except for the termination shock. At this time the solar atmosphere shows a well developed and long-lasting stable structure of polar CORONAL HOLES, often extending far down to low latitudes, and a well-developed narrow streamer belt region encircling the solar equator. A quasi-stationary flow of high-speed SOLAR WIND originates from well above the coronal holes and from above a certain height propagates radially out into the heliosphere at about 800 km s^{-1}. From above the streamer belt region a much slower solar wind originates and starts propagating into the heliosphere. Due to the ∼26 day rotation of the Sun and depending on the shape of the coronal holes the faster wind starts pushing the slow wind ahead. This is the origin of corotating interaction regions (CIRs) ahead of fast solar wind streams which develop high-pressure regions and eventually shocks bounding them. As the solar wind is carrying out frozen-in solar magnetic field lines the different plasma packets cannot mingle with or penetrate into each other. CIRs, however, undergo substantial developments with solar distance and latitude which are not yet fully investigated due to the limited simultaneous observations throughout the heliosphere. They are able to accelerate charged particles up to the MeV region and cause recurrent decreases of the galactic and anomalous COSMIC RAYS. The origin, development and effects of CIRs are discussed in this article.

Origin and formation of corotating interaction regions

The solar wind (see SOLAR WIND: GLOBAL PROPERTIES) results from the supersonic expansion of the solar CORONA, the Sun's hot outer atmosphere. It consists of ionized gas or plasma that propagates out into interplanetary space with velocities between about 250 and 850 km s^{-1}. The coronal expansion is modulated by the solar magnetic field that originates from the SOLAR PHOTOSPHERE and penetrates the corona. The interaction between the field and the expansion of the corona results in a highly structured solar corona which varies considerably with the solar activity cycle (see figure 3 of SOLAR WIND: GLOBAL PROPERTIES). Near solar minimum the solar corona generates basically two very different types of solar wind: the fast solar wind originating from coronal holes and the slow solar wind related to the streamer belt region.

Coronal holes and the fast solar wind

Coronal holes appear dark on images of the corona because they have lower than average temperatures. They are regions of open magnetic fields and the source of fast solar wind streams with speeds above 600 km s^{-1}, low plasma densities (3 cm^{-3}) and high temperatures (3×10^5 K). During the decline of the solar activity cycle large-scale coronal holes develop in the polar regions of the Sun and often create extensions towards the equator. They rotate rigidly with the equatorial rotation rate of the Sun (in contrast to the photosphere which rotates more slowly at higher latitudes than at the equator). High-speed streams generally originate from unipolar magnetic field regions and often develop into stable large-scale structures observed for many months at decreasing and low solar activity. The high-speed flow is a remarkably stable equilibrium state of the solar wind which often lasts for many months.

The streamer belt region and the slow solar wind

The CORONAL STREAMER belt is a region of closed magnetic loops containing dense and hot plasma. The magnetic equator is usually completely covered by magnetic arcades. The fields are sufficiently strong to constrain the plasma from expanding outward. At larger coronal heights the magnetic field weakens and the arcades can be opened by the pressure of the coronal plasma which is then free to expand outward. This outflow is observed as helmet-like streamers in the corona and as slow and dense solar wind far from the Sun. The slow solar wind with speeds of about 250 to 400 km s^{-1}, is generally less ordered, denser with ∼10 cm^{-3} and has a lower helium content indicating a higher release location in the corona. A magnetic field polarity reversal is embedded in the slow solar wind, which reflects magnetic control of the expansion. It is possible that the slow solar wind is purely transient and associated with intermittent reconfigurations of the coronal magnetic fields in the streamer belt region.

At solar minimum, the CORONAL LOOPS and the streamers are mainly observed in a narrow belt around the solar equator. The coronal magnetic field can be approximated by a dipole which is slightly tilted against the rotation axis of the Sun with the tilt increasing with solar activity. At higher solar activity the tilted streamer belt reaches higher heliolatitudes until at solar maximum most of the corona is covered by loops and appears bright so that a dipole field approximation is no longer applicable.

The formation of a corotating interaction region

A corotating interaction region develops in the heliosphere when a quasi-stationary high-speed solar wind stream follows and compresses a slow solar wind steam along the same radius-vector from the Sun. This happens due to the solar rotation when a coronal hole (or a coronal hole extension), as a quasi-stationary source of fast solar wind, is situated to the east of a source region of slow solar wind at the same heliographic latitude. The radially aligned parcels of plasma have different solar origin and carry different magnetic field lines inhibiting interpenetration. At the stream interface a region of compressed plasma starts to build up. The interaction region develops to a corotating pattern aligned with the Parker spiral (Parker 1958). While traveling out, the compression region

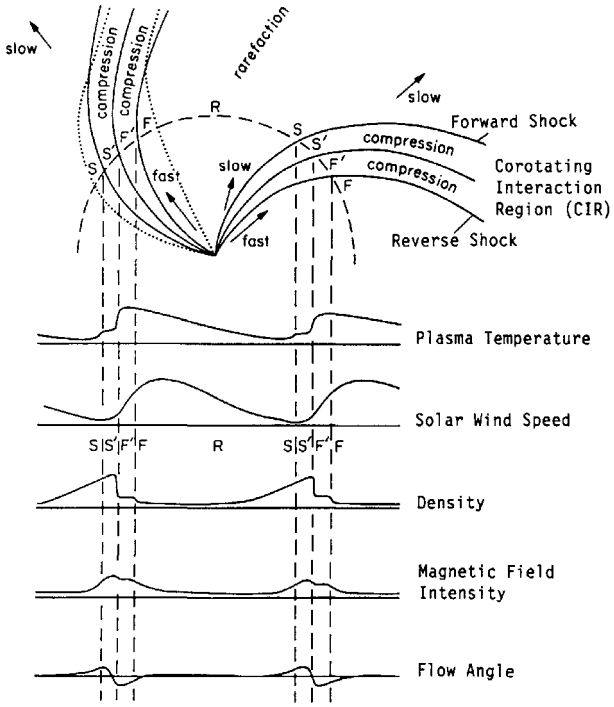

Figure 1. Schematic diagram of two CIRs corotating with the Sun and solar wind and magnetic field signatures associated as observed for example at 1 AU. (From Richardson I *et al* 1993 *J. Geophys. Res.* **98** 13.)

widens, becomes more pronounced, and develops shock waves at the leading and trailing edges.

Figure 1 shows schematically the solar wind plasma and magnetic field properties in the ecliptic plane associated with CIRs. The circular dashed arc represents the orbit of a 1 AU spacecraft. Solar wind streams are denoted S (slow wind), S′ (compressed, accelerated slow wind), F′ (compressed, decelerated fast wind) and F (unperturbed fast wind). The S′ and F′ regions together, separated by a stream interface (SI), constitute the corotating interaction region (CIR). In the outer heliosphere it is bounded by a forward and a reverse shock. Interplanetary magnetic field lines (dotted) link the shocks to the observer, e.g. at 1 AU where the lower parts of figure 1 show schematic changes in plasma temperature, speed, density and flow angle (compared to radial).

CIRs are well developed at 1 AU except for the shocks. A prominent feature is the stream interface (SI) separating the originally slow dense plasma from the originally fast thin plasma. Stream interfaces are identified by abrupt simultaneous drops in plasma density and rises in the proton temperature. The pressure peaks close to the interface. In the process of pressure release the slow and dense plasma ahead of the interface is deflected in the sense of the corotation motion while the less dense plasma behind the interface is oppositely deflected.

Coronal origin of the stream interface and the corotating interaction region in general is the western border of a coronal hole. Details of this border structure are often propagated out into interplanetary space, where changes observed within the corotating interaction region, despite temporal evolution and dynamics, can often be traced back to the source region with remarkable accuracy of about 2°. This is confirmed by measurements of the elemental and charge state composition of the solar wind. Compositional signatures (e.g. Mg/O ratios) are the best indicators of coronal origin and can be used to define the complex interfaces between different solar wind types (see SOLAR WIND COMPOSITION).

Interplanetary development of CIRs

The formation and evolution of CIRs is a strong function of coronal morphology and temporal characteristics of the source regions and the transition region between closed and open magnetic field lines.

In the inner heliosphere the transitions between slow and high velocities are commonly steeper at 0.3 AU than beyond 0.5 AU. When the plasma streams and the interface propagate outward the continuing interaction between the streams increases the pressure in the region considerably. The interface becomes more azimuthal. The velocity difference across the interface exceeds the local wave speeds and two shocks bounding the interaction region develop. As the wave speed is lower in the slower, cooler stream the forward shock is generally formed first at the downstream border of the interaction region whereas the reverse shock at the up-stream edge develops at larger distances. Forward–reverse shock pairs are commonly observed beyond 2 to 3 AU.

Beyond 10–18 AU the forward shocks start to encounter the reverse shock of a CIR released about half (in the case of two CIRs per rotation) or one solar rotation earlier (which is actually the same CIR). At these distances merged interaction regions (MIR) develop and all solar wind material has at least been shocked once.

CIRs and their successors continue to evolve while convected to greater heliocentric distances. Shocks decline in frequency and strength and MIRs are replaced by corotating pressure enhancements.

CIRs and energetic particles

Origin, injection and acceleration of energetic CIR particles

The first hints of CIRs in the early 1970s were 27-day recurrent particle events with specific features, for example slow rise times and no obvious velocity dispersion due to particle propagation. Beyond 1 AU corotating energetic particle events, as they are now called, usually consist of two reasonably well separated particle intensity peaks centered approximately on the locations of the forward and reverse shock. Above 0.5 MeV the intensities at the reverse shock are usually larger than at the forward shock. This is shown in figure 2 for an event in January 1993 observed by Ulysses (see SOLAR WIND: ULYSSES) at 5 AU and at 24°S. It is obvious that around 100 keV the peaks of the proton intensities are about equal at the two shocks F and R whereas above 3 MeV there is hardly any

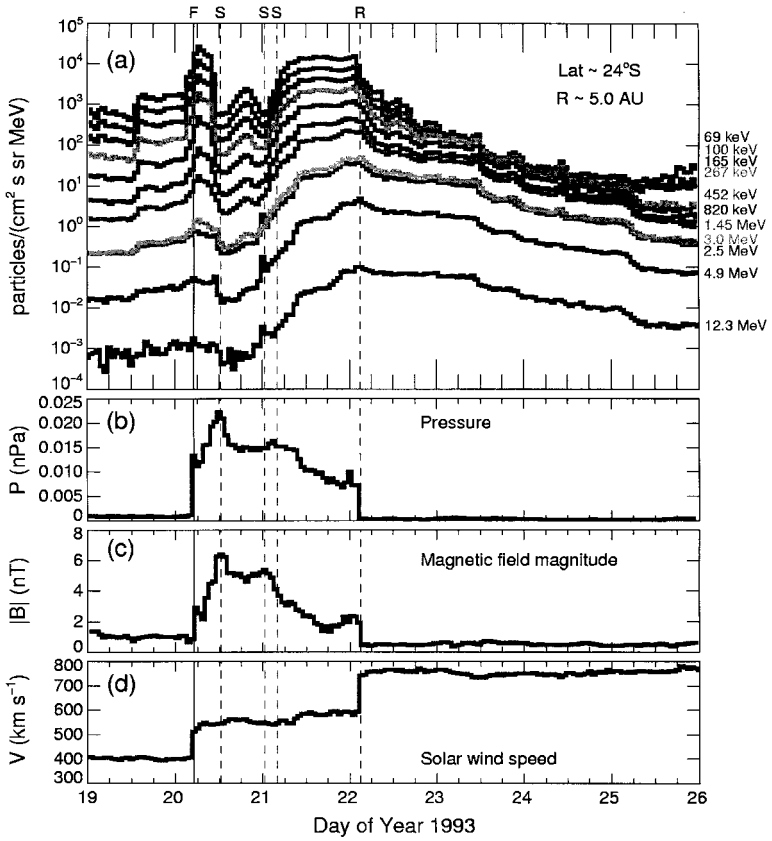

Figure 2. Hourly averages of (*a*) the 50 keV to 20 MeV proton intensities measured by two Ulysses instruments, (*b*) the pressure, P, (*c*) the magnetic field magnitude, $|B|$, and (*d*) the solar wind speed, V, from day 19, 1993, to day 26, 1993. The intensity measured in each of the 11 discrete energy channels is denoted by the geometric mean of the upper and lower energy bounds of that channel. The solid (marked F) and dashed (marked R) vertical lines denote the times of arrival of the forward and the reverse shock, respectively. The dashed vertical traces, marked S, denote the arrival times of the stream interfaces. (From Mason G *et al* 1999 *Space Sci. Rev.* **89** 327.)

increase left at the forward shock. The intensities decrease considerably, especially at low energies near the stream interfaces marked S in figure 2.

It took several years until CIRs were established as a cause for the recurrent particle increases. We now know that CIRs are capable of accelerating particles from the solar wind or suprathermal particles to energies between tens of keV up to ∼10 MeV at a wide range of solar distances and latitudes (see SOLAR WIND: ENERGETIC PARTICLES). Highest intensities are observed at ∼4 AU with a $1/r^2$ fall-off at large distances and a decay rate in the direction of the Sun of ∼300%/AU. Highest intensities versus latitude are observed around 20° with an e-folding angle of ∼8°. Ulysses observed the transport of CIR ions to latitudes well above the shock locations up to the highest latitudes of 80° in certain cases. CIR particles propagate away from source region along the magnetic field lines connecting the shock with the observer as shown in figure 1. At 1 AU a sunward flow is generally observed. However, non-field-aligned flows at peak intensities were reported at 1 AU as well. Generally, a strong inhibition of particle transport across stream interfaces is observed.

The spectral forms of CIR ions can be described by a power law spectrum from 30 keV/n to 1 MeV/n and a steepening spectrum above. At the high-energy end the spectrum merges with the ambient cosmic ray and anomalous cosmic ray (ACR) spectra. At the reverse shock the spectrum is generally harder than at the forward shock, but the forms do not change out to distances of several tens of AU.

The ion intensity peaks in the streamer belt region coincide with forward and reverse shock observations. Low-energy ions (tens of keV), however, are observed at and below 1 AU even in the absence of shocks. The time profiles are the same from He through Fe. Compositions are similar to the solar system observations except for factors of two to three enhancements of He and C relative to oxygen. The He/O and Ne/O ratios increase with the solar wind speed. The He/H abundance increases from 1 to 5 AU. The Mg/O ratio is the same for both forward and reverse shock periods and close to the average in solar wind slow and fast streams. Electrons are observed from 50 to hundreds of keV at several AU; however, only small intensities are observed at 1 AU.

Dirac House, Temple Back, Bristol, BS1 6BE, UK

Figure 3 shows the time history of CIRs and related particle increases for 12 solar rotations observed by Ulysses near 5 AU in 1993. A major restructuring of the corona is reflected in the time profiles of the particle intensities as well, e.g. by the shift in longitude between events 9–12 and 13–14. Sequences like this one are typical for the period prior to and at solar minimum displaying either one or two CIRs per rotation.

The huge three-dimensional extent of CIRs and its importance in structuring the quiet heliosphere became obvious only from Ulysses observations at higher latitudes in 1994. The maximum latitude extent of CIRs correlates well with the highest latitudes of the coronal streamer belt (which can also been described as tilt of the heliospheric current sheet) with the tendency of the reverse shock extending to somewhat higher latitudes and the forward shock extending only to lower latitudes than the streamer belt at larger radial distances.

The observation of CIR related accelerated particles (and modulation effects on galactic and ACR particles) almost up to the poles even in the absence of local shocks is surprising. Observed effects can best be ordered by field line connection to remote shocks and particle transport along the field lines with transit-time-dependent loss rates.

It is generally agreed that diffusive or first-order Fermi acceleration at the shocks is responsible for corotating energetic particle events. Charged particles originally from the high-speed solar wind are multiply scattered between the shock front and magnetic irregularities upstream. Acceleration is most efficient in the region of well developed shocks at about 3–5 AU. Energetic ion increases have also been observed at trailing edges of compression regions even when no reverse shock was detected, suggesting that the presence of the shock is not mandatory for moderate acceleration.

Pick-up ions are also accelerated within the corotating interaction regions, e.g. by stochastic acceleration in the magnetosonic turbulence. A possible injection/acceleration mechanism for pick-up ions at (quasi-)perpendicular shocks is shock surfing where particles are trapped between the electrostatic shock potential and the upstream Lorentz force. Some of the pick-up ions already constitute a suprathermal particle population. These ions becomes further accelerated by shock drift acceleration or in a Fermi type shock acceleration process if they are able to diffuse across field lines.

Modulation of cosmic rays and ACRs by CIRs

In addition to the CIR related intensity increases (from the acceleration of charged particles) above about 30 MeV/n recurrent decreases are also observed. These particles originate from the local interstellar space outside the heliosphere (galactic cosmic rays) or from local sources within the heliosphere (ANOMALOUS COSMIC RAYS or ACRs). The cosmic ray flux is lowest close to the reverse shock. This is in good agreement with 1970s observations from the PIONEER spacecraft. Ulysses found at high latitudes that in contrast to the solar wind speed galactic cosmic

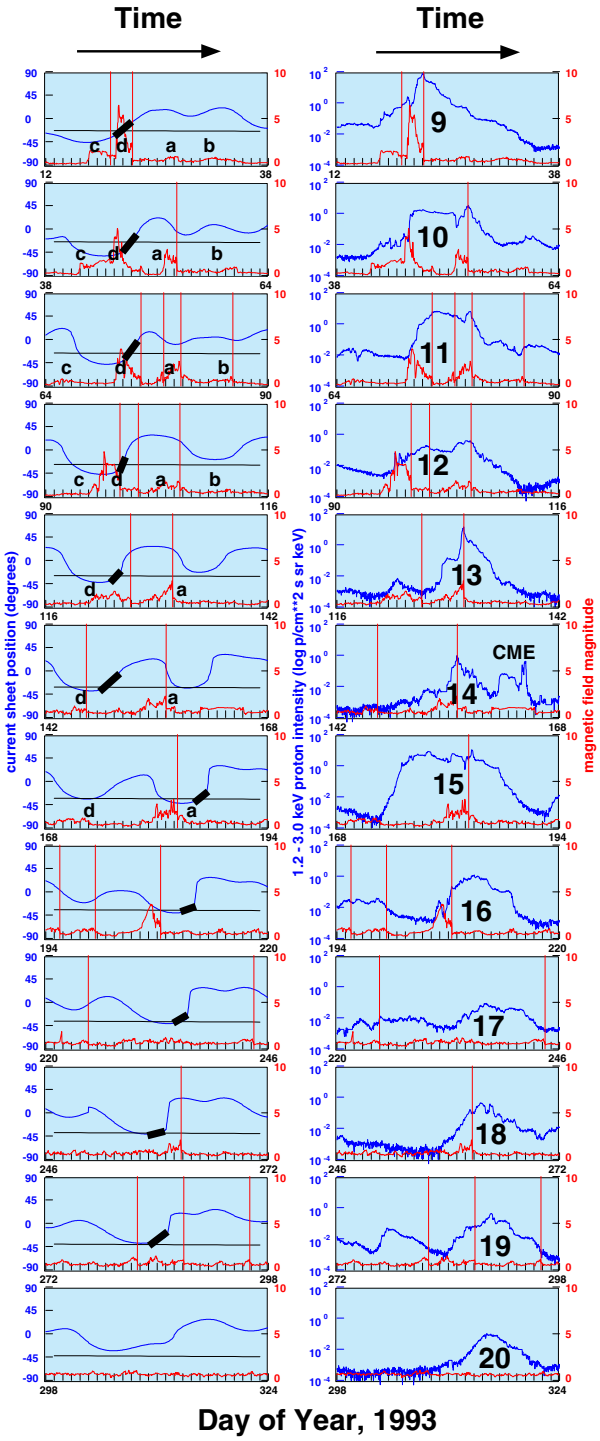

Figure 3. Data from 12 solar rotations, each of 26 days, starting on 12 January 1993. Time runs from left to right. The left column shows, in blue, the expected latitude of the current sheet at the position of the spacecraft. The black trace shows the position of the spacecraft, while the red trace shows the magnitude of the magnetic field. The right column shows, in blue, the 1.8–3.8 MeV proton intensity. The vertical lines show the observed times of reverse shocks, whilst the solid bars show the expected positions of the interaction regions. (From Kunow H *et al* 1999 *Space Sci. Rev.* **89** 221.) **This figure is reproduced as Color Plate 57.**

rays continued to be modulated on the time-scale of one solar rotation. The amplitude of the recurrent cosmic ray decreases show a maximum at 35° and is highest between 1 and 2 GeV for galactic cosmic ray protons.

Solar Wind: Energetic Particles

The energetic particle populations that we observe in the SOLAR WIND are accelerated in a variety of local and distant sources. We distinguish different populations by their temporal, spatial and angular distributions, energy spectra, abundances and ionization states. They tell us the physics of acceleration mechanisms and the properties of remote sites that are otherwise invisible or inaccessible.

Sources

The acceleration of particles to high energies is a remarkably common occurrence in the ionized plasmas of the heliosphere and presumably throughout the Galaxy. Often the presence of energetic particles in distant sources is inferred from observations of the photons they produce as they collide with matter. Radio emission, hard x-rays and gamma rays are produced when energetic electrons and ions interact with magnetic fields or with material in the ambient plasma. However, at times it is also possible to observe directly a sample of the accelerated material that has propagated to us at high speed along the often-tangled magnetic fields in space. In the heliosphere these energetic particles have disclosed a variety of new acceleration sites where the matter is too tenuous for photon production.

Particles are known to be accelerated to MeV and even GeV energies in solar FLARES, at the shock waves driven out from the Sun by SOLAR CORONAL MASS EJECTIONS (CMEs), in planetary MAGNETOSPHERES and at planetary bow shocks. They are also accelerated at co-rotating interaction regions (CIRs) between high- and low-speed streams in the solar wind (see SOLAR WIND: COROTATING INTERACTION REGIONS) and at the solar wind termination shock at the outer edge of the heliosphere (see SOLAR WIND SHOCK WAVES AND DISCONTINUITIES). In addition, we observe the galactic cosmic rays that have probably been accelerated by shock waves from supernovae. We distinguish these different populations of energetic particles and identify their sources by the particle arrival timing and associations with other phenomena, by their spatial distribution and arrival directions, by their energy spectra, and by the abundances of elements and the ionization states of the ions in these populations.

As measurements have become more sensitive and complete, it has become possible to distinguish particle sources that were previously unclear. One important example has been the identification of different sources for the impulsive and gradual solar energetic particle (SEP) events as flares and CME-driven shocks, respectively. Once it was believed that all of these particles came from flares, the so-called 'flare myth'. Another example has been the new evidence that particles upstream of the Earth's bow shock are actually accelerated by that shock and are not merely escapees from the magnetosphere (see MAGNETOSPHERE OF EARTH: BOW SHOCK).

Impulsive solar flares

Impulsive solar flares are sources that provide us with considerable information on particle acceleration. We can observe the accelerated particles in space and the photons produced near the Sun. Most of the acceleration in flares takes place on closed magnetic loops in the CORONA. As these loops become tangled from circulation at their photospheric footpoints or as new magnetic flux emerges from the photosphere, energy can be suddenly released by magnetic reconnection. The associated wave turbulence is the probable source of energy for stochastic acceleration (see SOLAR FLARES: PARTICLE ACCELERATION MECHANISMS). As particles scatter into the loss cone, they plunge into increasingly dense material near the footpoints of the loops where they lose energy by Coulomb interactions. A small fraction of the electron's energy is lost to x-ray bremsstrahlung and a small fraction of the ions interact to produce γ-ray lines from excited nuclei in the beam or the ambient material. Electrons escaping along open field lines produce type III radio bursts as they stream out along the magnetic field through plasma of decreasing density. Finally, satellites in space can observe both the energetic electrons and ions directly.

As the particles stream out along magnetic field lines they are scattered somewhat by Alfvénic fluctuations of the magnetic field, although the scattering mean free path of ~1 AU is comparable with the distance to the Sun. This, together with different particle velocities and pitch angles with respect to the field, can spread the particle arrival times over a period of several hours. Typical profiles of particle intensity versus time for a series of impulsive events are shown in figure 1(a). Different particle speeds produce 'velocity dispersion' in the earliest arrival times, a sophisticated way of saying that the fastest particles arrive first. The propagation time, $t = L/\mu v$, where L is the distance along the field line, μ is the average cosine of the pitch angle and v is the particle velocity. Photons and relativistic particles take at least 8 min to propagate 1 AU, 50 keV electrons or 100 MeV amu^{-1} ions take 18 min, and 1 MeV amu^{-1} ions take 2.9 h. This relationship can be used to associate all particle species and energies with a particular flare at the Sun, within measurement errors of a few minutes. Type III radio observations provide additional information that can track the 10–100 keV electron population in direction and distance as it moves out from the Sun along the field line. Particles from impulsive events are only seen over a solar-longitude interval of ~30° where field lines are fairly well connected to the flare (see SOLAR FLARES: IMPULSIVE PHASE). Although poorly measured, this longitude interval is of interest because it is controlled by the random walk of magnetic field lines.

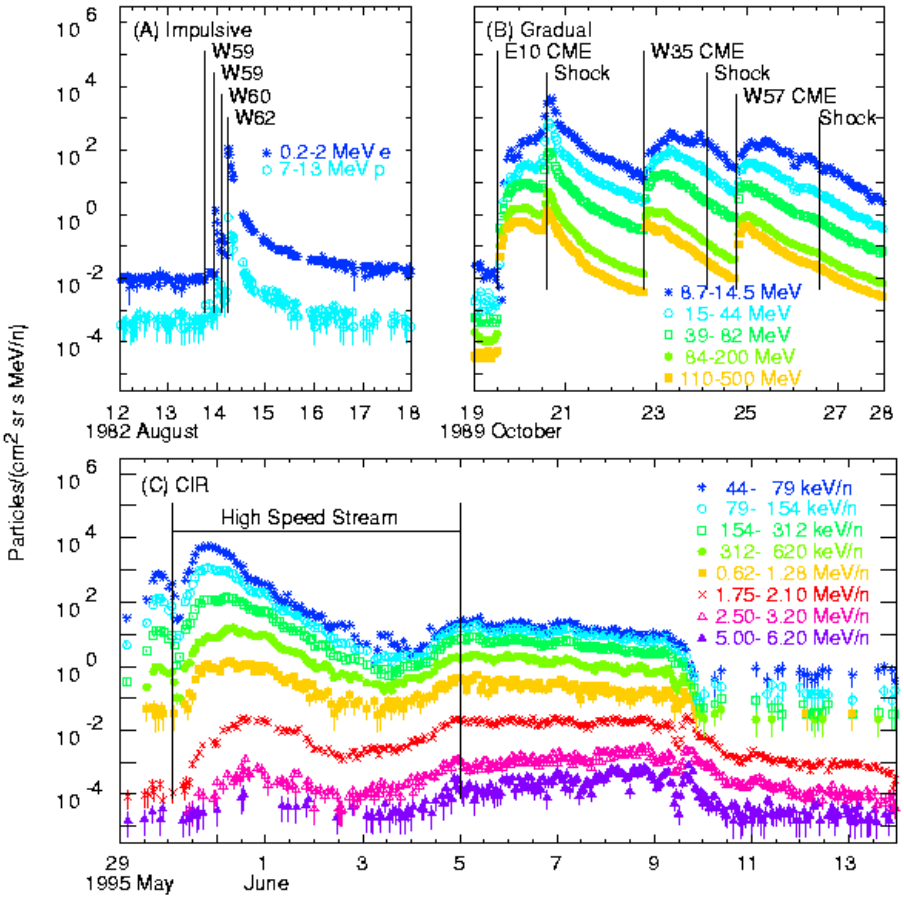

Figure 1. Intensity–time profiles are shown for various sources using the same time and intensity scales for each. (a) Electron and proton data from ISEE 3 are shown for a series of flares at the times and solar longitudes indicated. (b) Proton intensities from the NOAA/GOES spacecraft are plotted for a series of gradual events at the energies shown. Times and longitudes of CME launch at the Sun and the shock arrival at Earth are indicated. (c) Intensities of He at various energies are shown during a CIR event as observed on the WIND spacecraft.

Particle abundances are one of the most distinctive features of impulsive-flare events. We often find the ratio of abundances of isotopes of He, ^{3}He/^{4}He~1 in these events while this ratio is ~5 × 10^{-4} in the solar atmosphere or the solar wind. For this reason, these impulsive-flare events are often called ^{3}He-rich events. High electron abundances and more modest enhancements of heavy ions also occur. On average, Ne/O, Mg/O, and Si/O are enhanced by a factor of ~3 and Fe/O by a factor of ~7 in these events, relative to the corresponding coronal or solar wind abundances (see table 1 and SOLAR ABUNDANCES). Element abundances derived from the intensities of broad γ-ray lines emitted by energetic particles inside the flares are consistent with those measured for the energetic particles in space. These abundances are taken as evidence of resonant wave–particle interactions during stochastic acceleration. The huge enhancement of ^{3}He may occur because intense beams of streaming electrons excite electromagnetic ion cyclotron waves between the gyrofrequencies of the dominant species, H and ^{4}He, in the flare plasma. The rare isotope ^{3}He, the only species whose gyrofrequency lies in this region, is preferentially accelerated as it absorbs energy from these waves. Heavy ions may be enhanced by other wave modes or by second-harmonic interaction with the same waves. Acceleration of particles by resonant interaction with waves also occurs in other regions of high magnetic field energy, such as the auroral region of the Earth where both the particles and resonant waves have been observed together in the phenomenon known as ‘ion conics’.

Measurements of ionization states of the energetic ions show that all elements up to Si are fully ionized, while Fe has ~20 of its 26 electrons removed, corresponding to an electron temperature of ~15 MK (1.5 × 10^7 K). This is not surprising for a flare temperature; atomic spectral lines of highly ionized Fe are often seen from flares. However, if the elements C, N, O, Ne, Mg,

Copyright © Nature Publishing Group 2002

and Institute of Physics Publishing 2002
Dirac House, Temple Back, Bristol, BS1 6BE, UK

and Si were fully ionized before acceleration, they would all have the same charge-to-mass ratio, $Q/A = 0.5$, hence the same magnetic gyrofrequency. In this case, it would be impossible to produce relative enhancements since all ions would resonate with the same waves. Actually, the pattern of enhancement is consistent with the values of Q/A that would exist in a 3–5 MK plasma, a typical active-region temperature. This suggests that the ions are drawn from the ambient plasma and accelerated early in flare; stripping then occurs later as the electron temperature rises.

Gradual events and CME-driven shocks

The most intense energetic-particle events we see near Earth are the 'gradual' events produced by particles accelerated at shock waves driven out from the Sun by fast CMEs. Essentially all (>96%) large proton events are associate with CMEs. Since most CMEs have speeds that are near or slightly above that of the solar wind, they do not produce shocks, nor do they accelerate particles. Particle acceleration only occurs for the fastest ~1% of CMEs. Shocks with speeds >500 km s^{-1} usually accelerate particles while those with speeds >750 km s^{-1} nearly always do. The largest SEP events of a solar cycle are produced by shocks with speeds of 1500–2000 km s^{-1}. Shock speeds can decrease by as much as a factor of 2 between the Sun and Earth. Acceleration of protons up to ~10 MeV usually continues to 1 AU and beyond in most moderate events. Acceleration of 100 MeV–1 GeV protons occurs primarily near the Sun in most events but continues out to 1 AU in the largest events. In the large 19 October 1989 event shown in figure 1(b), particle intensities peak at the time of shock passage (on 20 October) even at energies of ~1 GeV.

Acceleration occurs at shock waves as particles are scattered back and forth across the shock surface, gaining an increment in speed on each transit. The upstream and downstream scattering centers serve as approaching 'walls' from which the particles are reflected. The distribution of particles streaming away from the shock is itself unstable to generation of Alfvén waves that add to the scattering of particles that follow behind. This nonlinear process serves to trap particles near the shock and increase the efficiency of acceleration. However, in shock acceleration, the energy of the particles comes from the kinetic energy of the shock, not just from the energy in the waves.

Ionization-state measurements have provided the clearest and most compelling evidence on the origin of the ions in the large gradual events. The ionization states are characteristic of a 1–2 MK plasma. Even C and O are not fully ionized and the mean ionization state of Fe, Q_{Fe} ~ 14. These ions could *not* come from the hot plasma of a flare; they represent ambient unheated coronal plasma. Ionization states of Fe have now been measured over an energy interval of 0.3–600 MeV amu^{-1} by 6 different experiments on 4 spacecraft. The highest-energy measurements were made in some of the largest events of the last solar cycle. Not only do these ions place an upper limit on the source temperature, but also the high-energy ions would be stripped of electrons in seconds at densities of 10^{10} cm^{-3} found in the low corona where flares occur. The ions must have been accelerated from ambient coronal plasma at low density. This conclusion is in agreement with observations that the peak intensities of GeV protons are produced when the leading edge of the CME is at 5–10 solar radii.

Table 1. Element abundances in energetic particle sources.

	Z	FIP	Photosphere	Gradual events (SEP corona)	CIR events (Coronal hole)	Impulsive flares	Anomalous CR	Galactic CR source
H	1	13.53	1.35×10^6	$(1.57\pm0.22) \times 10^6$	$(1.81\pm0.24) \times 10^6$	$\sim 1 \times 10^6$	~1000±500	$(1.74\pm0.43) \times 10^5$

At energies of a few MeV amu^{-1}, most element abundances in gradual SEP events do not vary significantly from event to event and the average abundances seem to directly reflect the abundances of the source plasma in the solar corona. In fact, SEP abundances provide the most complete information we have on coronal abundances on a total of 22 elements (see table 1). Element abundances in the corona differ from those in the photosphere in a way that depends upon their *first* ionization potential (FIP), or perhaps upon their first ionization time scale. Elements with FIP < 10 eV (e.g. K, Na, Al, Mg, Si and Fe) have abundances that are enhanced by a factor of ~4 relative to high-FIP elements (e.g. C, N, O, Ne, Ar). Low-FIP elements are ionized in the photosphere, while high-FIP elements are neutral. An ion–neutral fractionation occurs because ions and neutral atoms are transported differently from the photosphere into the corona. Once elements reach the 1–2 MK corona they all become highly ionized long before they are accelerated.

A characteristic feature of gradual SEP events is their large and complex spatial structure that produces a wide variety of time profiles when viewed by spacecraft at different longitudes relative to the CME. Figure 2 shows time profiles of proton intensities seen by 3 spacecraft whose configuration relative to the CME is shown in the inset. As the spiral interplanetary field lines are swept over a spacecraft, the longitude of the magnetic connection point to the shock swings eastward with time. In this event, the 3 spacecraft become better connected to the intense acceleration region near the nose of the shock as time increases. HELIOS 1 is best connected. Here the intensity rises to a flat profile where the intensity is controlled by limits on the rate particles can stream away from the shock. A sharp peak in intensity is seen as the shock passes the spacecraft. The other two spacecraft see lower intensities around the flank of the shock; intensities increase as their connection point moves toward the nose of the shock. Behind the shock all 3 spacecraft enter an invariant-spectral region where particle intensities decrease slowly with time as the containment volume for the particles slowly expands.

Energy spectra of ions from the 20 October 1995 event are shown in figure 3(b). These spectra were obtained during the invariant spectral period in this relatively small event by the WIND spacecraft. The proton spectrum from the plateau region in the large event of 19 October 1989 is also shown in the figure for comparison. This event, shown in figure 1(b), was the largest event that occurred during the last solar maximum.

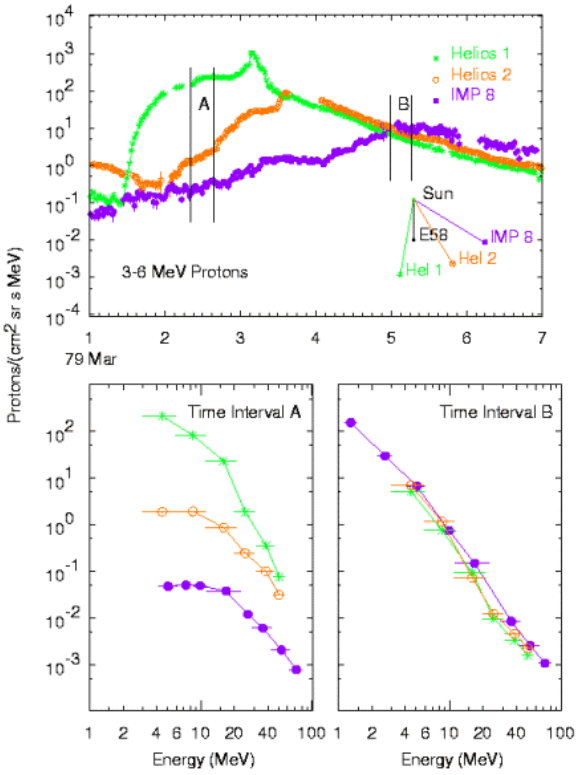

Figure 2. Intensity–time profiles of 3–6 MeV protons observed by 3 spacecraft are shown for a gradual event of modest extent. Spacecraft locations around the CME are shown in the inset. Lower panels show proton energy spectra taken early in the event (a) and during the 'invariant' spectral period (b).

Acceleration at the Earth's bow shock

The bow shock produced when the solar wind encounters the Earth's magnetosphere is also a source of accelerated particles. These were first observed as intense bursts of particles (and resonant waves) seen by the ISEE spacecraft in the region sunward of Earth. Since magnetic flux tubes contact the Earth's bow shock for a short time, the energies of the accelerated ions are usually below 100 keV amu^{-1}. Bursts were observed only during periods when the magnetic field connected the spacecraft to the bow shock. As the solar wind sweeps field lines past the Earth, they remain in contact with the bow shock for a limited period. For the nominal field direction, this contact point is usually swept across the sunward face of the shock from the dusk to the dawn side; the field direction becomes increasingly parallel to the shock normal. However, it was not possible in the early measurements to distinguish which elements comprised the 'ions', or to clearly establish that the particles were accelerated at the shock rather than simply leaking out from the Earth's radiation belts.

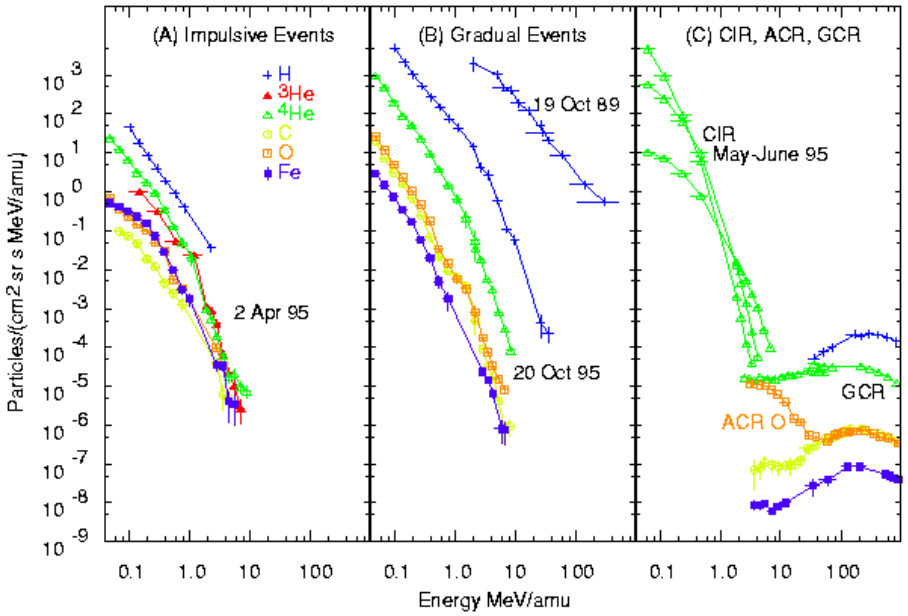

Figure 3. Energy spectra of various particle species indicated are shown for different particle populations. (a) Spectra for a small impulsive-flare event on 2 April 1995 observed on the WIND spacecraft are shown. (b) Spectra for various species in the small 20 October 1995 event observed on the WIND spacecraft are shown and a proton spectrum observed by NOAA/GOES during the large 19 October 1989 event (see figure 1(b)) is shown for comparison. (c) Spectra of He during the May–June 1995 CIR event (see figure 1(c)) show variation with time. The low-energy GCR spectra of various species during solar minimum are shown, and the low-energy rise in O from the presence of ACRs is noted on the figure.

The first measurements of element abundances in these 'upstream events' were made aboard the WIND spacecraft. It was found that the ions had the same element abundances as the high-speed solar wind and that events were much more common during high-speed solar-wind streams when the bow shock was strongest. In one case an upstream event even occurred during a small solar ^{3}He-rich event so that the intense burst of ions flowing upstream from the shock was also ^{3}He-rich. Clearly the source of the accelerated ions was these available particles from the upstream solar wind, not those from the magnetosphere.

Co-rotating interaction regions (CIRs)

CIRs are formed when high-speed solar-wind streams, emitted from coronal holes on the Sun, overtake the low-speed solar wind emitted earlier in the solar rotation. This interaction produces a pair of shocks: a forward shock propagates outward into the slow solar wind and a reverse shock propagates sunward into the high-speed solar wind. The shocks usually begin to form outside 1 AU and they continue to strengthen out to several AU. Particles are accelerated at both shocks, although the reverse shock seems to produce greater intensities and harder energy spectra. Thus particles from the reverse shock are most easily observed near Earth flowing sunward through the high-speed stream.

The time evolution of He intensities from a large CIR is shown in figure 1(c). Particles from the forward shock are seen on 29 May. As the Sun rotates, the Earth crosses the stream interface from the slow to the fast solar wind on 30 May. At first, low-energy particles predominate from the newly formed shock. Later, as we become connected to the strengthening shock farther away from us, high-energy particle intensities increase while those at low energies are attenuated by the greater transport distances. This behavior is the inverse of the velocity dispersion seen in both impulsive and gradual SEP events. For the unusual event of May–June 1995, particles were seen for 17 d while the sun rotated through an angle of ~225° and the reverse shock propagated across the high-speed stream and far into the following low-speed solar wind. The evolution of the energy spectra of He in this event is shown in figure 3(c).

Averaged element abundances of energetic particles from CIRs are included in table 1. These abundances are most similar to those of the high-speed solar wind that serves as the source. The enhancement of low-FIP elements relative to high is only a factor of ~2, indicating that abundances of the material from coronal holes suffers less fractionation than that in the corona and in active regions. However, departures from solar-wind abundances are also seen. Elevated abundances of H and He, for example, probably result from the acceleration of interstellar pickup ions (see below) although O, the

and Institute of Physics Publishing 2002
Dirac House, Temple Back, Bristol, BS1 6BE, UK

talisman of this source, is not enhanced relative to C, N or Ne, for example.

Anomalous cosmic rays (ACRs)

ACRs are yet another shock-accelerated particle population with unique element abundances. In the interstellar material outside the heliosphere, elements with FIP less than the ionization potential of H, 13.6 eV, are ionized while those of higher FIP are neutral. Interstellar H absorbs the photons of higher energy. As the solar system moves through this gas, neutral atoms easily penetrate, but ions are largely excluded by the magnetic fields. As these interstellar neutrals approach the Sun they are ionized by solar photons or, in the case of H, by charge exchange with the solar wind. These new ions are suddenly able to sense the presence of the magnetic fields of the solar wind. Thus they are 'picked up' by the solar wind and they acquire a velocity distribution that extends to twice the solar-wind speed. The ions are eventually convected out to the solar-wind termination shock that is estimated to be formed ≥100 AU from the Sun. Here, the higher initial injection speed of the pickup ions leads to their preferential acceleration. The energetic ions are modulated as they propagate back to 1 AU where they are observed (see COSMIC RAYS).

The ACRs were first observed by the anomalously high intensities of O (relative to C, for example) at ~10 MeV amu^{-1} near solar minimum (see figure 3(c)). O, as well as He, N and Ne, persisted during solar minimum but were then modulated with the 11 yr solar cycle in a manner similar to the galactic cosmic rays. The theory of the singly ionized interstellar pickup ions and of their acceleration at the termination shock was advanced 20 years before pickup ions were first observed in the solar wind. Recently, ionization states of ACRs have also been directly measured, confirming that most are singly ionized while a small fraction have become more highly ionized during acceleration and transport. Approximate abundances of ACRs at the termination shock are included in table 1; these abundances depend upon assumptions made to correct for solar modulation.

Galactic cosmic rays (GCRs)

Cosmic rays, probably accelerated at SUPERNOVA shock waves in the Galaxy, have a constant presence throughout the heliosphere (see COSMIC RAYS: PROPAGATION IN THE HELIOSPHERE). GCRs are easily distinguished from other particle populations by their high energies and their unusual element abundances. As observed, GCRs contain unusually high abundances of Li, Be and B that are produced in nuclear reactions with interstellar matter during the ~10^7 yr lifetime of the GCRs. It is possible to correct for this matter traversal to derive GCR source abundances that are shown in table 1. The first suggestion of the existence of an ion–neutral fractionation process based upon FIP was made for the GCR source abundances by comparing them with the 'universal' abundances of elements derived from meteorites (essentially equivalent to solar photospheric abundances). Similarities between the abundances of GCRs and those of large gradual SEP events were noted many years ago, suggesting that stellar coronae or stellar energetic particles provide the seed population for the GCRs. Competing theories explain the enhancement in low-FIP elements in GCRs by the preferential acceleration of INTERSTELLAR GRAINS that are rich in those elements. However, we have seen that the process of separating ions and neutral atoms across electromagnetic fields, seen in the SEP, CIR and ACR abundances, is quite common in the heliosphere. It would be surprising if this process were confined to the heliosphere while an entirely different mechanism governed the GCR abundances.

The low-energy portion of the spectra of the dominant species in the GCRs is shown in figure 3(c). Above ~1 GeV amu^{-1} the differential intensity spectra attain an $E^{-2.6}$ dependence that continues to ~1 TeV amu^{-1} where the spectrum steepens to form a 'knee'. The low intensities of particles here and at higher energies can only be measured indirectly by large detector arrays at ground level. Hence, element abundances and their evolution as a function of energy have not been measured here.

Solar cycle variations

Different epochs in the 11 yr solar cycle bring an enormous change in the character of the energetic particles we see in the solar wind near Earth. The most favorable 'season' for observing ACRs and low-energy GCRs is at solar minimum when their intensities are highest. These particles are suppressed as the solar cycle increases. In fact, ACRs have never been observed during the years around solar maximum.

It is not surprising that the numbers of both impulsive and gradual SEP events increase as solar activity increases and more flares and CMEs occur. The number of impulsive-flare-related events varies from a few per year at solar minimum to a few hundred per year at solar maximum. The number of gradual events varies from about 5 yr^{-1} at minimum to 30 yr^{-1} at maximum. Of course these numbers depend upon the intensity threshold and the particle species and energy used to count events. However, the numbers are not the whole story. The events at solar minimum are also smaller and have softer energy spectra than those at solar maximum (see the proton spectra for the two gradual events in figure 3(b)). These are the products of less-energetic flares or of weaker shocks.

For CIR events, the variation is more complicated. Energetic particles from CIRs can be seen at most phases of the solar cycle. However, they are difficult to observe

Copyright © Nature Publishing Group 2002
Brunel Road, Houndmills Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2002
Dirac House, Temple Back, Bristol, BS1 6BE, UK

(or to count) during solar maximum because they are often obscured by SEP events and the CIRs themselves are disrupted by CMEs. Thus the events are best studied near solar minimum. However, at times *very* near solar minimum, such as during 1996, the heliospheric current sheet becomes very flat and lies near the solar equatorial plane. Thus, the polar high-speed streams and the equatorial low-speed streams can flow out radially with no regions of interaction. During these times there are few CIRs formed and few particles accelerated.

Solar Wind: Global Properties

The most fundamental problem in solar system research is still unsolved: how can the Sun with a surface temperature of only 5800 K heat up its atmosphere to more than a million K? In fact, the solar atmosphere is so hot that not even the Sun's enormous gravity can contain it. Part of it is continuously evaporating into interplanetary space: the SOLAR WIND. As a highly ionized magnetized plasma it dominates a huge volume around the Sun which is called the heliosphere. Only far beyond the outermost planets is a transition into the interstellar gas flowing through our Galaxy expected to occur.

On the rare occasions of solar eclipses, every observer is stunned by the high degree of structure in the then uncovered CORONA. No wonder that the solar wind emerging from there is similarly inhomogeneous and creates a complicated three-dimensional shape of the plasma heliosphere. Interactions between outflowing streams of different speeds and solar transient phenomena cause further complications. Thus, the solar wind as we see it from the Earth's orbit is characterized by an enormous variability in all its basic properties. It is this very variability that allows the solar wind to have a surprisingly large impact on the Earth. Some effects even make it down to the ground!

The solar wind proves to be one key link between the solar atmosphere and the Earth. Although the energy transferred by the solar wind is miniscule compared to both sunlight and those energies involved in the Earth's atmosphere, the solar wind is capable of pin-pricking the Earth system until it eventually reacts in a highly nonlinear way.

In this article the chief characteristics of the solar wind in context with its sources in the corona will be presented. The next section first describes the basic properties of the solar wind as observed in the comparatively simple situation around solar activity minimum. Next the corona and inner heliosphere are discussed in their full 3D extent. The fate of the stream structure as it evolves with increasing distance from the Sun is then dealt with. Finally we summarize the current knowledge of the different types of solar wind, ending with the admission that none of them is really explained yet.

The solar wind at 1 AU

Basic properties

The existence of the solar wind was theoretically modeled by E Parker in 1958 and experimentally verified in 1962. Since then, it has been observed throughout wide parts of the heliosphere, as close as 0.29 AU and as far as (by now) 70 AU from the Sun, mainly in the ecliptic plane, but also above both solar poles. Some typical parameters as measured at the Earth's orbit (i.e. at 1 AU distance from the Sun) are given in table 1.

Table 1. Typical parameters of the slow solar wind at 1 AU.

Flow speed v_p	350 km s^{-1}
Proton density n_p	9 cm^{-3}
Flux density $n_p v_p$	3×10^8 cm^{-2} s^{-1}
Composition	96% protons, 4% He^+ ions, minor constituents, plus an adequate number of electrons to maintain nearly perfect charge neutrality
Proton temperature T_p	4×10^4 K
Electron temperature T_e	1.5×10^5 K
Magnetic field B	4 nT

The solar wind flow speed is usually much higher than the local sound and Alfvén speeds, and typical Mach numbers are around 10. This implies that the plasma dynamic pressure is much higher than both the magnetic pressure and the thermal pressure. It also means that the magnetic field is frozen-in in the expanding flow. The field lines can be regarded as 'stream lines' of the flow. Generally, they maintain their identity on their way through the entire heliosphere since, due to the near absence of collisions in the tenuous plasma, the particles can hardly ever leave their original field lines. All particles move, on the average, radially away from the Sun. Therefore, the stream lines interconnecting particles emerging from the same source on the rotating Sun are curved like Archimedean spirals. The curvature is determined by both the flow speed and the distance from the Sun. The average Parker angle between the stream lines and the radial direction to the Sun at 1 AU amounts to about 45°. With increasing distance to the Sun the Parker spiral winds up further and further: from Jupiter's orbit in the direction of the local magnetic field can be considered almost perpendicular to the solar wind flow. Actually, the plasma keeps moving radially, in analogy to the needle in the spiral grooves of an old-fashioned record.

Solar wind stream structure

The solar wind exhibits a remarkable variability, even at times of low solar activity. As a typical example, figure 1 shows the main solar wind parameters obtained near the Earth's orbit during a whole solar rotation. They were recorded in early 1974, i.e. close to a solar activity minimum, and the basic pattern seen then remained almost unchanged through several months:

- For two intervals of some 60° in longitude (corresponding to a durations of several days) the flow speed exceeds 600 km s^{-1}.
- In both these high-speed streams the plasma density is lowest and the proton temperature is highest (while the electrons are somewhat cooler), just opposite to the low-speed regions in between.
- Both high-speed streams are regions of unipolar magnetic fields (indicated by the + and − signs),
- In a short interval in the middle of the figure, interplanetary shock waves went by, characterized by abrupt increases in speed, density, temperature and magnetic field strength (not shown here). This type of shock wave is caused by transient activity on the

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

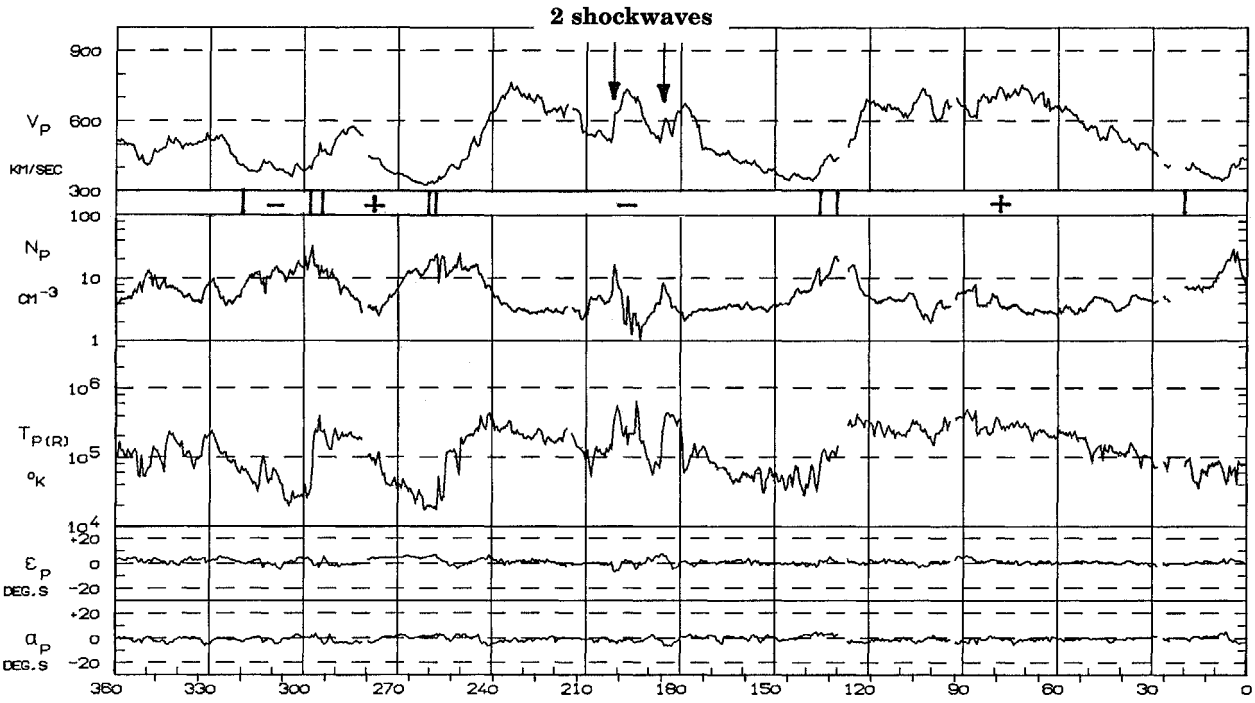

Figure 1. The solar wind proton parameters (flow speed, density, temperature and flow angles relative to the radial direction) during a full solar rotation in early 1975, as observed by the Helios 1 solar probe close to 1 AU. Typical for this phase of minimum solar activity are the two large high-speed streams with the extended compression regions in front. Note also the two transient-related shock waves.

Sun, e.g. SOLAR CORONAL MASS EJECTIONS (CMES). Usually, not more than one such event occurs per solar rotation at solar minimum.

- The left part of the figure shows a less well-ordered pattern of flow speeds and polarities.
- The flow angles ε_P (out of the ecliptic) and α_P (azimuthal) fluctuate within about 10° around the radial direction. More pronounced deflections are observed in compression regions ahead of high-speed streams and at shock waves.

Observations as shown in figure 1 revealed that solar wind variability cannot be attributed to just transient disturbances of an otherwise quiet or structureless solar wind. In particular the persistent occurrence of high-speed streams with flow speeds up to 800 km s^{-1} was realized to be an intrinsic feature of the solar wind phenomenon. With decreasing solar activity in the years 1973–75, these high-speed streams developed into stable large-scale structures. Some of them were observed at the same solar longitude for several months, i.e. they were stationarily corotating with the Sun through several solar rotations.

In the Skylab era the coronal sources of the high-speed streams could be identified: these are regions of diminished brightness at soft x-ray and EUV wavelengths (so-called CORONAL HOLES), indicating significantly lower electron densities and temperatures. The boundaries are remarkably sharp and coincide in detail with those of the high-speed streams properly mapped back to the Sun. Coronal holes mark the regions in which coronal magnetic field lines open freely into interplanetary space (see articles by Kohl and de Forest). At times of low solar activity they cover mainly both polar caps. In contrast, closed loop-like structures are always related with active centers such as SUNSPOTS which most often are located at lower heliographic latitudes. Coronal holes and the high-speed streams emerging from them have to be regarded as features of the quiet Sun, not the active Sun.

The solar wind in three dimensions

The 3D heliosphere in terms of the 'ballerina model'

On the basis of these early discoveries, a three-dimensional model of the heliosphere and the stream-structured solar wind emerged. It is most adequately visualized in terms of the ballerina model first proposed by H Alfvén in 1977.

Figure 2 is an artist's view of the inner heliosphere as it may appear immediately before a typical solar activity minimum, e.g. in 1975. We find the Sun's poles to be covered by large coronal holes. They are areas of open magnetic field lines, the northern hole being of positive (outward directed) polarity, the southern hole being negative. One solar cycle later the polarity reverses, of course. Some tongue-like extensions of the coronal holes reach well into the equatorial regions. The Sun's equatorial

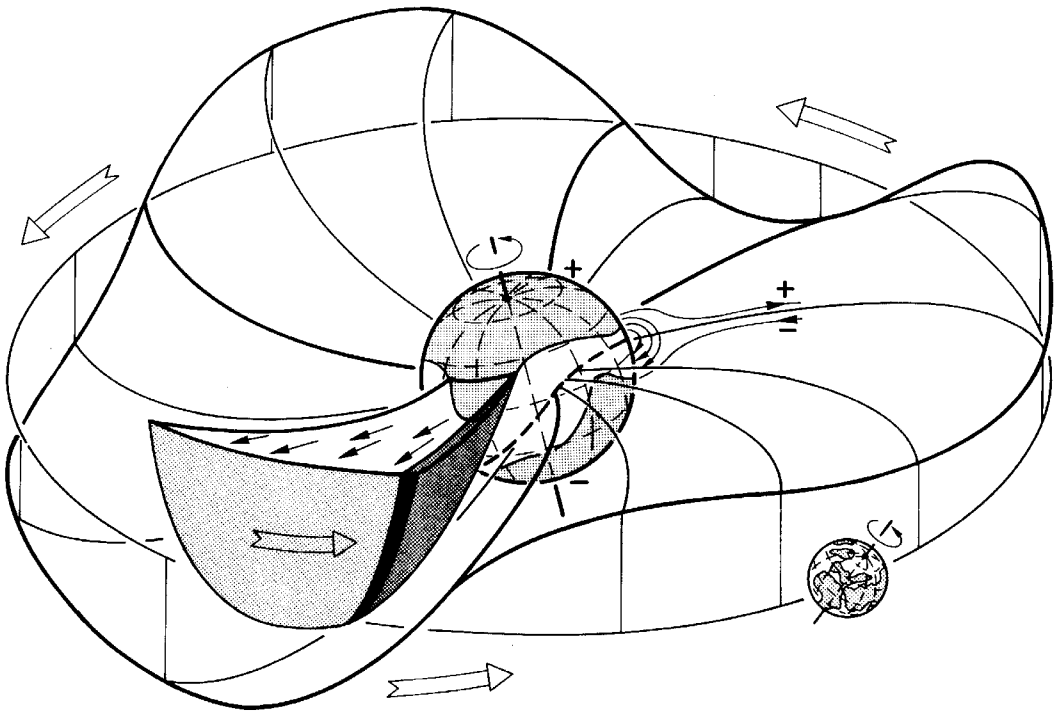

Figure 2. The 'ballerina model' of the 3D heliosphere, according to H Alfvén.

region is governed by bright active centers (including some sunspots left over from the past cycle) and their loop-like and mainly closed magnetic structures.

What looks like the skirt of a spinning ballerina is the warped separatrix between positive and negative solar magnetic field lines dragged out into interplanetary space by the radially outflowing solar wind plasma. This heliospheric current sheet is formed on top of the closed magnetic structures at the transition between closed and open flux tubes, i.e. generally in the middle of the near-equatorial 'belt' of activity. If the spinning skirt passes an observer sitting, say, at the earth, he would notice a polarity switch and call it a crossing of a magnetic sector boundary. The size and number of magnetic sectors is closely related to the structure of the underlying corona. i.e. the shape of the activity belt and the coronal holes, respectively (for more details see the article SOLAR WIND: MAGNETIC FIELD).

The heliospheric current sheet: shape and origin

The coronal holes are the sources of high-speed solar wind. The emission of slow solar wind is sharply confined to a belt centered at the warped current sheet of about 40° width in latitude. The warps of both the current sheet (which can be taken to be the heliomagnetic equator) and the coronal hole boundaries with respect to the heliographic equator allow some high-speed streams to extend to low latitudes so that they become observable at times even in the plane of the ecliptic. This occurs preferentially in the 2 years before activity minimum, when the large-scale coronal structure is rather stable, and high-speed streams reappear at the same heliographic longitudes for many solar rotations.

At times of minimum solar activity there are almost no warps left in the current sheet which is then planar like a disk lying very close to the plane of the heliographic equator. This is demonstrated in figure 3 where two images registered by the LASCO coronagraphs on board SOHO in early 1996 were merged. They give a very typical example of the appearance of the extended corona at the most recent activity minimum. The inner part was taken in the light of the green corona line at 530.3 nm produced by Fe XIV ions at temperatures of 2×10^6 K. This spectral line is particularly well-suited to outline hot magnetic structures in the inner corona. The outer part taken in white light shows the larger-scale electron density distribution.

Images of this type taken during the months around solar activity minimum have revealed that:

- the appearance is nearly symmetric about the solar axis, with a flat high density sheet right in the equatorial plane,
- the green (inner) patterns merge well into the white (outer) patterns, indicating that hot magnetic loops are closely associated with high density streamers on top,

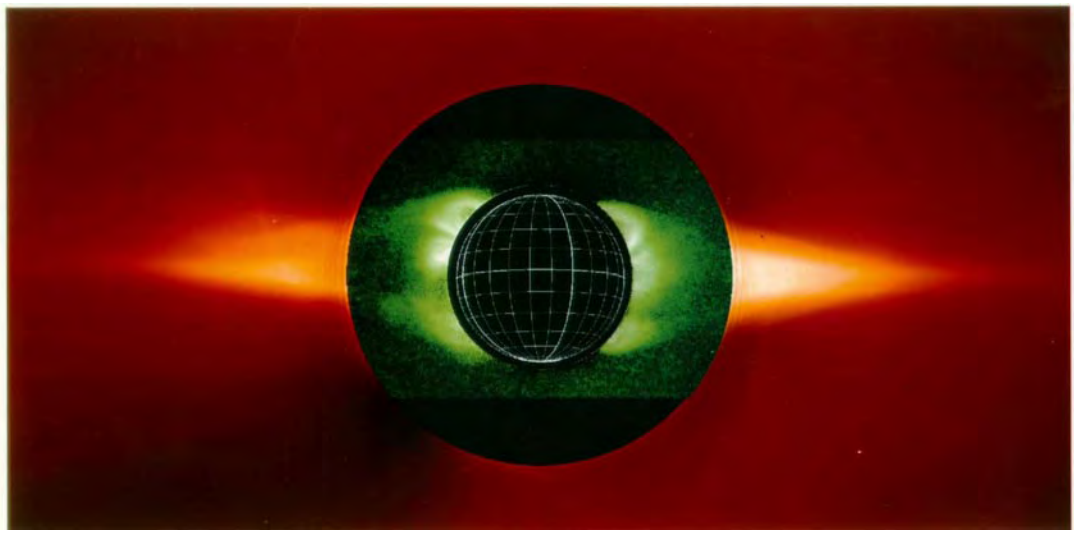

Figure 3. A coronagraph view of the extended minimum corona (on 1st February 1996), composed by a green-line emission image and a white-light image taken by the LASCO coronagraphs on-board SOHO. **This figure is reproduced as Color Plate 54.**

- the dense sheet emerges from bright apparently closed loop systems (called helmet streamers) centered at latitudes of 30–45° in both hemispheres; the loop tops usually reach out to about 1.5 R_s, in some cases to well beyond 2 R_s; their helmet-like outer extensions are clearly bent towards the solar equator,
- around the equator, there is a more diffuse bright pattern, clearly separated from the high latitude loops and strongly varying with time,
- there is no detectable green-line emission above either of the poles, confirming that the density and temperature in polar coronal holes is rather low; their edges appear to be sharp and well-defined and remain stable on time scales of several days.

The structure of the corona is governed by the solar magnetic field. The magnetic topology is not just that of a simple magnetic dipole, not even at the comparatively quiet minimum phase. Higher-order multipole components are always involved. A coronal image like figure 3 leads to the immediate impression that there are several magnetic loop systems anchored at the Sun. As a consequence, there must be a series of polarity changes around the limb, apart from the global polarity switch from 'positive' at the northern coronal hole to 'negative' in the south. The radial extent of these multipole moments is much more limited than that of the overall magnetic dipole centered in the polar coronal holes.

Comparison of coronal images like figure 3 with photospheric magnetograms shows that the mid-latitude loop systems are located well on top of magnetic neutral lines which often reach all around the visible half of the Sun. This is also the location of polar crown filaments well known from H-alpha observations. The near-equatorial magnetic features are more variable, both with space and time, due to the dynamics of some remaining active regions. They cause the green-line corona to vary in intensity by a factor of 10 and more. This variability in conjunction with the smaller scale and often inclined magnetic structures may be the reason for the more diffuse appearance in the equatorial regions.

The formation of antiparallel magnetic fields beyond the closed loops would require the existence of current sheets. Since large streamers coexist at different latitudes, multiple current sheets must also exist, unless they merge somewhere. They form a streamer sheet of initially 1 solar diameter width. Processes still to be explored may eventually lead to the formation of the large-scale interplanetary heliospheric current sheet imbedded in a flow of slow solar wind. Note that the transition from closed to open magnetic topology at the top of a streamer is generally not yet understood, nor is the release of slow solar wind from these regions.

The flatness and stability of the distant heliospheric current sheet(s) is probably due to the persistence of the mid-latitude streamers. In other words, the current sheet is determined by mid-latitude phenomena rather than by streamers above the near-equatorial activity belt. The mid-latitude streamers are apparently bent towards the equator by the more than radially expanding polar coronal hole magnetic field and high-speed plasma flow. After all, that would mean that the heliospheric current sheet close to the Sun's equator is being shaped by forces originating in the Sun's polar regions!

More information can be found in the articles CORONAL LOOPS, CORONAL STREAMERS, and FILAMENTS.

Solar wind stream boundaries

Coronal holes attract attention not only by their surprisingly sharp boundaries. The high-speed solar

wind streams emerging from them are also very distinctly separated from adjacent slow flow. The boundary layer between high-speed wind at 600 km s^{-1} and slow wind at 300 km s^{-1} is often found to be less than 1.5° with respect to heliographic latitude! In longitude, mutual interactions between flows of different speeds tend to smooth the originally steep profiles with increasing distance to the Sun. Only when the Helios solar probes approached the Sun as close as 0.29 AU were similarly thin boundary longitudinal boundary layers confirmed and a 'mesa-like' shape of high-speed streams was recognized. In high-speed wind, remnant signatures of the coronal network could be identified, proving its originally filamentary nature. Close to the Sun, all the transition from slow to fast wind was observed to occur apparently as the transition from one flux tube to the next! These discoveries led to the conclusion that high- and slow-speed wind are very different in nature, emanate from well-separated sources in the corona, and are due to basically different acceleration mechanisms.

Figure 4 is an impressive experimental confirmation of what has been said in this subsection. This unusual polar plot shows the solar wind speed as measured from the Ulysses space probe during its passage across both solar poles in the years 1992–97. The magnetic polarity is also indicated. Clearly, high-speed wind is encountered predominantly at latitudes beyond 20° in either hemisphere. During the fast passage through the ecliptic plane (left part of figure 4) abrupt changes from fast to slow and wind and back occurred. In contrast, the rather slow orbital motion of Ulysses away from and towards the ecliptic (right part) allowed mid-latitude fast streams and interstream slow flow to be observed alternately for many solar rotations. Beyond about 35° no slow wind and no 'wrong' sector polarity were found any more. For more details about Ulysses see the article SOLAR WIND: ULYSSES.

Further signatures of stream structure

There are some more signatures indicating the basically different nature of high-speed wind from coronal holes and low-speed flow in the streamer belt. They are mainly associated with constituents other than protons and their ionization states (for details see the article SOLAR WIND: COMPOSITION).

- The helium abundance is 3.6% in high-speed wind, very constant in time and almost identical for all streams. In slow wind the abundance is only 2.5% and highly variable. This is one strong indication that high-speed wind is released at lower altitudes in a gravitationally stratified corona.

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills, Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

- The ionization state of heavy ions is significantly lower in fast flow, indicating a lower coronal temperature in its source region.
- In the slow solar wind there is a much more pronounced first ionization potential (FIP) effect, i.e. the elements with a FIP of less than 10 eV are significantly overabundant in comparison to photospheric values (see the article by von Steiger).
- The angular momentum carried away by the solar wind from the rotating Sun is almost completely contained in the slow flow. This is another strong indication that the fast wind starts from rather close to the solar rotation axis, while the slow wind is released only beyond 30 R_s.

On the other hand, there are also some stunning similarities between the two types of solar wind:

- The momentum flux density $n_p\, v_p^2\, m_p$ does not differ by more than 5%. Using this quantity alone no stream structure at all would be discernible! That means that both types of wind put identical dynamic pressure on any obstacle, e.g. planetary magnetospheres or the pouring up interstellar gas, implying important consequences for the 3D shape of the heliosphere as a whole.
- Similarly, the total energy flux density summoned by the Sun in order to release the solar wind is equal all around the Sun. Of course, the fast flow carries more kinetic energy $n_p\, v_p^3\, m_p$, with it, but the Sun has to bring up much more energy $n_p\, v_p\, Gm_p\, M_S/R_s$, in order to lift the high density slow wind out of its gravitational field, and the sum of both remains constant.

There is no conclusive answer yet as to whether these invariances happen by chance, whether they are intrinsic solar phenomena, or are the result of global rearrangement of the different flows beyond the corona. The solution of this problem might hold a key to the understanding of the corona and the generation of the solar wind .

Solar wind streams on their way out into the heliosphere

Solar wind streams and their interactions

A fast stream may follow a slow one if the coronal hole boundary is inclined by some angle to the Sun's rotation axis which is almost perpendicular to the equatorial plane. These two types of plasmas flow side by side in the first place, but start interacting with each other with increasing distance from the Sun. The Parker spiral of a fast plasma stream is less tightly wound up and thus pushes the slow plasma with the more strongly curved field lines. Compression and deflection of the plasma on both sides of the stream interface finally yields the typical profiles found at 1 AU as shown in figure 1. The transition from slow to fast flow in these corotating interaction regions (CIRS) now extends over some 10–30° in longitude (see SOLAR WIND: COROTATING INTERACTION REGIONS). In many cases, the stream interface survives as a tangential discontinuity which allows us to still recognize what was originally fast and slow flow. The total range filled with plasma affected (i.e. compressed and deflected) by these interactions amounts to some 30° at 1 AU. However, the plasma packed into that range stems from coronal source regions originally spanning some 90° in longitude! Generally, at about 1 AU distance from the Sun all solar wind in the ecliptic plane will have undergone some processing due to stream–stream interactions. In other words: no longer will there be any solar plasma in its original state, and primordial coronal imprints on the plasma will be lost by then. For this reason, one may draw a borderline between the inner and the outer heliosphere near 1 AU.

At the backside of fast streams no interaction of the flows occurs and no CIRs develops since here the different Parker angles lead to a separation of the flows rather than a compression. The stream boundaries are found to extend over some 60° at 1 AU (see, e.g., the stream in figure 1 on the right-hand side). However, mapping back the flow to the Sun assuming a strictly radial flow at the locally measured speed, the original rectangular profile at the Sun is nicely reconstructed!

At even larger distances from the Sun, the compression waves at the CIRs steepen to finally form corotating shock waves. There are fast forward shocks at the frontside, i.e. traveling to the slow wind side, and fast reverse shocks traveling seemingly backward, i.e. into the fast wind coming from behind. Thus, the originally steep stream profiles are further eroded (see also the article SOLAR WIND: COROTATING INTERACTION REGIONS). The corotating shocks at CIRs, similar to transient-related interplanetary shock waves, can accelerate ionized particles to considerable nonthermal energies, as explained in the article SOLAR WIND: ENERGETIC PARTICLES.

Beyond several AU, the CIRs themselves interact and merge by a variety of processes to form merged interaction regions (MIRS). They may be purely corotating MIRs (CMIRs), or include ejecta and shocks from CMEs to form global MIRs (GMIRs). After all, there is an increasing loss of detail of the solar source conditions with further increasing distance from the Sun, such that even the signatures of the solar rotation are lost beyond about 40 AU. At much larger distances, by interaction with the local interstellar medium the solar wind undergoes the termination shock of the heliosphere where it is diverted and decelerated. This region of subsonic flow, the heliosheath, is separated from the impinging interstellar plasma at the heliopause. Inside, the solar wind flow is diverted into the heliotail which is many thousands of AU long. On the upstream side, outside the heliopause, a bow shock may form to divert the interstellar material around the heliospheric obstacle. For details see the article SOLAR WIND: INTERACTION WITH THE LOCAL INTERSTELLAR MEDIUM.

Radial variations of average solar wind parameters

The radial profiles of the basic solar wind plasma parameters are of special importance in that they narrow

Dirac House, Temple Back, Bristol, BS1 6BE, UK

down the degrees of freedom available for modeling solar wind expansion. In-situ measurements as close as 0.29 AU (i.e. 60 R_s from Sun center) have recently been complemented by optical observations from close to the Sun's limb out to 32 R_s. On the other hand, the Pioneer and Voyager spaceprobes are currently expanding our knowledge of heliospheric signatures to beyond 70 AU. In the inner heliosphere, the local properties of the flow and its radial expansion are basically determined by the coronal sources and their topology. From about 1 AU distance on, stream-stream interactions and local plasma processes begin playing a dominant role in the solar wind's radial evolution.

- The flow speed profile of the slow wind close to the sun has been inferred from the coronagraphs on SOHO: small density blobs could be traced which are thought to float along with the flow. It begins to accelerate from about 3 R_s only, and by 10 R_s it is barely faster than 250 km s^{-1}. This profile is consistent with an isothermal expansion at a temperature of about 1.1 MK and a sonic point near 5 R_s, in good agreement with the simple Parker model. There is a further speed increase of about 50 km s^{-1} until about 1 AU.
- The UVCS instrument on SOHO by applying the Doppler dimming technique was able to determine the fast wind acceleration profile. This type of flow starts in the very low corona and attains a speed of 300 km s^{-1} at 3 R_s and 800 km s^{-1} at 10 R_s. From there on it travels at constant speed. Further details of solar wind acceleration and expansion in the sun's vicinity are found in SOLAR WIND: CORONAL ORIGINS.
- In the outer heliosphere, the speed differences between fast and slow flows are wiped out, and the heliospheric plasma expands at an average constant speed of 400 to 500 km s^{-1}. A slowdown of the solar wind by action of the interstellar gas has not yet been noted.
- The density is consistently found to drop off as R^{-2} as would be expected for a medium which expands spherically at constant speed. However, inside 1 AU the average gradient is $R^{-2.1}$, according to the mentioned speed increase of the slow wind. Also, there is a slight relative over-expansion of the slow wind (by some 10%), at the expense of a commensurate fast wind compression.
- The proton flux density goes most accurately as R^{-2}, on the grand average, from at least 0.3 AU on outward. However, inside 1 AU, the mass flux in fast streams grows by some 15% and decreases accordingly in slow wind. The conclusion is that flux tubes carrying the fast, low-density wind are compressed by some 15% in cross section by the flux tubes carrying the slow, high-density plasma.
- UVCS measured strikingly large line widths of O^{5+} lines in fast flow from polar coronal holes. If interpreted in terms of kinetic ion temperatures, values of more than 100 MK would be obtained! Also, there is an extreme temperature anisotropy, i.e. the temperature perpendicular to the magnetic field directions is much higher than that parallel to it. These findings support the concept of ion cyclotron heating in this type of solar wind inferred from in-situ observations at 0.3 AU from the Helios solar probes
- The proton temperature in slow wind drops with distance from the sun as $R^{-1.33}$. That is exactly what would be expected for an adiabatic expansion. Extrapolation back to the corona leads right to the observed coronal temperatures of about 2×10^{-6} K. That means that this type of solar wind escapes wave heating by originating from sources with closed magnetic fields without intense MHD-wave emission. In contrast, the fast wind cools off as $R^{-0.78}$, thus indicating substantial additional heat input beyond the corona due to heat conduction and local dissipation of convected wave energy. In the range between 1 and 20 AU temperature variations of $R^{-0.5}$ to $R^{-0.7}$ were reported. Apparently, that is a result of compression heating caused by stream-stream interactions.
- The electron temperature falls off, by and large, significantly slower than expected for adiabatic and isotropic expansion. For details the reader is referred to SOLAR WIND: KINETIC PROPERTIES and the specialized literature.

Signatures of what is affecting the earth system

Generally, the solar wind flow is diverted around the Earth by its magnetosphere which is maintained by the Earth's intrinsic magnetic field (see MAGNETOSPHERE OF EARTH). Solar wind particles cannot enter, unless there occurs a MAGNETIC RECONNECTION of interplanetary and planetary field lines. That may happen if the northward pointing Earth field on the front of the magnetosphere is hit by solar wind carrying a southward pointing interplanetary field. In such cases, significant geomagnetic disturbances of various kinds are initiated (see, e.g. the article SOLAR–TERRESTRIAL CONNECTION: COUPLING BETWEEN SOLAR WIND, MAGNETOSPHERE, IONOSPHERE, AND NEUTRAL ATMOSPHERE, MAGNETOSPHERE OF EARTH: GEOMAGNETIC STORMS AND SOLAR WIND ORIGINS and others).

In the present context it is important to discuss by which means the usually radially pointing interplanetary field can be tilted in such an abnormal way.

- Compression and deflection of the solar wind flow in CIRs has important consequences for its magnetic field, too. Naturally, it undergoes the same compression and participates in the deflection process. Thus, there may arise enhanced out-of the-ecliptic field components, particularly in the vicinity of magnetic sector boundaries which often happen to be embedded in CIRs at 1 AU. The action of potential magnetic reconnection is enhanced by the pressure pulse from the compressed plasma.

Dirac House, Temple Back, Bristol, BS1 6BE, UK

- High-speed streams are also characterized by the occurrence of large amplitude transverse Alfvén fluctuations. They are easily recognizable by large excursions in the directions of both the interplanetary magnetic field (including geo-effective southward excursions) and the plasma flow. The field magnitude and the plasma density remain about constant. Typical fluctuation periods at 1 AU range from fractions of a minute to a few hours. Probably, these waves are remnants from coronal activity since they travel outward only, without evidence for local damping (for details see the chapters by Roberts and Gurnett). There is a close correspondence between the southward pointing of the interplanetary magnetic field in the course of Alfvénic fluctuations and geomagnetic activity, leading to clear association between medium-level geomagnetic activity and high-speed solar wind.

The recurrence of this particular type of geomagnetic activity every 27 d, i.e. exactly in the rhythm of solar rotation, had led J Bartels to postulate the existence of M regions on the Sun already in the 1930s. He thought they were long-lived stable regions on the Sun which emit certain particles capable of stirring geomagnetism. After all, he was strikingly right except for one aspect: these M regions are not to be sought in active regions on the Sun, as he thought, but rather in the inactive parts: the M regions are to be associated with the coronal holes representative of the inactive sun, and the geomagnetism is stirred by the streams of high-speed plasma emanating from them.

The major geomagnetic storms are also due to large southward excursions of the interplanetary field, but these are caused by transient processes on the Sun, e.g. coronal mass ejections and their interplanetary counterparts. The interested reader is referred to the articles on CMEs and geomagnetic effects, and SOLAR–TERRESTRIAL CONNECTION: SPACE WEATHER PREDICTIONS.

Slow variations during the solar activity cycle

What does the interplanetary medium sense from changes in solar activity during the solar cycle? That can best be described using the ballerina model (figure 2). It shows the slightly warped heliospheric current sheet separating inward and outward going magnetic field lines around activity minimum. Starting from this state the warps in the skirt begin to grow with increasing activity. They finally break up and turn over at activity maximum. Then, the current sheet begins reorganizing itself according to the overall magnetic field of the Sun which has just undergone a global polarity reversal. The warping diminishes, and at the following minimum the ballerina skirt is flat again; just the magnetic polarity is reversed. Thus, a full magnetic cycle of the Sun (called the Hale cycle) takes 22 yr, i.e. two activity cycles. This is described in more detail in the article SOLAR WIND: MAGNETIC FIELD.

According to the structural changes of the corona, the solar wind also changes. The remarkably stable shapes of both coronal holes and solar wind high-speed streams in the years before minimum activity are replaced by increasingly irregular patterns. The few remaining fast streams are smaller in size and amplitude, and they come from small, isolated, transient coronal holes.

Almost all around the Sun now emits slow wind. That applies to the poles as well, as indirect measurements using interplanetary scintillations of radio pulsar signals have shown. It is hard to conceive that this can be the same type of slow flow as is found in the streamer sheet at solar minimum. This 'maximum type' slow solar wind is found to emerge from substantially larger areas often located far from any current sheet. It is highly variable and usually contains some 4% of helium, thus indicating its release at lower altitudes in the corona than the 'minimum type' slow wind..

The whole structure is additionally confused by abrupt disturbances due to interplanetary shock waves driven by CMEs. (see articles on CMEs and SOLAR WIND SHOCK WAVES AND DISCONTINUITIES). Naturally, the occurrence rate of big solar transients follows solar activity very closely, and one would expect to find considerable variations of the average solar wind's properties going in parallel. It turns out, though, that this is actually not the case, at least not for the plane of the ecliptic where most long-term observations were made so far. There is not much change: the average speed drops from some 500 km s^{-1} at minimum to 400 km s^{-1} at maximum. Other quantities such as particle densities, and the fluxes of mass, momentum, and energy are modulated by not more than about 20%. It is interesting to note that that they all reach their minima at activity maximum, despite the many CME and shock events at that time!

Outside the ecliptic plane and especially at very high solar latitudes the solar cycle modulation can be expected to be completely different. At solar minimum there is only fast wind characterized by its high speed and very low density. With increasing activity and the associated disappearance of the polar coronal holes the share of slow type solar wind grows, with its high values of particle and mass flux densities. Thus, the modulation of the average solar wind properties at high latitudes is expected to be much more pronounced than in the ecliptic plane. We will certainly learn more details once the spaceprobe Ulysses has performed its second run across the Sun's poles.

Summary

In conclusion, it can be stated that the ballerina model (see figure 2) as conceived in the mid-1970s describes the 3D heliosphere at activity minimum in connection with the solar corona fairly well.

It is now well established that there are two basic types of quasi-steady solar wind which differ markedly by their main properties, the location and magnetic topology of their sources in the corona, and probably in their acceleration mechanism. Therefore, in table 2 the more specific values are given separately for both types:

Table 2. Average solar wind parameters at 1 AU, for the time around solar activity minimum.

	Slow wind	Fast wind
Flow speed v_P	250–400 km s^{-1}	400–800 km s^{-1}
Proton density n_P	10.7 cm^{-3}	3.0 cm^{-3}
Proton flux density $n_P v_P$	3.7×10^8 cm^{-2} s^{-1}	2.0×10^8 cm^{-2} s^{-1}
Proton temperature T_P	3.4×10^4 K	2.3×10^5 K
Electron temperature T_e	1.3×10^5 K	1×10^5 K
Momentum flux density	2.12×10^8 dyn cm^{-2}	2.26×10^8 dyn cm^{-2}
Total energy flux density	1.55 erg cm^{-2} s^{-1}	1.43 erg cm^{-2} s^{-1}
Helium content	2.5%, variable	3.6%, stationary
Sources	Streamer belt	Coronal holes

Some further characteristics of different solar wind types at solar activity minimum are:

- The *fast solar wind* emerges from magnetically open coronal holes which are representative of the inactive Sun, i.e. the 'quiet' Sun. Consistently, the 'quiet' type solar wind is found in high-speed streams. Although the major coronal holes usually cover the polar caps at latitudes beyond 40–60°, the solar wind emerging there over-expands significantly and fills up all heliosphere except for the 40° wide streamer belt close to the heliomagnetic equator.
- The *slow solar wind of the minimum type* originates from above the more active regions on the Sun. It is constrained to the warped streamer belt and comprises the large-scale heliospheric current sheet. The low helium content in this type of solar wind indicates a larger release height. It is not clear yet how slow solar wind can be released at all. The transition from closed loops down below to an open field topology of the free solar wind flow above requires some kind of reconnection, be it in a steady-state mode or involving transient phenomena. It is conceivable that the slow solar wind might be released in a transient mode, in analogy to water drops dripping from the ceiling of a limestone cavern. (A thorough discussion of solar wind acceleration processes can be found in the articles SOLAR WIND: THEORY and SOLAR WIND ACCELERATION.)

Note that there is no continuous transition between these two types. Rather, the boundary layers between them are very thin close to the Sun and correspond in detail to the boundaries of the coronal holes.

There are two additional types of solar wind which can be considered products of the active Sun rather than the quiet Sun:

- the *slow wind of the maximum type* emerges from substantially larger areas distributed all over the Sun and often located far from any current sheet. It contains twice as much helium than the minimum type,
- *plasma clouds* released in huge eruptions at the sun can often be discerned by the unusually high helium percentages (up to some 30%) and other signatures (see the article SOLAR WIND: MANIFESTATIONS OF SOLAR ACTIVITY). Around activity maximum, these clouds contribute about 10% to the total solar wind flow, on the average.

In conclusion, it is only fair to state that for none of the mentioned types of solar wind is there a unique and generally accepted theoretical model. At present, existing theories are highly controversial. For example, an exciting alternative model for generating the fast or even all solar wind is acceleration in the form of numerous smallest-scale high-velocity jets (other terms in use: microflares, nanoflares, coronal bullets) that were discovered in very high resolution UV observations of the Sun (see TRANSITION REGION: EXPLOSIVE EVENTS). Apparently, such a model is in extreme contrast to Parker's classical thermal expansion model and its derivatives. This clearly illustrates that the understanding of solar wind acceleration is not yet on firm ground, and further research is needed.

Solar Wind: Interaction with Comets

Cometary plasma tails are formed by the interaction of solar wind plasma with ionized gaseous material from a cometary nucleus over large volumes of space. The electromagnetic interaction proceeds as mass is added into, and slows, the solar wind flow near the comet.

The concept of a continuously flowing, but gusty, solar wind was postulated in the 1950s by Biermann to explain observations of cometary plasma tails. These spectacular tails are one of two effects of the solar wind that can be seen from the Earth's surface, the other being Earth's aurorae. Plasma tails were observed to point away from the Sun, with a small aberration angle due to the comet's orbital speed. Early theories included only the effects of solar wind particles, which proved to be inadequate, but later the crucial role of the magnetic field, frozen into the flow, was realized by Alfvén. The field should drape around an active cometary coma, ultimately forming the tail.

The earliest space probes confirmed the existence of both the solar wind itself and its magnetic field, frozen in to the highly conducting, radially flowing plasma at the Sun, but direct cometary exploration by spacecraft did not occur until the mid-1980s. So far four COMETS have been explored at close range with instrumentation to study the solar wind interaction: Giacobini–Zinner (by NASA's ICE in 1985), Halley (by ESA's GIOTTO, Russia's Vega 1 and 2 and the Japanese SUISEI and SAKIGAKE in 1986), Grigg-Skjellerup (by ESA's Giotto in 1992) and Borrelly (by NASA's DEEP SPACE 1 (DS1) in 2001). In addition, the Ulysses spacecraft encountered the distant (3.8 AU) tail of COMET HYAKUTAKE in 1996.

We now know that the interaction of a comet with the solar wind is quite different to that of a magnetized planet. As a comet approaches the Sun in its orbit, neutral atoms and molecules sublime away from the icy cometary nucleus, taking dust with the expanding flow of gas. The neutral atoms and molecules are ionized, on a timescale longer than a week, by sunlight or by charge exchange with the solar wind. Following ionization they interact with the electric and magnetic fields in the solar wind, slowing the flow. The solar wind drapes around the cometary nucleus, ultimately forming the comet's plasma tail. The solar wind interaction is thus quite different to that of a magnetized planet, where a magnetopause forms a blunt obstacle in the supersonic solar wind flow. These general concepts, which were predicted prior to cometary encounters by spacecraft, have been confirmed by spacecraft observations. Although many aspects of the interaction process have been elucidated, others are not yet understood and many unexpected results were gained. These are left as problems for future space missions.

Here we describe the evolution of the solar wind interaction with a comet as it nears the Sun, how particles are ionized and how they interact with the highly conducting solar wind plasma. We consider the expected boundaries and plasma regions in the solar wind–comet interaction together with the physical processes which are involved and the results from the cometary space missions of the mid-1990s. We then look at the outstanding problems for future space missions in this area.

Gas emission from comets

As well as the properties of the solar wind itself, the gas production rate of the comet is a vital parameter which determines the size and nature of the comet–solar wind interaction region. During the approach of a comet towards the Sun, the gas production rate increases owing to the increased surface temperature and the interaction changes from that of a bare nucleus to the fully developed coma structure. Also, different comets have different gas production rates, for example the production rates of Grigg–Skjellerup, Giacobini–Zinner and Halley were in a ratio of approximately 1:10:100 at the times of the encounters; for Halley the rate was 6.9×10^{29} molecules s^{-1}, corresponding to about 20 t s^{-1}. The Borrelly production rate was comparable with that of Giacobini– Zinner.

At distances greater than approximately 3 AU from the Sun the surface of a cometary nucleus is cold and no gas emission occurs. The bare nucleus interacts with the solar wind in the same way as unmagnetized, inactive asteroids or moons. A wake is formed behind the nucleus devoid of ions, assuming that the nucleus size is larger than or comparable with the solar wind ion gyroradius. The more mobile electrons set up potential structures which close the wake and may charge the night side of the nucleus, producing potentials of volts to kilovolts. The solar wind particles ram straight into the cometary nucleus, perhaps affecting the surface layers, while the solar wind magnetic field diffuses rapidly through the object. On the side of the nucleus facing the Sun, sputtering processes due to the incoming solar wind ions may produce neutral particles which move away from the comet perhaps to be ionized and picked up by the solar wind.

As the comet approaches the Sun more closely, sublimation processes begin to produce an outflow of gas. The species driven away and the rates at which this happens depend critically on the surface temperature and therefore the position in the orbit. A dense 'ionosphere' forms near to the comet, bounded by a contact surface. New, 'pick-up' ions are produced on a much larger distance scale of ~106 km, forming an enormous region over which the comet–solar wind interaction occurs. The new ions form an electromagnetically unstable population in the flowing solar wind. The solar wind is slowed, forming a bow shock and several other features. The interaction of a comet with the solar wind at large and small heliocentric distances is shown in figure 1.

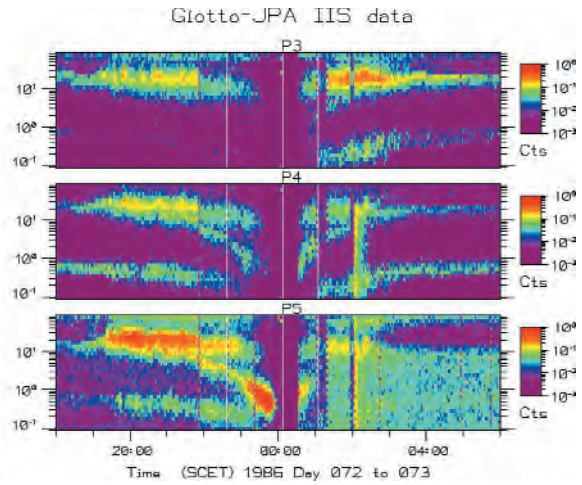

Figure 2. Summary of the Johnstone Plasma Analyser (JPA) Implanted Ion Spectrometer (IIS) results from Giotto covering 1.5 million kilometers each side of comet Halley, with closest approach at 00:03 spacecraft event time (SCET). The three panels show different look directions of the instrument, and in each panel the color scale shows number of particles. The solar wind is the lower trace in each panel, below 1 keV and decreasing in energy closer to the comet. The upper traces, at over 10 keV but decreasing closer, are the cometary water group ions. The number of cometary ions increases nearer to the comet and the solar wind slows, illustrating the interaction process. The bow shock is seen at ~19:35 inbound and ~02:45–03:15 outbound.

The Borrelly results in particular contain what may be evidence for an extended although well-defined source of neutral particles in the cometary coma, and an association with dust/gas jets from the nucleus is being sought. The observation in the plasma data, which leads to this tentative conclusion, was of a significant asymmetry in the cometary ion spectra in the interaction region. However, it is not clear why this should be much more pronounced at Borrelly than at the earlier cometary encounters.

Ionization and interaction with the solar wind

Before the encounters with any comets by spacecraft, the process of ion pick-up and implantation into the solar wind flow, which loads the flow with additional mass, was expected to be the key to the comet–solar wind interaction. Following the spacecraft encounters, the importance of pick-up ions has been confirmed (e.g. figure 2) and we now have a better understanding of the wave–particle interactions, particle distributions and wave properties which are key features of the deceleration of the solar wind in the cometary environment.

When a cometary neutral atom or molecule is ionized, it immediately responds to the electric and magnetic fields in the solar wind. In real space its path follows a cycloid; the exact form depends on the relative orientation between the solar wind velocity and the magnetic field. In its simplest form, where the electric and magnetic fields are perpendicular, the path is analogous to that of the valve on a bicycle wheel: rotation around the magnetic field (axle) superimposed with a drift speed (along the ground) given by $\boldsymbol{E}\times\boldsymbol{B}/B^2$. In velocity space, which uses velocities rather than distances as coordinates, this corresponds to a ring distribution. Because the ring distribution is unstable, plasma waves are produced.

Prior to the spacecraft encounters, it was expected that particles would scatter in pitch angle to form a shell distribution from the ring as the instabilities developed, and a first look at the data from Vega, Suisei and Giotto confirmed this. For a ring distribution, the maximum energy of a pick-up ion in the comet frame is $2mv_{sw}^2\sin^2\tau$, where m is the picup ion mass in amu, v_{sw} is the solar wind speed and τ is the angle between the solar wind and magnetic field vectors. This compares with a maximum of $2mv_{sw}^2$ for a shell distribution. Note that, for an average solar wind energy of 1 keV, and for ions of mass 18 (H_2O^+), the maximum shell energy is 72

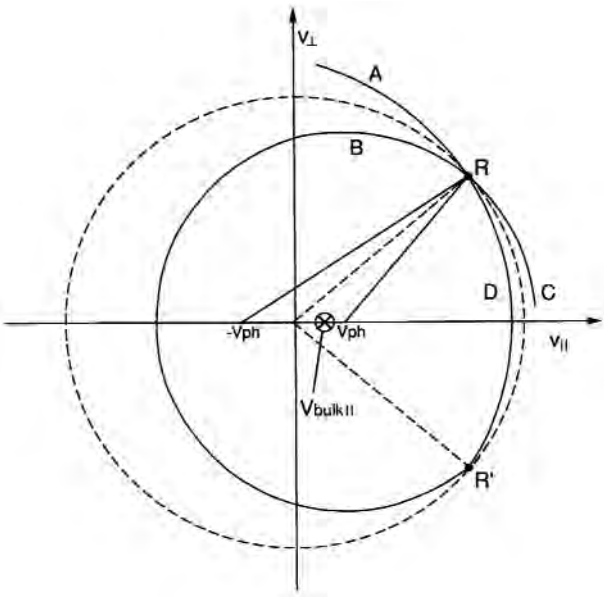

Figure 3. Velocity space diagram illustrating the ion pick-up process. Particles scatter from the original ring RR (onto the bispherical shell BD, due to interactions with upstream (B) and downstream (D) propagating waves.

keV. The Giotto IIS covered from 70 to 85 keV in order to cover fully the bulk of the pick-up ion distribution. Sensors on Suisei, Vega and ICE could only measure part of the pick-up ion distribution, in the last case only the high-energy tail.

From the shell, velocity diffusion was expected to broaden the shell in energy. Given enough time, a Maxwellian would finally be produced. Results from Giotto show that this later stage may only be approached in the very inner regions of COMET HALLEY.

More accurate theory reveals that simple shells are an approximation because the energy of the waves and the energy lost by the particles must be taken into account and energy must be conserved. This led to the idea of a 'bispherical shell' distribution for the cometary ions, which was subsequently confirmed in the data from Halley. The situation is illustrated in figure 3, where the scattering of particles in pitch angle from the ring R onto the spherical arcs RB and RD can be seen. In these cases, energy from the particle distribution goes into plasma waves. These ideas have been developed further in simulations and models; in particular, a bispherical model was used to predict the wave spectrum successfully and to compare the energy available

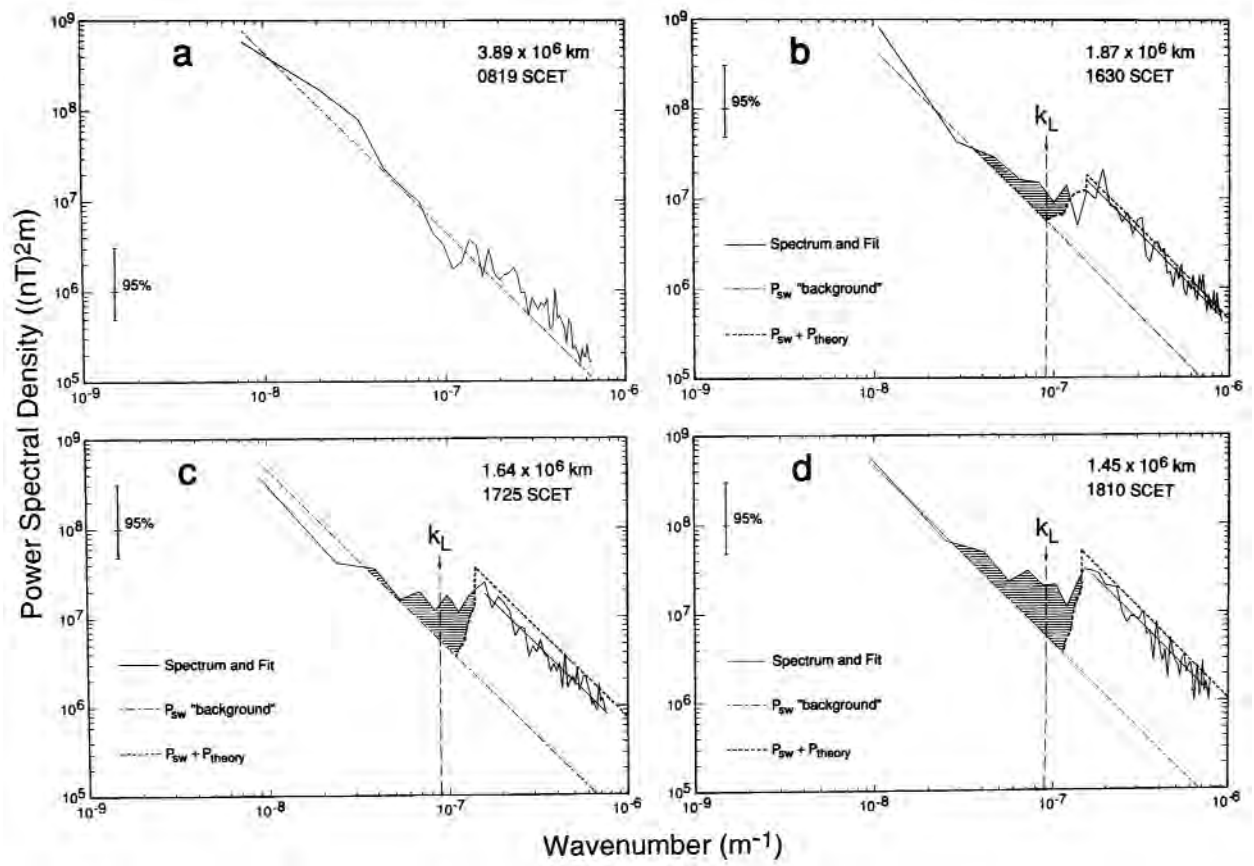

Figure 4. Observed (full curve) and predicted (broken curves) magnetic wave power spectra at different distances from comet Halley. The predictions are made using a bispherical shell model and the resonance of particles with different wave frequencies depending on their position on the shell, with no parameters.

from the ring distribution with the energy released and the energy in the waves. In this elegant model, produced by Huddleston and Johnstone in 1992, particles at different positions on the shells resonate with specific frequencies of plasma waves and this can explain the observations without the need for further parameters in the theory (see figure 4).

From the Giotto data at comet Halley, well upstream of Halley the cometary ion distributions were found to follow the ring prediction, while closer to the comet the distributions were more shell like. The velocity distributions in the solar wind frame show a small amount of acceleration in the upstream region, significant enough to be seen by the energetic particle instrument, but the most significant acceleration was seen downstream of the cometary bow shock. The bulk velocity of the pick-up heavy ion population was found to be consistent with bispherical distributions in the region of the shock, despite the particle acceleration seen in that region.

In the case of comet Grigg–Skjellerup, it was shown that the ion distributions were ring like almost up to the bow shock, except that one-sided distributions were seen for a time outbound. Non-gyrotropic distributions were found particularly in the inner regions at Grigg–Skjellerup, owing to the different ion implantation rates between adjacent cusps of the cycloid in those regions. This can cause additional instabilities to operate.

One of the most dramatic features in the Grigg–Skjellerup results was the existence of large amplitude waves in the magnetic field and modulations of the particle distributions. It is thought that this is due to the textbook conditions of the encounter, as the solar wind velocity and magnetic field were mutually perpendicular at the time of encounter.

Mass loading by cometary ions was predicted and observed at comets. Models for the deceleration were compared with the measurements at comet Halley and good agreement was found.

Comet-associated energetic ions beyond the pick-up prediction had not been expected at comets, except in one paper immediately before the 1980s encounters. However, they were seen at all of the comets visited so far (except Borrelly as DS1 had no energetic ion detector) and mechanisms have been suggested for their acceleration. These included adiabatic acceleration, the interaction of ions with waves across a sharp gradient in solar wind flow speed (Fermi I) or the interaction with upstream and downstream propagating waves (Fermi II). The form of the bulk of the cometary ion distribution function depends on the point in the mass-loaded flow at which the observation is made. Well upstream of the comet the one-dimensional distribution function is a delta function modified on the low energy side owing to the bispherical distributions. Closer to the comet, where the solar wind speed is lower and some mass loading has occurred, the distribution is modified both by the slowing solar wind and by adiabatic acceleration. Downstream of the bow shock, two populations are found owing to the velocity jump across the shock. All of these distributions are further modified by the Fermi I or II processes. Comparison of models with data showed that Fermi II alone may not be sufficient to explain the Halley observation. The proportion of downstream propagating waves was larger than expected, which may account for some additional acceleration. Additional energy may go into particle acceleration from the solar wind deceleration.

Boundaries and regions in the comet–solar wind interaction

Two boundaries in the mass-loaded flow were expected in the 1970s and 1980s by workers including Wallis, Biermann and Schmidt, separating plasmas with different properties. These were the bow shock and the contact surface. The reality turned out to be much more complex with several new boundaries seen by the spacecraft.

Figure 5 is a schematic diagram which shows the trajectories and boundary observations of all the cometary encounters so far (except Borrelly as no peer-reviewed papers have appeared thus far). As mentioned above, the bow shock and cavity boundary were the only boundaries predicted to form prior to the spacecraft encounters. The data have added at least four additional features: the mystery boundary, the cometopause, the magnetic pile-up boundary (MPB) and the ion pileup

boundary (IPB). The observations are summarized in table 1. We will now discuss each of the boundaries in turn.

Bow shock

he bow shock was one of the predicted boundaries in the comet–solar wind interaction region. In the predictions, the mean molecular weight of the flow reached a critical value of 4/3 in the first simple one-dimensional model before a strong singularity, the bow shock, occurred. In more realistic two- and three-dimensional simulations a weak bow shock forms at a value lower than 4/3, dependent on the gas production rate. The Mach numbers of these weak shocks were approximately 2.

Observations at comets showed that this boundary was present at all of the spacecraft encounters but its properties changed dramatically between crossings at the same comet depending on the interplanetary magnetic field orientation. In all cases the cometary ions dominated the dynamics in terms of pressure. The width of the feature varied from a few water group ion gyroradii in the quasi-perpendicular case to many gyroradii in the quasi-parallel case. Where sufficient data were available, the bow shock was shown to occur at the predicted point in the mass-loaded flow. Also, the Mach number of the features between 1 and 2 supported the interpretation of a weak bow shock. The various particle populations (electrons, protons, alpha particles, cometary water ions) also increased in temperature across the boundary. While there is some evidence that the GZ data can be explained in terms of a reforming shocklet model and the Suisei and Giotto–Halley inbound data could have been affected by interplanetary disturbances, there is broad agreement that the boundary seen in the various cases was a bow shock.

Mystery boundary

One of the dramatic plasma discoveries at comet Halley was the clear bifurcation of the cometary ion peak in the 'cometosheath' region between the bow shock and contact surface. The explanation for the bifurcation has already been alluded to, namely the different velocities either side of the bow shock which give different pick-up shell radii. However, this does not explain the very suddenly enhanced splitting of the water group ion population which occurs at approximately 500 000 km from the nucleus caused by a change in solar wind velocity there. This boundary, called the mystery boundary as its origin is still not understood, is also characterized as the end of a region of significantly enhanced densities of hot (0.8–3.6 keV) electrons. The mystery boundary also ends a region of higher solar wind density and velocity, and following the boundary the number of ions in the ram direction increases sharply. There is no strong effect in the magnetic field to match these sharp and significant features in the plasma data.

The boundary is still present on the outbound pass (although suitable electron data are not available) and also appears to be at comet Grigg–Skjellerup. Also, it has been argued that comparable boundaries were also observed by Vega, Suisei and ICE. However, it is not present in any of the MHD or multifluid models and its origin has still not been explained. Although the boundary itself is still a mystery, it is conceivable that the increased numbers of hot electrons in the region it bounds could play a role in the x-ray emission from comets discovered in the 1990s.

Cometopause

Analysis of the data from Vega-2 has shown the existence of a relatively sharp boundary some 160 000 km from comet Halley separating regions of different chemical composition, according to measurements in the ram direction. In these data the protons showed a sudden decrease in density and the cometary ion density also suddenly increased, as seen in the ram direction. In addition, the proton velocity and water group velocity was quite different each side of the transition. It was suggested that the cometopause is a permanent boundary in the comet-solar wind interaction. The analysis of Giotto data from a similar region revealed a much broader transition between a mass-loaded solar wind region and a heavy ion dominated region with no significant velocity difference.

In this region it is certainly clear that charge exchange collisions are becoming more important, which would give a shift from a solar wind dominated flow to cometary ion domination. This is the physics which has been put forward to explain the cometopause transition but it remains to be explained why the transition was seen to occur more rapidly on Vega than Giotto. A sharp

and Institute of Physics Publishing 2002
Dirac House, Temple Back, Bristol, BS21 6BE, UK

boundary is not predicted by models and one possibility is that a convected change of interplanetary conditions could explain the Vega observations.

Magnetic Pile-up Boundary (MPB)

In the Giotto data, it is more widely accepted that a separate MPB is seen some 45 000 km or 11 min later than the cometopause. The main characteristics of this boundary on the inbound pass were a sudden magnetic field jump (tangential discontinuity), a slowing and reduction of electron density and a decrease in the electron perpendicular pressure. A dramatic increase in the rate of charge exchange and a proton density decrease was also seen. There are signs of a similar boundary outbound in the magnetometer data. This boundary, inside which the magnetic field drapes strongly around the contact surface, was not predicted by models and, interestingly, was absent in the Vega data at comet Halley. This, and the observation that the cometary ion density shows no significant discontinuity, has led some to speculate a solar wind origin while others have postulated that on the night side it becomes the plasma tail boundary.

An MPB was also observed at Grigg–Skjellerup; in the magnetic field, electron and ion data.

Discontinuities X, X′, Y and Z

Three additional boundaries have been pointed out in the Giotto data between the MPB and the IPB, called X, Y and Z. Discontinuity X is in a region where cometary ions are gradually being lost by charge exchange; there is also a sudden, significant drop in proton density there. A similar boundary X′ occurs a little later. Transition Y is the start of a sharp decrease in ion temperature. Discontinuity Z, 4 min before closest approach, marks the transition from radial outward flow of cometary ions away from the nucleus to stagnant plasma.

Ion Pile-up Boundary (IPB)

In the Giotto data at approximately 10 000 km, a significant unexpected peak in counts was found. The gradient of the log count rate changed from r^{-1} (inside) to r^{-2} (outside). This can be interpreted as the limit of ionospheric plasma. A magnetic field maximum also appeared at this point. In this region, significant chemical changes are occurring, for example the fraction of the H_3O^+ ion became dominant close to this point. This boundary was also seen by the Vega probes at comet Halley. It was not predicted in models and it remains the most significant deviation from these models in the inner regions.

The early interpretations of this region, including temporal effects in the neutral gas, change of upstream solar wind parameters and local electron impact ionization, were all rejected in favor of a reduction of the rate of recombination of ions and electrons caused by increased electron temperature. Observations and theory now back up this explanation.

Cavity boundary

Giotto was the only spacecraft to cross the expected cavity boundary; nevertheless, it is reasonable to suppose that this is one of the permanent boundaries in the comet–solar wind interaction. The Giotto observations showed that the magnetic field was excluded from the cavity, and the boundary itself was approximately 25 km wide. Near the cavity boundary, bursts of ions were seen. The position of the boundary can be understood by a balance between inward magnetic gradient forces and outward ion–neutral drag. The pile-up of ions just inside the cavity boundary was predicted by models and this perhaps plays the role of the inner shock, a long-predicted structure in the inner coma. Inside the cavity boundary the cometary plasma is stagnant.

One interesting feature discovered in the inner regions was the existence of negative ions. The density variation with distance is steeper inside the cavity boundary compared with outside, and the existence of these ions was not predicted by models. What is now clear is that their existence is an important clue to the photochemical processes at work.

Remote observations

While spacecraft encounters have added immensely to our knowledge of the comet–solar wind interaction, there is still a vital role for remote studies of comets from the ground and from space. From the ground it is possible to use the plasma tail of any comet as a probe of the solar wind. Study of tail features such as kinks and knots can reveal the solar wind speed. In particular, disconnection events, where the plasma tail is removed from a comet and a new one forms, can be used to infer the presence of discontinuities in the solar wind. One of the curious features is the formation of rays in the cometary coma. It is still not clear precisely what relation this bears to tail formation and to the *in situ* results.

Composition may also be studied from the ground; indeed, one of the early discoveries was that the blue color of a plasma tail is due to emission mainly from the CO^+ ion. Many other species were found from telescopic measurements and confirmed by *in situ* measurements.

The use of different wavelengths has also revealed new features. The discovery of x-ray emission from Comet Hyukatake, and subsequently also from Hale–Bopp and Encke, using the Rosat satellite, has shown that unexpected discoveries are still possible from remote observations. Several mechanisms have been suggested for the emission but the most likely appears to be that the x-rays are from the decay of excited states formed as a result of charge exchange between heavy solar wind ions and cometary ions.

and Institute of Physics Publishing 2002
Dirac House, Temple Back, Bristol, BS21 6BE, UK

The 1996 discovery, made using the Ulysses spacecraft, that the ion tail of comet Hyukatake was at least 3.8 AU long opens up a new area of remote observations of comets using particles and fields instruments on interplanetary spacecraft. Associations of magnetic signatures in Pioneer Venus Orbiter (PVO) data with an unknown comet had in fact already been made using data from 1982. This was the largest of other similar signatures from PVO and other spacecraft, and searches of data from other interplanetary spacecraft are in progress for this type of event. However, the Ulysses–Hyakutake event is unique in that there was a clear association with a comet and there were also indications of cometary ions even at that large distance.

Outstanding problems

It is clear that the solar wind interaction with a comet is radically different to that with a magnetized planet. An induced magnetosphere forms, owing to the implanted cometary ions loading the flow over vast regions of space and causing the draping of magnetic field within the extended 'obstacle'. The unstable implanted ion distributions cause plasma waves, which scatter the ions to form a bispherical distribution in velocity space. Particle acceleration is caused by wave–particle interactions in the disturbed cometary environment. Non-gyrotropy of the ion distributions is significant where the ion implantation rate varies significantly over the cycloid. This is particularly relevant at small, or weakly outgassing, comets.

Of the various boundaries observed in the interaction region, only the bow shock and contact surface were predicted. These were confirmed as permanent features of the developed solar wind interaction. Other permanent boundaries are the mystery boundary and the IPB. Other boundaries, which may not be permanent, are the cometopause and the MPBs. Although the latter was seen both at Halley and Grigg–Skjellerup it was absent during the Vega flybys of Halley and hence it may not be permanent.

The encounters thus far have left us with a number of intriguing questions about the areas they visited, including the following. How important is the Fermi I mechanism in particle acceleration? Is the inner shock really a layer just inside the cavity boundary? How permanent are the boundaries in the comet–solar wind interaction, and what is their formation mechanism? How does the cometary plasma tail form and what is the importance of tail rays? Could the mystery region hot electrons cause x-ray emission in the cometary environment?

There are also significant questions about the regions not visited, or only fleetingly sampled, so far. These include many features of the cometary ionosphere, photochemical interactions and the formation of negative ions, the exploration of the tail formation region, the dependence of features on gas production rate as the comet approaches the Sun, the role of reconnection in the interaction processes and the dependence on different solar wind conditions. Some of these questions should be answered by ESA's ROSETTA mission which will rendezvous with comet Wirtanen in 2011 and fly with the comet as it nears the Sun and its activity develops. At present this is the only planned mission with suitable instrumentation to explore further the solar wind–comet interaction.

Solar Wind: Interaction with Local Interstellar Medium

The solar wind forms a bubble, called the heliosphere, in the local interstellar medium (LISM), within which the solar system resides and whose size and properties are determined by the manner in which the solar wind plasma and the partially ionized LISM are coupled. In the last decade, great progress has been made in our understanding of the physical processes thought to describe the outer heliosphere. Fundamental to these advances has been the recognition that the interstellar medium is coupled intimately to the heliosphere itself and that much of outer heliospheric physics cannot be understood independently of the local interstellar medium. With the possibility that the aging spacecraft Voyager 1, 2 and Pioneer 10, 11 might encounter the heliospheric boundaries in the not too distant future, interest in the far outer reaches of our solar system and the LISM has been rekindled (see also PIONEER MISSIONS, VOYAGER MISSION). A convenient, if slightly vague, definition of the outer heliosphere, and one that is adopted here, is that it is that region of the solar wind influenced dynamically by physical processes associated with the LISM. Thus, for example, neutral interstellar hydrogen is the dominant (by mass) constituent of the solar wind beyond an ionization cavity of ∼6–10 astronomical units (AU) in the upstream direction (the direction antiparallel to the incident interstellar wind). The neutral hydrogen is coupled weakly to the solar wind plasma via resonant charge exchange—a coupling which leads to the production of pick-up ions that come to dominate the internal energy of the solar wind. The solar wind changes then from a small plasma beta β_{SW} (the ratio of plasma pressure to magnetic field pressure) environment to one in which $\beta_{SW} > 3$.

Figure 1 shows the complex interaction between solar wind plasma and the LISM. While clearly simplistic, it serves to illustrate the primary physical processes. The interstellar plasma may or may not impinge supersonically on the heliosphere. The LISM flow is diverted about the heliospheric obstacle either adiabatically or by a bow shock (BS). The LISM plasma is coupled to the neutral interstellar hydrogen (H) primarily through charge exchange. Charge exchange corresponds to a neutral atom surrendering an electron to a passing ion (typically a proton), so creating a new charged particle and (a hydrogen) atom. Thus, when neutral H charge exchanges with LISM plasma that has been decelerated, heated and diverted about the heliosphere, the neutral H acquires a subpopulation that too is heated, decelerated and diverted. This neutral hydrogen, together with the LISM H, is called component 1 and is created in region 1 of figure 1. If the charge exchange mean free path is sufficiently small in the region of decelerated LISM flow, a 'wall' of neutral hydrogen will form in the upstream direction (the hydrogen wall). This is because resonant charge exchange is essentially a scattering rather than an extinction process.

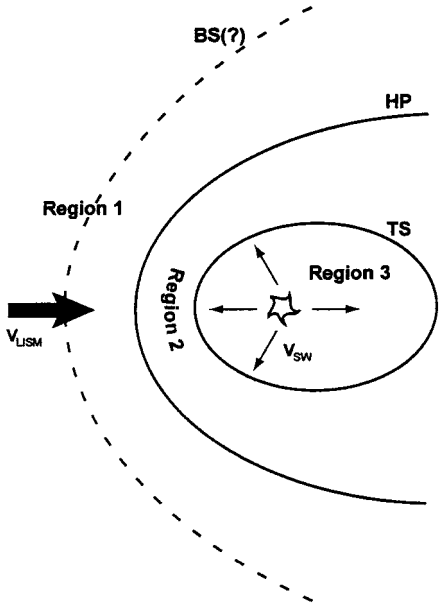

Figure 1. Schematic of the solar wind–local interstellar medium (LISM) boundary regions which act as neutral hydrogen sources whose characteristics are identifiably distinct. The solar wind is enclosed by the termination shock (the curve labelled TS) and is identified as region 3, the shocked solar wind, the heliosheath, is bounded by the termination shock (TS) and the heliopause (HP) and is identified as region 2, while the interstellar medium is found beyond the heliopause. The interstellar medium may or may not form a bow shock (BS) depending on whether the interstellar flow velocity V_{LISM} is supersonic. The radial solar wind flow vector is denoted by V_{SW}.

A boundary, called the heliopause, separates the heliosphere and the LISM plasma, and is either a contact or a tangential discontinuity. The supersonic solar wind is decelerated, diverted and heated by a reverse shock called the termination shock (TS). (See the accompanying article on SOLAR WIND SHOCK WAVES AND DISCONTINUITIES by R. Lepping for definitions of terms related to hydrodynamic and MHD discontinuities.) The location of the termination shock is determined by the steady and temporal solar wind pressure exerted on the LISM.

Neutral interstellar hydrogen that crosses the heliopause into the heliosphere can also experience charge exchange. Neutral H atoms that are created by charge exchange with the very hot subsonic plasma downstream of the heliospheric termination shock possess thermodynamic attributes that correspond to their origin, i.e. very hot ($\sim 10^6$ K) with an outwardly directed velocity component. This population of neutral atoms is called component 2, is created in region 2 (figure 1), and it streams away from the heliosphere and is quite distinguishable from component 1. By means of secondary charge exchange with the LISM plasma, component 2 acts to transport heat from the heliosheath (the region located between the heliospheric termination shock and the heliopause) into the LISM and this leads to an increase in the LISM tempera-

ture in the immediate vicinity of the heliopause. The final neutral component, component 3, possesses characteristics quite distinct from the other two components and has its origin in the supersonic solar wind (region 3, figure 1). Component 3 has large outward radial velocities and relatively low temperatures but is dynamically unimportant owing to its very low energy density.

The ions born of charge exchange in the supersonic solar wind, the pick-up ions, are, however, of considerable dynamical importance since they remove both momentum and energy from the bulk solar wind flow. The solar wind is decelerated, so reducing the ram pressure and hence the expected size of the heliospheric cavity, and the solar wind acquires a tenuous non-thermalized population of suprathermal ions (typical energies ∼1 keV). The initial pick-up ion population is unstable, generating low-frequency magnetic turbulence which can scatter both pick-up ions and cosmic rays. Some fraction of the pick-up ions is further energized, possibly by shock acceleration, to form the anomalous cosmic ray component, although the precise injection mechanism awaits clarification.

Clearly, a heliosphere mediated by neutral interstellar hydrogen possesses qualities that are likely to be very different from a heliosphere in which the role of neutral hydrogen is neglected. Below, we shall concentrate primarily on global models of the heliosphere in which interstellar neutral hydrogen is accounted for self-consistently. It should be noted that LISM conditions were very different in the past than they are at present (and indeed will be in the future) and thus the structure of the heliosphere may have been very different from the models discussed here.

The material presented here has been reviewed extensively by Holzer (1979) and Zank (1999) and the reader is referred to these works for more detail and an extended bibliography.

The local interstellar medium

Many of the pertinent physical parameters of the LISM are poorly constrained and so, by implication, the detailed solar wind–LISM interaction is not yet well understood. Our best inferences about the LISM flow velocity and temperature have been made from observations of neutral interstellar hydrogen (H) and helium (He) within the heliosphere, using either resonantly scattered solar UV light techniques (since H atoms in the heliosphere are illuminated by the Sun in the HI resonance line, i.e. the Lyman-α line) or *in situ* spacecraft measurements of the He distribution. The bulk velocity of the LISM flow is ∼26 km s^{-1} and the plasma temperature is ∼8000 K. The H and H$^+$ number densities are not well determined, although approximate limits can be derived. For H I (i.e. neutral H only), number densities lie in the range of ∼0.15–0.34 cm^{-3}, while for H II (ionized H), the range is ∼0.03–0.14 cm^{-3}, depending on whether the EUV radiation field is included or not. This leads to a limit on the total number density of both neutral and ionized interstellar hydrogen in the range ∼0.15–0.34 cm^{-3}.

Although most models assume that the relative motion of the heliosphere through the interstellar medium is supersonic, it is by no means clear that such an assumption is completely warranted. Our knowledge of both the local interstellar magnetic field strength and orientation and the energy density in interstellar cosmic rays is somewhat rudimentary. Cosmic rays with energies of 300 MeV/nucleon and less may contribute $\sim(3 \pm 2) \times 10^{-13}$ dyn cm^{-2}, which can yield an interstellar flow that is subsonic. The magnetic field orientation appears to be perpendicular to the interstellar flow velocity vector and estimates for the magnetic field strength range from ∼1.3–2 μG.

Evidently, our knowledge about important LISM plasma and neutral H parameters is rather poor and this must therefore be taken into account when evaluating models of the global heliosphere. Nonetheless, the basic underlying physical processes appear to be reasonably well understood.

Global heliospheric structure

The dynamical or ram pressure (given by ρu^2, ρ being the fluid mass density and u the flow speed) and thermal pressure p of the solar wind decrease with increasing heliocentric distance and must reach a value which eventually balances the pressure exerted by the LISM. The relaxation towards pressure equilibrium between the solar and interstellar plasmas is characterized by (a) a transition of the supersonic solar wind flow to a subsonic state, and (b) a divergence of the interstellar flow about the heliospheric obstacle. The transition of the supersonic solar wind is most likely accomplished by means of a shock transition, the termination shock (denoted by TS), and it is anticipated that at least the Voyager spacecraft will encounter this boundary in the early twenty-first century. The divergence of the LISM flow about the heliosphere may be accomplished either adiabatically (if the relative motion between the Sun and the LISM is subsonic) or by means of a bow shock in the case of supersonic relative motion. If we neglect both the deceleration of the solar wind by resonant charge exchange and temporal variations in the solar wind ram pressure, the minimum radius $R_{\rm TS}$ of the solar wind shock transition can be estimated from

$$\frac{R_{\rm TS}}{r_0} = \left(\frac{\gamma + 3}{2(\gamma + 1)} \frac{\rho_0 u_0^2}{p_\infty} \right)^{1/2} \qquad (1)$$

where $\rho_0 u_0^2$ is the solar wind ram pressure at $r_0 =$ 1 AU, γ the solar wind adiabatic index and p_∞ the total LISM pressure. The LISM pressure term can include the thermal gas, cosmic rays, the interstellar ram pressure, the magnetic field pressure and MHD turbulence, and may be expressed as

$$p_\infty = \rho u^2 + p_{\rm th} + \eta B^2/8\pi + p_{\rm CR} + p_{\rm dust} + p(\delta B^2)$$

where the terms are all evaluated in the LISM and the factor η attempts to include the effects of interstellar magnetic field obliquity.

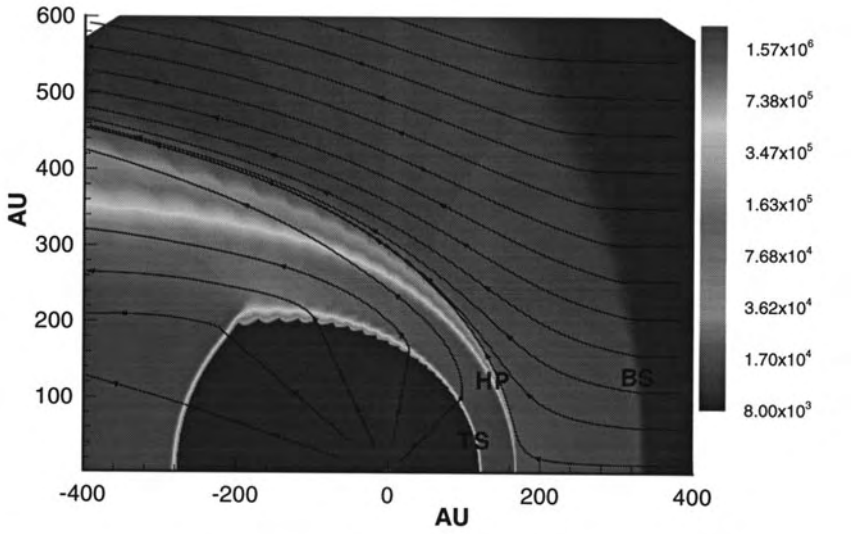

Figure 2. Gray-scale plot of the $\log_{10}$ (temperature) and streamlines for a 2D two-shock model of the solar wind–LISM interaction in the absence of neutral interstellar hydrogen. The termination shock (TS), heliopause (HP) and bow shock (BS) are identified.

Although one can estimate the location of the TS and the heliopause, the discontinuity separating solar wind material from the interstellar plasma (a contact discontinuity in the case of gas dynamics), using simple pressure balance arguments, the interaction of the solar wind with the LISM is fundamentally multi-dimensional. Thus, the main advances in our understanding of global heliospheric structure since the original analytic models have been more recent and based largely on computer simulations. The initial simulations were of purely one-fluid gas dynamic models and only now has the inclusion of neutral interstellar hydrogen been considered self-consistently.

To model the interaction of the solar wind with a partially ionized LISM, the following set of 3D MHD equations must be solved

$$\frac{\partial \rho}{\partial t} + \nabla \cdot \rho \boldsymbol{u} = Q_\rho \tag{2}$$

$$\rho \frac{\partial \boldsymbol{u}}{\partial t} + \rho \boldsymbol{u} \cdot \nabla \boldsymbol{u} + (\gamma - 1)\nabla e + (\nabla \times \boldsymbol{B}) \times \boldsymbol{B} = \boldsymbol{Q}_m \tag{3}$$

$$\frac{\partial}{\partial t}\left(\frac{1}{2}\rho u^2 + e + \frac{B^2}{8\pi}\right) + \nabla \cdot \left[\left(\frac{1}{2}\rho \boldsymbol{u}^2 + \gamma e\right)\boldsymbol{u} + \frac{1}{4\pi}\boldsymbol{B} \times (\boldsymbol{u} \times \boldsymbol{B})\right] = Q_e \tag{4}$$

$$\frac{\partial \boldsymbol{B}}{\partial t} - \nabla \times (\boldsymbol{u} \times \boldsymbol{B}) = 0 \tag{5}$$

$$\nabla \cdot \boldsymbol{B} = 0 \tag{6}$$

together with the equation of state $e = \alpha n k_B T/(\gamma - 1) = p/(\gamma - 1)$. Here $\alpha = 2$ if only electrons and protons are considered as part of the LISM plasma, otherwise α can be larger when, for example, cosmic rays are included. The charge exchange terms Q_ρ, $\boldsymbol{Q}_m$ and Q_e represent pick-up ion source terms for the density, momentum and energy equations; ρ, $\boldsymbol{u}$ and p denote plasma density, velocity, and total pressure, and the electrons and ion temperatures are assumed to be equal. The adiabatic index $\gamma = 5/3$. The source terms couple the plasma and neutral H distribution and, in principle, one needs to compute the evolution of both distributions simultaneously.

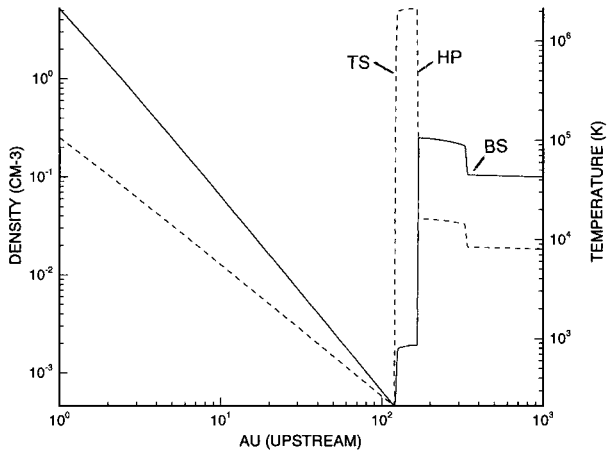

Figure 3. One-dimensional cuts along the stagnation axis in the upstream direction of the plasma-only 2D simulation shown in figure 2. The solid curve shows the plasma density and the dashed curve the plasma temperature profile. The termination shock (TS), heliopause (HP) and bow shock (BS) are marked.

Two approaches have been taken to evaluate the

Figure 4. (*a*) A 2D plot of the global plasma structure for the two-shock model when neutral H is included self-consistently. The shading refers to $\log_{10}$ (temperature). The streamlines are included. (*b*) A 2D plot of the corresponding component 1 neutral distribution, where the shading now refers to the number density. The hydrogen wall is clearly visible between the bow shock (BS) and the heliopause (HP).

neutral H distribution. One approach is to solve the Boltzmann equation

$$\frac{\partial f}{\partial t} + \boldsymbol{v} \cdot \nabla f + \left(\frac{\boldsymbol{F}}{m} \cdot \nabla_v \right) f = P - L \qquad (7)$$

for neutral H directly. Here, $f(\boldsymbol{x}, \boldsymbol{v}, t)$ is the neutral hydrogen distribution function expressed in terms of position $\boldsymbol{x}$, velocity $\boldsymbol{v}$ and time t. $\boldsymbol{F}$ is the force acting on a particle of mass m, typically gravity and radiation pressure. The terms P and L describe the production and loss of neutral particles at $(\boldsymbol{x}, \boldsymbol{v}, t)$ and both terms are functions of the plasma and neutral distributions.

An alternative approach, and one that is much less prohibitive computationally, is to recognize that the heliosphere–LISM environment comprises three thermodynamically distinct regions: the supersonic solar wind (region 3), the very hot subsonic solar wind (region 2), and the LISM itself (region 1) (figure 1). Each region acts as a source of neutral H atoms whose distribution reflects that of the plasma distribution in the region. One may identify neutral components 1, 2 and 3

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

with neutral atoms originating from regions 1, 2 and 3. Each of these three neutral components is approximated by a distinct Maxwellian distribution function appropriate to the characteristics of the source distribution. This observation allows the use of simpler production and loss terms for each neutral component. The complete highly non-Maxwellian H distribution function is then the sum over the three components, i.e.

$$f(\boldsymbol{x}, \boldsymbol{v}, t) = \sum_{i=1}^{3} f_i(\boldsymbol{x}, \boldsymbol{v}, t).$$

Under the assumption that each of the neutral component distributions is approximated adequately by a Maxwellian, one obtains an isotropic hydrodynamic description for each neutral component, and thus a closed multifluid model describing self-consistently the interaction of the solar wind with the partially ionized LISM.

Before discussing the models which include interstellar neutrals self-consistently, consider briefly the 2D structure of the heliosphere in their absence. Figure 2 illustrates the 2D plasma temperature and streamlines for the H^+ fluid at steady state. This particular model does not include either interplanetary or interstellar magnetic fields and assumes a supersonic interstellar wind. Three major boundaries or interfaces are present: the bow shock which compresses and diverts the interstellar flow about the heliosphere, the heliopause which separates the interstellar medium and the solar wind, and the termination shock at which the supersonic solar wind is decelerated abruptly. The termination shock possesses a characteristic bullet shape, quite unlike the approximately spherically symmetric heliosphere that is assumed typically. The supersonic solar wind velocity is constant until the very strong shock (Mach number $\simeq$ 170), and figure 3 illustrates the radial density and temperature profiles along the stagnation line in the upstream direction. The termination shock is located at ~120 AU for this simulation. The solar wind temperature decays adiabatically with increasing heliocentric distance. An extended and very hot tail of subsonic solar wind is formed (called the heliotail) in the downstream direction.

A major effect of charge exchange on the heliospheric interfaces is to decrease the distances to the TS, HP and BS, illustrated in figure 4(*a*). The decrease in distance results primarily from the reduction in solar wind ram pressure, due to the mediation of the wind by charge exchange.

Besides the distance to the various heliospheric boundaries, charge exchange affects the shape of the termination shock, making it more spherical than the purely ionized gas dynamic description. This is a consequence of charge exchange in the heliosheath, which ensures that the shocked solar wind plasma remains subsonic in this region.

Owing to the deposit of interstellar protons in the solar wind when charge exchange is included, the solar wind flow now departs slightly from simple spherical symmetry, and the contribution to the internal energy of

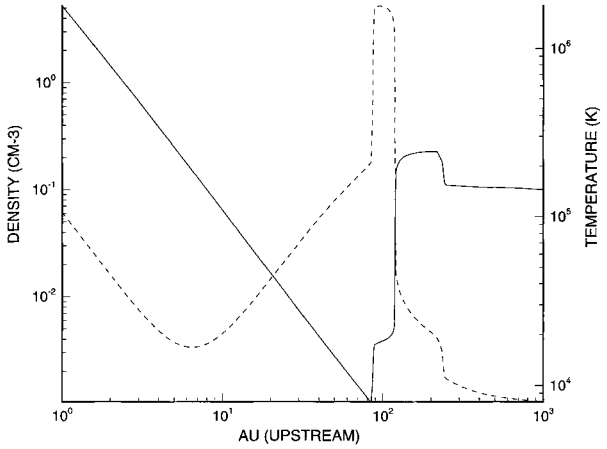

Figure 5. One-dimensional cuts along the stagnation axis in the upstream direction of the coupled plasma-neutral 2D simulation shown in figure 4(*a*). The solid curve shows the plasma density and the dashed curve the plasma temperature profile.

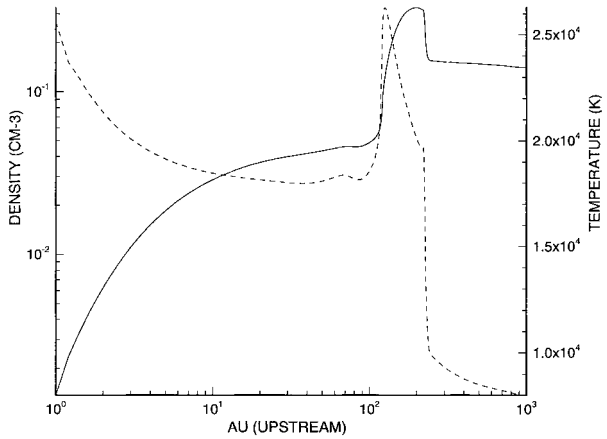

Figure 6. One-dimensional cuts along the stagnation axis in the upstream direction of the coupled plasma-neutral 2D simulation shown in figure 4(*b*). The solid curve shows the component 1 density and the dashed curve the component 1 temperature profile.

the supersonic solar wind by pick-up ions is substantial. This is illustrated in the 1D radial plots of the plasma density and temperature along the upstream stagnation axis (figure 5). The tail region is also cooler when the proton fluid and neutral fluid are coupled compared with no-charge exchange models. The cooling is a consequence of the very hot heliotail being cooled by charge exchange with cooler component 1 neutrals.

To enter the heliosphere, a hydrogen atom has to cross three thermodynamically distinct regions. Through resonant charge exchange, the diverging LISM flow and the shocked solar wind flow act to divert some fraction of the incident interstellar neutral H flux away from the heliosphere. This effective swapping of trajectories by an interstellar neutral and a proton can also lead

Dirac House, Temple Back, Bristol, BS1 6BE, UK

to an enhancement in the neutral interstellar density and temperature in the vicinity of the solar wind–LISM stagnation region.

Figure 4(*b*), a 2D plot of the component 1 neutral H density distribution, shows that inflowing component 1 neutrals are substantially decelerated and filtered by charge exchange with the interstellar plasma between the BS and HP in the upstream direction. This leads to the formation of a hydrogen wall with maximum densities ∼0.2–0.3 cm^{-3}, column densities ∼10^{14} cm^{-2} and temperatures ranging from 18 000 to 28 000 K (depending on the assumed LISM parameters). The pile-up in the neutral gas results from the deceleration and deflection of the neutral flow by charge exchange with the interstellar plasma, which is itself decelerated and diverted due to the presence of the heliosphere. Note that the charge exchange mean free path is typically less than the separation distance between the heliopause and bow shock and so a large part of the incident interstellar neutrals experience charge exchange.

Component 2, produced via charge exchange between component 1 and hot shocked solar wind plasma between the TS and HP, streams across the HP into the cooler shocked interstellar gas and heats the plasma through a second charge exchange. This leads to an extended thermal foot abutting the outside edge of the HP. This heating of the plasma by component 2 serves to broaden the region between the BS and HP, as well as to (indirectly) further heat the component 1 interstellar neutrals after subsequent charge exchanges. Some minor heating of the unshocked LISM also occurs upstream of the BS, thereby marginally reducing the Mach number of the incident interstellar wind.

The temperature of component 1 neutrals once inside the heliosphere remains fairly constant in the upstream region, and represents a substantial increase over the assumed LISM temperature. A further increase in the component 1 temperature occurs in the downstream region.

The number density of component 1 crossing the TS is approximately half the assumed incident LISM number density, an effect termed 'filtration'. The density varies only weakly between the TS and ∼10 AU from the Sun in the upstream region. In the downstream direction, component 1 densities are lower within the heliosphere. The 1D component 1 density and temperature profiles are plotted in figure 6, and the heated hydrogen wall is exhibited clearly.

A further effect of filtration is to decelerate the upstream neutral gas from 26 km s^{-1} in the LISM to ∼19 km s^{-1} at the TS in the region of the nose. Deflection of the flow also reduces the radial velocity component at angles away from the nose. Such a deceleration is in accord with observations which measure the Lyman-α resonance line scattered by neutral H in the heliosphere.

Models which assume a subsonic LISM flow do not have a bow shock. Instead, upstream of the heliopause, the LISM flow is compressed adiabatically. This more gradual compression leads to the formation of a lower-amplitude hydrogen wall that is more extended in the radial direction. It is also less extended in the transverse direction because of the localized nature of the adiabatic compression. The maximum density of the wall in the upstream direction is smaller than that of the two-shock counterpart (though still larger than the incident LISM number density). However, because it is wider, the column density is comparable with the two-shock case.

The heliosphere is less distorted along the axis of symmetry than for the two-shock case, and is smaller due to the higher assumed LISM pressure.

Three-dimensional models of the solar wind during solar minimum introduce some interesting differences from the 2D models discussed above. The presence of an anisotropic solar wind with a high-velocity, low-density, high-temperature polar stream acts to divert both the subsonic solar wind and the LISM plasma flow into the ecliptic region of the heliosphere. The presence of a high-density band of plasma about the ecliptic plane increases the filtration of neutrals compared with the higher polar regions. With an increased neutral flux of H over the poles, the polar wind experiences comparatively greater deceleration than the ecliptic wind, so reducing the degree of anisotropy seen in 3D gas dynamic simulations. In addition, the global distribution of neutral H is anisotropic in heliolatitude. Structurally, the heliosphere at low latitudes can revert to a 'bullet' shape, typically seen only in models which neglect to include interstellar neutral hydrogen. It should be borne in mind that these remarks pertain primarily to the period of solar minimum observed by the Ulysses spacecraft.

Very few simulations include either the interplanetary or interstellar magnetic fields dynamically, and those that do neglect neutral H completely or use an extremely simplified description. Nonetheless, it appears that the magnetic field in the heliosheath can acquire a very interesting structure. Along the stagnation line in the heliosheath, the flow velocity decreases approximately as r^{-2} (r the heliocentric radial distance), leading to an amplification in the azimuthal magnetic field in the region. This, together with the $\boldsymbol{J} \times \boldsymbol{B}$ force causes the equatorial current sheet to bend either upward or downward (depending on solar cycle) away from the equatorial plane. This leads to the formation of an asymmetric 3D magnetic shell or wall in the outer region of the upstream heliosheath with a gap in the neighborhood of the displaced current sheet. The region between the termination shock and the magnetic wall is occupied by solar wind originating from the middle and high latitudes whereas, thanks to the gap in the magnetic wall, the solar wind in the region between the magnetic wall and heliopause originates from the low-latitude equatorial neutral sheet region.

Inferred structure of the heliosphere

Until Voyager 2 encounters the termination shock and heliopause, we are forced to rely on remote observations to

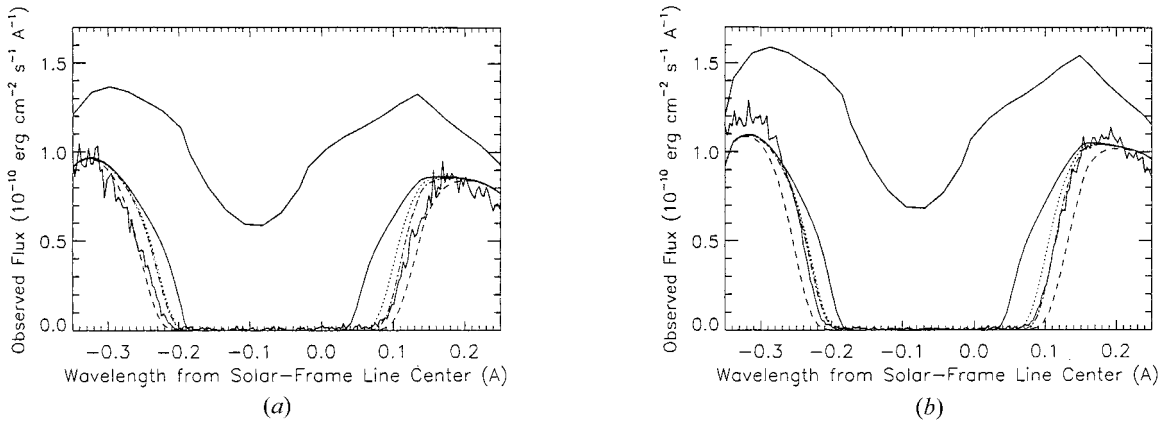

Figure 7. The solid jagged curves are GHRS Lyman-α absorption profiles towards (*a*) α-Cen A and (*b*) α-Cen B. The uppermost solid curve is the assumed intrinsic stellar Lyman-α emission profile. The smoothed solid curve which exhibits saturated absorption corresponds to the intrinsic stellar emission line after absorption from the LISM only. Corresponding theoretical absorption profiles are plotted for an $M = 1.5$ (M the Mach number) LISM (the dashed curve), an $M = 0.7$ LISM (the dotted curve) and an $M = 0.9$ LISM. All three theoretical models show that additional Lyman-α absorption on the red side results from the presence of a heliospheric hydrogen wall and a marginally subsonic model appears to fit the data best.

infer the structure of the heliosphere. The most promising approach presently is to use the Lyman-α absorption line in the direction of nearby stars. A neutral hydrogen pile-up or wall may be detectable in directions where the decelerated H is red-shifted out of the shadow of the interstellar absorption if the interstellar column density is sufficiently low. Red-shifted excess absorption in HUBBLE SPACE TELESCOPE GHRS Lyman-α observations towards α-Cen (seen previously by Copernicus and IUE) have been interpreted as evidence for the existence of the solar hydrogen wall.

Shown in figure 7 are Lyman-α observations towards α-Cen A and B (the jagged solid curves), and the wavelength scale is relative to the Lyman-α line center in the heliocentric rest frame. The upper solid curve is the assumed intrinsic stellar Lyman-α emission profile. The accurate representation of the intrinsic stellar profile is unimportant since the absorption features of interest vary sharply. The remaining smooth solid curve (the saturated absorption curve) in figure 7 gives the attenuation of the stellar Lyman-α emission by interstellar H. The column density for H was fixed by scaling to the deuterium column density, assuming the commonly accepted value of D/H = 1.6×10^{-5}. Figure 7 shows very clearly that additional absorption is required both redward and blueward of the interstellar feature if the fit is to be completed. Furthermore, the fit must be applied preferentially to the redward side, so arbitrarily changing the D/H ratio is unacceptable. The additional redward absorption has been interpreted as evidence for the detection of the hydrogen wall. The blueward absorption suggests the possibility of a hydrogen wall about α-Cen A and B.

Since the column depth of the hydrogen wall is three orders of magnitude smaller than the column depth in the LISM toward α-Cen, it may be surprising at first glance that the heliospheric optical depth at +0.1 Å is of the same order as the LISM optical depth at that wavelength. The key difference is that the hydrogen wall is heated and decelerated, which both broadens and redshifts the heliospheric component away from the −0.07 Å centroid of the LISM absorption and toward the +0.1 Å wavelength of interest.

Figure 7 also shows the Lyman-α absorption at the red edge of the LISM feature for three heliospheric models—a subsonic LISM model (dotted line), a barely subsonic LISM model (dash-dot line), and a supersonic model (dashed curve). The primary and very important conclusion to emerge from such modelling is that the synthetic Lyman-α profiles support the interpretation of the observed additional redward Lyman-α towards α-Cen as evidence for the remote detection of the hydrogen wall. Thus, it appears that the hydrogen wall has indeed been observed! The unprecedented accuracy of the Hubble GHRS observations suggests further that, with the refinement of solar wind–LISM interaction models, the question of whether the heliosphere has a one- or a two-shock structure may be answered in the foreseeable future.

The future

Evidently, many more physical processes remain to be incorporated in models describing the interaction of the solar wind with the LISM. This will undoubtedly be accomplished in the next decade as computational power increases and the underlying physics is better understood. However, the most important limitation that the field currently faces concerns the paucity of information about the state of the local interstellar environment.

Ingenious efforts have been made to obtain *in situ* and remote sensing measurements of interstellar pick-up ions and neutrals, which have advanced our theoretical understanding of the solar wind–LISM interaction considerably. Possible future missions dedicated to solar

Dirac House, Temple Back, Bristol, BS1 6BE, UK

wind/LISM questions, such as Interstellar Probe, will advance the field (and others) tremendously and in directions that we may not yet even fully appreciate.

In concluding, we should not lose sight of the fact that the interaction of the solar wind with the LISM represents only one, admittedly important, astrophysical example of the interaction of a stellar wind with a partially ionized interstellar medium. This subject, although only cursorily studied so far, may well prove fundamental to our understanding of the evolution of stellar winds in the warm interstellar medium and to the evolution of the interstellar medium itself. In this respect, the solar wind interaction with the LISM is truly a subject at the interface of space physics and astrophysics.

Solar Wind: Interplanetary Radio Bursts

Solar radio emissions at long wavelengths (λ greater than 10 m or frequencies smaller than 30 MHz) are produced in the upper CORONA and in the interplanetary medium, sometimes at very large distances from the Sun, up to the orbit of Jupiter and beyond. They are essentially produced by local instabilities, resulting from the interaction of the ambient SOLAR WIND with disturbances: streams of subrelativistic particles, and shock waves, whose origin is mostly in the solar corona; they provide a unique means to detect perturbations originating from SOLAR ACTIVE REGIONS and to track their progression through the solar wind. These emissions are produced in a frequency range over which the Earth's ionosphere transmits either poorly or not at all; a spacecraft in orbit well above the ionosphere must carry the instruments.

Solar radio astronomy at long wavelengths: specificities and problems

Electromagnetic waves at long wavelengths cannot reach the Earth because the ionosphere stops them. The cut-off frequency depends on the ionosphere peak electron density and is about 20 MHz by day and 10 MHz or less by night. Observations at long wavelengths thus require putting the radio instrument on a spacecraft well above the ionosphere. Table 1 shows a few typical frequencies and the corresponding wavelength regimes.

Table 1. The frequency/wavelength regimes.

Frequency	Wavelength	Band	Distance range from center of Sun
300 MHz	1 m	metric	lower corona up to 2–3 $R_\odot$
30 MHz	10 m	decametric	2–3 to ∼10 $R_\odot$
3 MHz	100 m	hectometric	∼10 to ∼60 $R_\odot$
300 kHz	1 km	kilometric	beyond ∼60 $R_\odot$
30 kHz	10 km		

Figure 1 shows the observed radio frequency of interplanetary radio bursts as a function of heliocentric distance (distance from the center of the Sun). A strong dependence is clearly seen, which is simply due to the fact that most radio sources consist of a narrow band emitted near the local plasma frequency and/or its harmonic. Since the plasma frequency is directly proportional to $\sqrt{N_e}$ (N_e is the local electron density), the distribution of frequencies as a function of distance closely follows that of the densities, with the usual dispersion. In a way radio observations in a large band provide a radial imaging of solar sources. This interpretation is very important, since most phenomena considered here are traveling phenomena that propagate outward from the Sun (streams of subrelativistic particles, shock waves, see below), mostly in the radial direction.

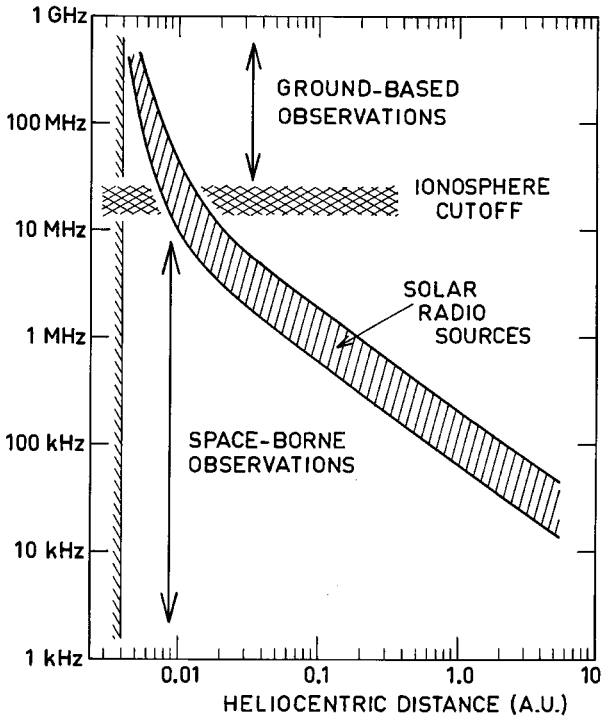

Figure 1. Heliocentric distance of radio bursts in the solar corona and interplanetary medium. The two regimes of observation—ground-based and space-borne—complement each other in order to study the physical processes involved in the radio bursts.

An important feature of radio observations from space is that they give access to sources in the interplanetary medium. In some cases, the spacecraft is even inside the radio source itself and local conditions of the solar wind plasma and of its perturbations can be measured. In the latter case, the observation of interplanetary radio bursts actually links phenomena on the Sun to *in situ* phenomena.

The antennas on spacecraft are usually wire antennas or booms from a few meters long to a few hundred meters long. Wire antennas require spinning spacecraft. The antenna length is generally short compared with the wavelength, so that they can be considered as pure dipoles, with no spatial resolution. Imaging radio sources is very difficult at low frequency (very long baseline arrays are required and have never been used as yet). Direction finding techniques are currently used on spinning spacecraft: from the analysis of the modulation of the radio signal over a spin, it is possible to deduce the source direction (direction of the source centroid), an estimate of its angular size, and its degree of circular POLARIZATION. Thus, the present radio instruments on spacecraft are essentially SPECTROGRAPHS, some of which have the direction finding capability. We note here that

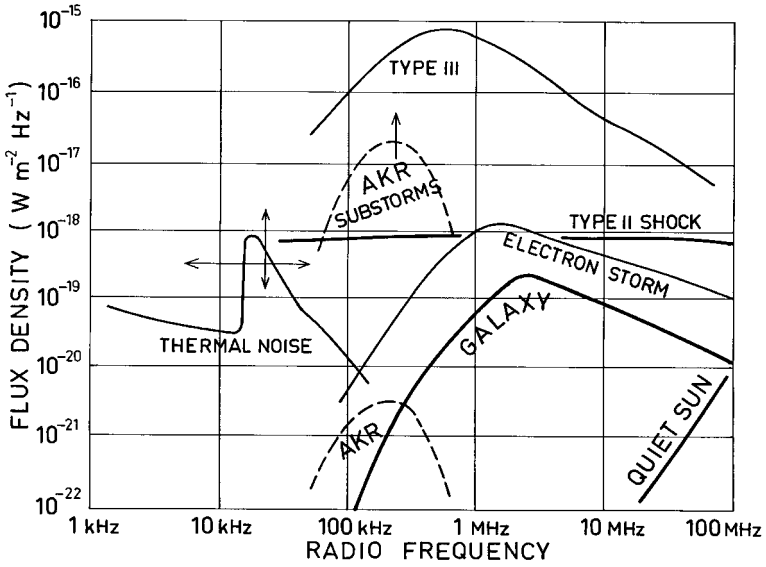

Figure 2. Flux densities of a variety of common radio sources in the range 1 kHz to 100 MHz.

the radio astronomy receivers on spacecraft are often part of more extensive radio and plasma wave investigations yielding information on *in situ* waves as well. These are observed by the same instruments and displayed on the same 'dynamic spectrum' and are sometimes essential to the understanding of radio wave production mechanisms.

Figure 2 shows instantaneous spectra of various radio events. Intense, sporadic sources are easily identified, sometimes more than 50 dB above the background. They originate from solar disturbances in the interplanetary medium and from radiation near magnetized planets, including the Earth. Above a few 100 kHz, all other sources, Galactic or extragalactic, merge into a background, which is well observed but not resolved; it is called the 'Galactic background'. Below 100 kHz, the background is determined by the electron quasithermal noise near the local plasma frequency. The radio intensity or flux density (in $\mathrm{W\,m^{-2}\,Hz^{-1}}$) is often displayed on a 'dynamic spectrum' where it is coded with a gray (or color) scale as a function of frequency and time. If time is usually displayed on the x-axis, frequency is represented on the y-axis, either increasing or decreasing upwards. In the latter case, the y-axis suggests the increasing distance from the Sun, which varies as $1/f$, since $N_\mathrm{e} \sim R^{-2}$ in the solar wind, and $f \sim f_\mathrm{p} \sim N_\mathrm{e}^{1/2}$.

The intrinsic properties of the radio source may be masked by propagation effects, on both large and small scales. Stereoscopic observations are required to assess these effects; they have shown that the radiation can be strongly beamed, sometimes in a non-radial direction. These effects provide additional information on the medium between the source and the observer. Such observations have been made in the past, either with dedicated stereoscopic missions or by combining simultaneous observations from different spacecraft on widely different orbits.

Radio signatures in the solar wind

Radio sources in the solar wind are sporadic and highly variable. A smaller variety of sources are seen than in the lower corona: only the type II (shock wave) and type III (electron stream) bursts are currently observed. Recent observations from the WIND spacecraft suggest the presence of type IV bursts and of fine structures associated with energetic particles.

A type II burst is detected in the dynamic spectrum plots as one or a few narrow bands of emission slowly drifting from high to low frequencies. The type II bursts are usually faint but can sometimes be tracked for several hours up to a day or more. Their observation proves the existence of a shock wave. Indeed, it is believed that a shock is needed to accelerate electrons to about 10 keV, where the distribution becomes unstable to the production of Langmuir waves, which are converted into radio waves through processes similar to the type III radiation. Thus, type II emission provides a unique means of tracking shocks remotely. It is particularly important in the interplanetary medium, where it can help track the progression of interplanetary shocks from the upper corona to the Earth (see table 1).

Type III bursts are produced by beams of subrelativistic electrons (1–100 keV) originating from active regions; they propagate along open magnetic field lines from the solar corona throughout the interplanetary medium. They produce the most frequent solar radio bursts in the interplanetary medium, which certainly are the most exhaustively studied and best understood. Radiation is emitted near the plasma frequency and/or its harmonic. As

the electrons move out from the Sun, they encounter decreasing plasma densities and therefore emit at lower and lower frequencies. The radio signature shows a frequency drift seen on spectrograms—the dynamic spectrum. At a given frequency, the duration of the burst is about the time it takes for the beam to cross the corresponding 'plasma level'. The duration thus increases as the beam expands and spreads out in the interplanetary medium.

Type III bursts sometimes occur in storms which consist of thousands of overlapping individual type III bursts. These interplanetary radio storms are the extension through the solar wind of the type III storms which are seen at metric and decametric wavelengths and are themselves often associated with the type I storms seen in the metric and decimetric regime. These radio events trace long-lasting storms of suprathermal electrons injected near active regions. They may help trace the expansion of the slow solar wind above active regions.

Generation mechanisms and source structure

Radio bursts in the interplanetary medium are caused by the interaction of beams of energetic electrons—produced during solar flares and at shock fronts—with the ambient solar wind plasma. The beam free energy is converted into Langmuir waves, and then some Langmuir wave energy is converted to radio waves at the fundamental and/or the harmonic of the local plasma frequency. This is known as the plasma mechanism and can account for almost all radio bursts in the interplanetary medium. On rare occasions type IV-like events have been observed up to 10 or 15 solar radii and on one occasion a group of very intense type III-like bursts was convincingly interpreted as being due to synchrotron emission caused by energetic electrons confined in a magnetic trap created behind an interplanetary shock wave.

The size of an interplanetary radio burst may be very large. Typically, the extent of the radio sources grows as the distance to the Sun, with a factor of proportionality close to 1. As already mentioned, propagation effects may be important and may account for a significant portion of the observed source sizes—up to 50%; the source position, beaming and polarization may also be modified. Stereoscopic observations have been shown to provide essential clues in order to understand and correct those effects and even gain information from them.

It is accepted, both on observational and theoretical grounds, that the radio emission is generated in localized, unresolved regions of the interplanetary medium, rather than uniformly along the path of the electron beam for the type IIIs, or along the shock front for the type IIs. In general, interplanetary radio sources can be modeled by taking into account two essential factors: the known finite extent of the radio source and the directivity of the radio emission.

Large scale structure and dynamics of the solar wind from radio burst observations

Type III bursts and the large-scale magnetic field

The interplanetary medium is structured by the flow of the solar wind, a fully ionized, magnetized plasma. Radio bursts can provide unique information on the structure of this medium because they reflect mostly local conditions at their source.

The interplanetary magnetic field assumes an Archimedean spiral shape, due to the combination of the solar wind expansion with the solar rotation. The energetic electrons, because of their small gyro-radius, have to follow (or spiral around) the average field lines. Thus, the analysis of the source location of interplanetary type III radio bursts should, in principle, yield a large-scale mapping of the interplanetary magnetic field, with an indication of electron density along it, and a tracking of the evolution of beams of electrons over large distances. When one spacecraft only can determine the direction of the centroid of the radio source, a hypothesis has to be made on the radiation mode and on the average density model. This works quite well up to 0.5 Astronomical Units (AU) but the deduced trajectories tend to show anomalous behavior beyond this distance, because of propagation effects, increasing source sizes and proximity effects. The use of a second spacecraft helps resolve some of the latter effects and eliminate the hypothesis of a density model and radiation mode.

Radio storms and the slow solar wind

The long-lasting interplanetary radio storms (type III storms) can be seen in the interplanetary medium at a variety of radio frequencies, rotating from east to west, as the Sun rotates. The analysis of these structures yields information on the solar wind density and velocity above active regions (where they are observed). The derived velocities tend to be smaller than the average solar wind velocity, consistent with a slow solar wind above solar active regions.

Type II shocks and coronal mass ejections

The observation of a type II burst is believed to demonstrate the passage of a collisionless shock wave, which cannot generally be witnessed by any other means. The first extensive studies of interplanetary type II radio shocks were made with the ISEE-3 data (essentially 1978–1984) and now with the WIND spacecraft (launched in November 1994). Many questions related to the nature of the type II source and its association with the shock front remain unsolved, although they often are basic questions if one desires to really use the type II observations as a tool for diagnosing the shock progression and evolution in the solar corona and interplanetary medium. It is generally believed that the interplanetary shock is (piston-) driven by the SOLAR CORONAL MASS EJECTION (CME), but there is no direct observational proof as yet. This is generally supported by timing considerations. However, the estimation of the shock velocity depends strongly on the choice of the density model, which remains an

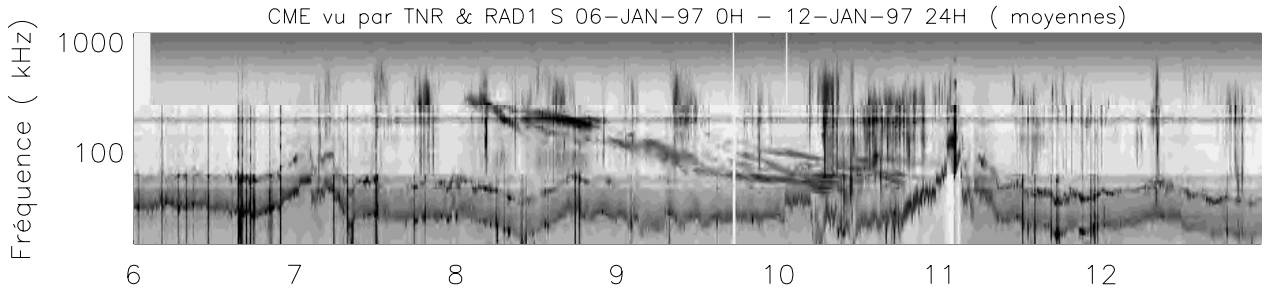

Figure 3. Dynamic spectrum obtained by the WAVES investigation on the WIND spacecraft, for the period 6–12 January 1997, and for the range from 4 kHz (*in situ* waves, bottom of *y*-axis) to 1 MHz (about 15 $R_\odot$, top of axis). The fluctuating line which runs through the plot (between about 10 and 60 kHz) is the plasma line which follows the fluctuations of the electron density at the spacecraft. The type II-like emission is seen as slowly drifting emission bands from 8 to 11 January.

unknown, and of the radiated mode, which is sometimes hard to identify. The situation is rather unclear for coronal shocks, even up to several $R_\odot$ from the Sun: some type II shocks could trace pure blast waves. Observations have not yet determined the precise location of the source with respect to the shock front, radially (upstream or downstream) or along the shock front: it is not known whether the shock radiates uniformly or if the radiation is only produced in regions where special conditions are met (for instance, parallel or perpendicular shock front, special range of Mach number, etc). There is sometimes evidence for multiple shocks, associated with single flare or CME events. The absence of spatial resolution often leads to oversimple models. Stereoscopic observations are expected to help resolve a number of these issues, in particular the location (centroid) of the radio source and the shock velocity.

Radio emissions may also reflect complex situations when the CME interacts with large-scale structures in the interplanetary medium, such as corotating interaction regions (CIR) or the heliospheric current sheet (HCS). This again may provide unique information on events that are otherwise difficult to detect but may have a strong terrestrial impact. As an example, figure 3 shows the dynamic spectrum of a very unusually strong type II-like radiation associated with the 6–11 January 1997 coronal mass ejection (CME). This event started on the Sun as a halo CME and was associated with a (faint) disappearing FILAMENT on the solar disk. Even though it is complex and hard to model, it yields definitive information on the strength of the interplanetary shock and its progression through the solar wind.

Shock-associated (SA) events

A class of large interplanetary type III bursts closely associated with meter-wave (coronal) type II bursts was proposed to be produced by electrons accelerated by shock waves in the solar corona: some events appeared to be the extension of 'herringbone structures', which are generally accepted to show evidence for shock acceleration. It was found that the shock-associated (SA) events are well correlated with major proton events, which are known to be mostly associated with interplanetary shocks.

This interpretation was challenged by some authors who argued that, in many cases, the good correlation between the SA time profiles and the concurrent microwave burst and/or hard x-ray burst strongly suggested that the SA events were caused by electrons accelerated in or near the microwave or x-ray source region, i.e. near the chromosphere rather than in coronal shock waves. Thus, there is an ongoing controversy on the origin of the electrons responsible for the SA events. Global observations of the full range of radio emissions (observed from both ground and space) associated with x-ray, EUV and optical observations are certainly necessary to fully assess the origin of the energetic particles, whose radio signature appears in the decametric and hectometric range.

In conclusion, interplanetary radio bursts provide a unique signature of energetic phenomena in the solar wind, including shock wave tracking. The difficulties encountered in their observation and interpretation testify to the complexity and richness of the radio diagnostic. The field of radio astronomy at long wavelengths is very active and much remains to be done. Stereoscopic observation is a first step towards a better tracking of disturbances in the solar wind and a better modeling of beaming and propagation effects: NASA's Solar TErrestrial RElations Observatory (STEREO) will have a major role in this step. A second step would be to do imaging at long wavelengths, which would require an array of small spacecraft. The long wavelength range is indeed the last window of the electromagnetic spectrum never to have been observed with spatial resolution.

Solar Wind: Kinetic Properties

The SOLAR WIND consists of electrons, protons, alpha particles and heavy ions. Its kinetic physics deals with the collective behavior of these particles in a statistical ensemble. Space-borne particle spectrometers enable us to measure the composition and three-dimensional velocity distribution functions (VDFs) of the particles. Vlasov kinetic plasma theory provides the adequate means for their theoretical description. Key issues of kinetic physics are to address the coronal origin and acceleration of the wind and the spatial and temporal evolution of the particles' VDFs (see SOLAR WIND: CORONAL ORIGINS, SOLAR WIND ACCELERATION). They are shaped through the forces of the Sun's gravitational field, the average-macroscale and fluctuating-mesoscale electric and magnetic fields of interplanetary space, and through multiple microscale kinetic processes such as binary Coulomb collisions and collective wave–particle interactions.

Velocity distribution functions (VDFs)

General considerations

The global solar magnetic field varies over the activity cycle, but the coronal field always consists of three main components: long-term open CORONAL HOLES (CHs), closed CORONAL STREAMERS and transiently open or closed CORONAL LOOPS. These components are respectively associated with uniform fast solar wind, filamentary slow wind, and transient variable-speed wind such as that related to SOLAR CORONAL MASS EJECTIONS. These three types differ substantially in their kinetic properties because of different solar boundary conditions and interplanetary plasma dynamics. The radial evolution of the internal state of the wind resembles a complicated relaxation process, in which the particles' free (as compared with local kinetic and magnetohydrodynamic equilibrium conditions) energy is converted into thermal, wave and turbulence energy on a wide range of scales. Spherical expansion and large-scale inhomogeneity compel the wind plasma to attain a variable state of dynamic statistical equilibrium between the particles and field fluctuations. In principle, these processes are described by the full Boltzmann–Vlasov equation for the phase-space distribution, $f_j(\boldsymbol{x}, \boldsymbol{v}, t)$, which is a measure of the number of particles in a volume surrounding position $\boldsymbol{x}$ and with velocities in a certain range around $\boldsymbol{v}$, and which evolves according to

$$\left\{\frac{\partial}{\partial t} + \boldsymbol{v}\cdot\frac{\partial}{\partial \boldsymbol{x}} + \left[\boldsymbol{g} + \frac{e_j}{m_j}\left(\boldsymbol{E} + \frac{1}{c}\boldsymbol{v}\times\boldsymbol{B}\right)\right]\cdot\frac{\partial}{\partial \boldsymbol{v}}\right\} f_j = \left(\frac{\mathrm{d}}{\mathrm{d}t} f_j\right)_{c,w} \quad (1)$$

with the interplanetary magnetic field, $\boldsymbol{B}(\boldsymbol{x}, t)$, electric field, $\boldsymbol{E}(\boldsymbol{x}, t)$ and the Sun's gravitational acceleration, $\boldsymbol{g}(\boldsymbol{x})$. Coulomb collisions or wave–particle interactions are also included and described by the Fokker–Planck collision integral or the quasilinear diffusion operator on the right-hand side of equation (1). Here the particle charge is e_j, its mass m_j, speed $\boldsymbol{v}$ and space coordinate $\boldsymbol{x}$. The speed of light is c. In addition to equation (1), Maxwell's equations have to be solved with the self-consistent current and charge density of the multicomponent wind, as calculated from the velocity moments of this equation. This complex problem has not been solved, but solutions of simplified versions of this problem, restricted to a single particle species, do exist.

Ion velocity distribution functions

The observed distributions of ions and electrons exhibit various shapes and change widely with the local *in situ* conditions, heliographic coordinates and the phase of the solar cycle. The proton VDFs range from Maxwellians in slow wind, embedding the heliospheric current sheet (HCS), to highly non-thermal ones in fast streams emanating from CHs. In fast solar wind the proton temperatures are anisotropic, with $T_{p\perp} > T_{p\parallel}$. Frequently, strong field-aligned proton beams with a drift speed larger than the local Alfvén speed occur.

The electrons are cooler than the protons in fast wind (T_e = 0.1–0.2 MK and T_p = 0.5–0.8 MK at 0.3 AU), but hotter in slow wind, which is more variable in abundance, more compressive and comparatively cold, with all particle temperatures becoming minimal at the HCS ($T_p = 5 \times 10^4$ K at 1 AU). The fast wind is permeated by Alfvén waves from coronal holes, which are broad-band in frequency and play a significant role in maintaining, through their dissipation, the ion temperatures above the level expected for adiabatic cooling. Whereas high-energy extensions are a universal property of the protons, they are less frequently seen in the alpha particles. Some typical proton distributions in fast wind are presented in figure 1, together with the radial profile of the average magnetic moment, $\mu_p = T_{p\perp}/B$, of the particles, which is displayed as a function of radial distance from the Sun. That μ_p increases radially indicates continuous ion heating perpendicular to the magnetic field in the interplanetary medium. The solid line in figure 1 shows results of a turbulence model which explains the heating by wave dissipation.

The heavy minor ions seem to trace wave effects in the wind. They stream faster than protons by the local Alfvén velocity, $\boldsymbol{V}_i \leq \boldsymbol{V}_p + \boldsymbol{V}_A$, and tend to surf on the ubiquitous Alfvén waves. This differential streaming originates in the CORONA and is observed by HELIOS to fade away with increasing heliocentric distance. Speed differences between protons and alpha particles are seen also by Ulysses beyond 1 AU and appear to be generated locally at shocks and stream interaction regions (see SOLAR WIND: ULYSSES). In fast wind, heavy ions have a high kinetic temperature, with $T_i \approx A_i T_p$ and A_i being the atomic mass number of the ion. They come in various ionization stages and have about coronal abundances in fast wind, but show element fractionation in slow wind. Helium is an exception. Its sizable relative abundance of about 3–5% on the average differentiates it from a minor constituent. In slow wind, the higher density and lower temperature enforce a state near collisional equilibrium.

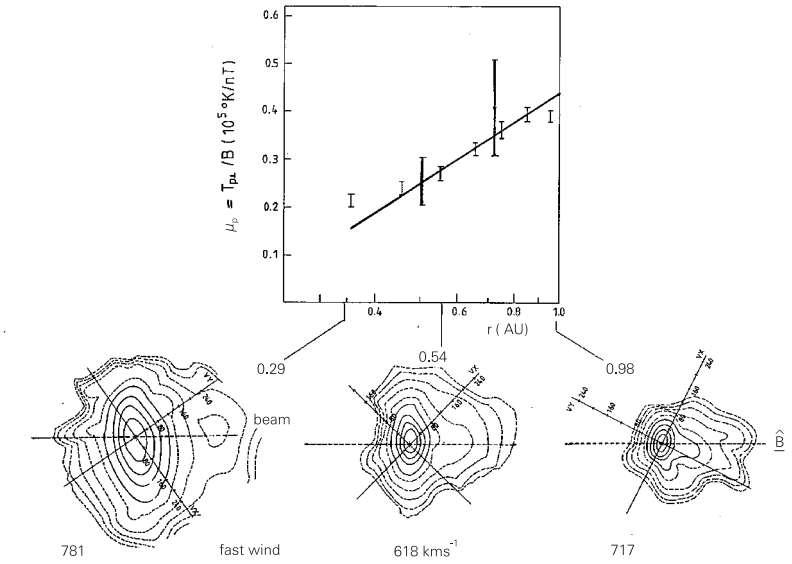

Figure 1. The observed proton magnetic moment versus heliocentric distance (top) and selected velocity distribution functions measured in high-speed wind. The solid isodensity contours correspond to 20% steps of the maximum, and the last broken contour is at 0.1%. Note the large temperature anisotropy in the core and the strong beam along the magnetic field.

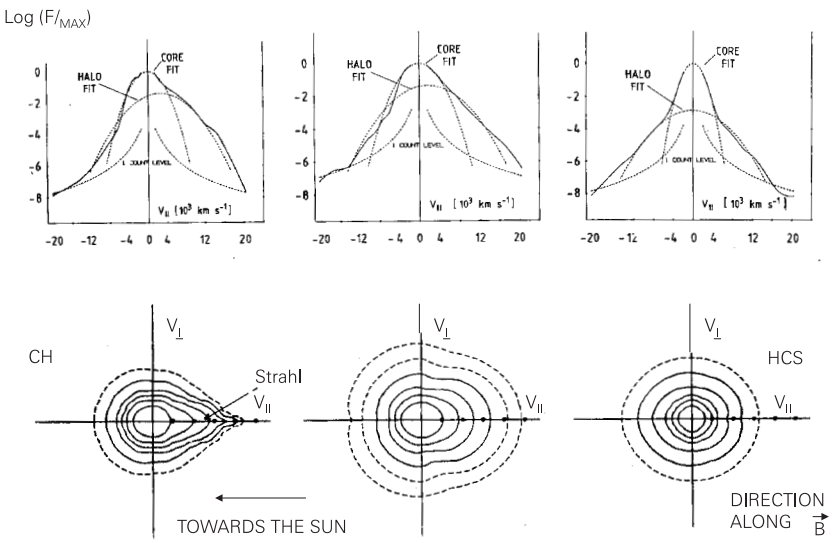

Figure 2. Electron velocity distribution functions as energy spectra (top) and velocity-space contours (bottom) for fast (left), intermediate and slow (right) wind. Isodensity contours are in 10% steps. Note the core–halo structure and the strahl of suprathermal electrons in fast solar wind.

Electron velocity distribution functions

The electrons are, because of their small masses, dynamically less important for the solar wind. Yet they ensure quasineutrality, constitute an electric field through their thermal pressure gradient and carry heat in the skewness of the bulk and the suprathermal tail of their VDFs. The distribution functions are determined mainly by the large-scale interplanetary magnetic field and the self-generated electrostatic potential, by Coulomb collisions in the thermal energy range at a few 10 eV and by various kinds of wave–particle interactions. The electrons are subsonic, i.e. their mean thermal speed considerably exceeds the solar wind (ion) bulk speed. Suprathermal electrons (at several 100 eV) may be considered as

test particles that quickly explore the global structure of the heliospheric magnetic field. It may attain the form of open field lines anchored in CHs, of bottles and loops originating around the solar equator or of flux ropes. This topology shapes the distributions, which can observationally be decomposed into two main components, a cold and almost isotropic collisional core and a hot variably skewed halo population. The VDFs are often modeled by two convecting bi-Maxwellians as illustrated in the top part of figure 2. On open field lines in the fast wind, the halo usually develops a high-energy extension with a very narrow pitch-angle distribution only 10°–20° wide. This electron population has been named the 'strahl' and responds sensitively to the local field orientation.

Common observations of the same plasma parcel of the wind by instruments on different spacecraft, when being radially aligned, allow one to characterize the radial gradients of electron thermal parameters. The core temperature is found to vary widely between isothermal and adiabatic, while the halo temperature behaves more isothermally. The halo density falls off more steeply in dense plasma. Electron parameters have been studied by Ulysses in the distance range from 1 to 4 AU. The halo is found to represent always about 4% of the total electron number. Since there is no reason for this ratio to be constant if the halo and core particles were completely decoupled, it appears that halo particles are not entirely decoupled from the core. The break-point energy in the electron spectra of figure 2 scales on average like 7 times the core temperature, a result which is predicted by a kinetic theory for electrons mediated by Coulomb collisions. Such a value of the break-point energy is also consistent with its interpretation as being equal to the electrostatic interplanetary potential trapping the thermal electrons.

Significant progress has been made, with the Ulysses electron measurements, in the understanding of the electron heat flux regulation. An empirical heat conduction law has been suggested, in which the heat flux is carried mainly by the halo electrons and scales like the halo particle flux times the halo thermal energy. This proportionality has experimentally been verified, demonstrating that solar wind heat conduction has nothing to do with the local temperature gradient but with the thermal energy convected by halo electrons. Their drift speed is closely tied to the Alfvén velocity. This supports the evidence for a regulation of the heat flux by whistler-mode waves.

Wave–particle interactions

It is widely recognized that plasma waves in the collisionless solar corona and wind play a role similar to collisions in ordinary fluids (see also SOLAR WIND PLASMA WAVES). In the expanding inhomogeneous solar wind particle distributions develop velocity-space gradients and deviations from Maxwellians, which drive plasma instabilities and lead to wave growth or damping. The kinetic wave modes of primary importance are the ion-cyclotron, ion-acoustic and whistler-mode waves, which are the high-frequency extensions of such fluid modes as the Alfvén, slow and fast magnetoacoustic waves.

Usually, the multicomponent plasma is analysed locally for stability, by Fourier decomposing linear fluctuations of the fields into plane waves with wave vector $\boldsymbol{k}$. Each species contributes a distinct dispersion branch for kinetic waves that are weakly damped normal modes or unstable in the presence of free energy. As an example, the dispersion equation for parallel propagating left (− sign) and right (+ sign) handed circularly polarized electromagnetic waves with wavevector component $k_\parallel$ along the background magnetic field, $\boldsymbol{B}_0$, reads

$$(k_\parallel V_A)^2 = z_{k_\parallel}^2 \left(\frac{V_A}{c}\right)^2 + \sum_j \hat{\rho}_j \Omega_j^2 \, \hat{\varepsilon}_j^{\pm}(z_{k_\parallel}, k_\parallel) \qquad (2)$$

where the fractional mass density of species j has been used, defined as $\hat{\rho}_j = n_j m_j / \sum_\ell n_\ell m_\ell$. The Alfvén velocity based on the total mass density, $V_A^2 = B_0^2/4\pi\rho$, is used to normalize the phase speed properly. The plasma frequency is given by $\omega_j^2 = 4\pi e_j^2 n_j / m_j$, and the gyrofrequency, carrying the sign of the charge, by $\Omega_j = e_j B_0 / m_j c$. For a given real wavevector, $k_\parallel$, complex solutions of the frequency $z_{k\parallel} = \omega_{k_\parallel} + \mathrm{i}\gamma_{k_\parallel}$ are sought, whereby a positive $\gamma_{k_\parallel}$ signifies a plasma microinstability. The dielectric constant involves a resonance integral over velocity-space derivatives of the VDF, corresponding to the pitch-angle gradient for a particle in the wave frame as defined by the phase speed, and reads

$$\hat{\varepsilon}_j^{\pm}(z_{k_\parallel}, k_\parallel) = 2\pi \int_0^\infty \mathrm{d}w_\perp \, w_\perp \int_{-\infty}^\infty \mathrm{d}w_\parallel \frac{w_\perp/2}{w_\parallel - w_j^{\pm}} \times \left[\left(w_\parallel - \frac{z'_{k_\parallel}}{k_\parallel} \right) \frac{\partial}{\partial w_\perp} - w_\perp \frac{\partial}{\partial w_\parallel} \right] f_j(w_\perp, w_\parallel). \qquad (3)$$

The symbols $w_{\perp,\parallel}$ refer to velocity components perpendicular and parallel to $\hat{\boldsymbol{B}}_0$ in the species j proper frame, with $\boldsymbol{w} = \boldsymbol{v} - U_j \hat{\boldsymbol{B}}_0$. The prime at $z_{k_\parallel}$ indicates the Doppler shift into the rest frame of species j, drifting at bulk velocity U_j, i.e. $z'_{k_\parallel} = z_{k_\parallel} - kU_j$. The VDF here is understood to be normalized to the particle number density n_j. Numerical investigations of equation (2) have been carried out in the literature under various conditions. The multicomponent solar wind plasma is usually at the margin of microscopic stability. Interacting with a wave, a particle sees a stationary electric field if its velocity meets the condition for cyclotron resonance, where $w_\parallel = w_j^{\pm} = (z'_{k_\parallel} \pm \Omega_j)/k_\parallel$. Energy and momentum between particle and wave are exchanged as a result of this wave–particle interaction. The velocity distributions are reshaped, until the free energy in the form of temperature anisotropy, beam drift or ion differential motion, and skewness or heat flux are reduced or removed. These processes are analytically described by quasilinear theory, based on equation (1) with the fields being decomposed into means

Copyright © Nature Publishing Group 2001

and fluctations, and are visualized by direct numerical simulation.

In addition to electromagnetic modes, electrostatic waves frequently occur with variable intensity in various regions of the heliosphere. Below the proton plasma frequency one has the ion acoustic modes and above the electron plasma frequency the electrostatic Langmuir oscillations and the free-space electromagnetic waves. These waves are derived from the simple dispersion equation

$$k^2 = \sum_j k_j^2 \int_{-\infty}^{+\infty} \mathrm{d}^3 w \frac{V_j^2}{\boldsymbol{k}\cdot\boldsymbol{w} - z_{\boldsymbol{k}}'} \boldsymbol{k}\cdot\frac{\partial}{\partial \boldsymbol{w}} f_j(\boldsymbol{w}) \qquad (4)$$

where k_j is the Debye wavenumber of species j, given by $k_j = \omega_j / V_j$. The thermal speed is $V_j = (k_B T_j / m_j)^{1/2}$, with the Boltzmann constant k_B. The dielectric function involves the Landau-resonance integral over the derivative of the VDF in the $\boldsymbol{k}$-direction. The dispersion relation (4) gives the wavevector k in dependence on the propagation direction $\hat{\boldsymbol{k}}$ and phase speed $z_{\boldsymbol{k}}/k$. The wavelength may vary between infinity and the very short electron Debye length $\lambda_e = k_e^{-1}$. Observationally, the occurrence of ion-acoustic waves is determined by the electron to proton temperature ratio, T_e/T_p, and the magnetic field direction. Highest wave intensities are observed around the HCS, where usually $T_e/T_p > 1$, implying weak Landau damping.

Most of the stability analyses carried out are based on idealized model distributions such as drifting bi-Maxwellians or Lorentzians with high-energy tails. Even the measured VDFs are implemented in dispersion codes to diagnose their stability or predict the associated wave activity. In summarizing our understanding of the role of microinstabilities in the solar wind, we see that the VDFs are generally found to be marginally stable but prone to instability. The four salient modes (and free energy sources) are (1) ion acoustic wave (ion beam, electron heat flux), (2) electromagnetic ion cyclotron wave (proton core temperature anisotropy), (3) magnetosonic wave (proton beam, ion differential streaming) and (4) whistler-mode and lower-hybrid wave (core–halo drift, electron heat flux). The quasilinear evolution of these wave instabilities, let alone their nonlinear evolution or possible saturation, and the associated spatial evolution of the VDFs in the nonuniform interplanetary medium have not yet been explored.

Solar Wind: Magnetic Field

The 'heliosphere' is the region surrounding the Sun that contains material and magnetic fields carried away from the Sun by the SOLAR WIND. It extends from the Sun, to the orbit of Pluto and out to the boundary of the solar wind with the interstellar medium. The 'heliospheric magnetic field' is the magnetic field that pervades the heliosphere. The 'interplanetary magnetic field' is that part of the heliospheric magnetic field which occupies the region between the planets, near to the ECLIPTIC plane.

The heliospheric magnetic field has been measured directly by instruments carried on several spacecraft which explored the region from 0.3 AU to beyond 65 AU (1 AU is the distance from the Sun to Earth). The heliospheric magnetic field has also been measured over a range of solar latitudes from $\approx 80^\circ$ S to $\approx 80^\circ$N in the region between 1 AU and 5 AU.

The magnetic field and the velocity of a fluid are vector fields, specifying a vector at each point in the region of interest. At a given instant, a vector field has a direction and a magnitude (magnetic field strength and speed respectively) at each point of the region. The direction of the vector field at any point is specified by two angles relative to a coordinate system whose origin is at that point. The location of a point in the heliosphere (e.g. a spacecraft position) is specified by another coordinate system, whose origin is at the center of the Sun.

When one places a piece of paper with a thin layer of iron filings on top of a bar magnetic, each filing lines up with the direction of the magnetic field at the filing's location. One can see a pattern in the set of iron filings, an imaginary set of curves that reveals a dipole pattern for the magnetic field lines.

Parker spiral

E N PARKER introduced a model for the basic structure of the heliospheric magnetic field based on the following assumptions:

(a) The solar wind moves radially away from the Sun at a constant speed V.
(b) The Sun rotates at an angular speed Ω, given by 2π divided by the solar rotation period.
(c) The solar wind is azimuthally symmetric about the solar rotation axis.
(d) The interplanetary magnetic field is frozen-in the solar wind and anchored at the Sun. This means that the solar wind, which flows radially relative to an inertial frame, flows along the magnetic field lines when viewed from the rotating Sun.

Consider a point in the heliosphere given by the coordinates R (the radial distance from the Sun), θ (the elevation angle above the solar equatorial plane) and ϕ (the azimuthal angle) in a Sun-centered coordinate system. At that point one can define a local coordinate system with unit basis vectors $\boldsymbol{r}$, θ, ϕ pointing in the radial direction, the meridional direction and the azimuthal direction respectively. Parker showed that, for a stationary magnetic field, the components of the magnetic field along these directions are given by the following expressions:

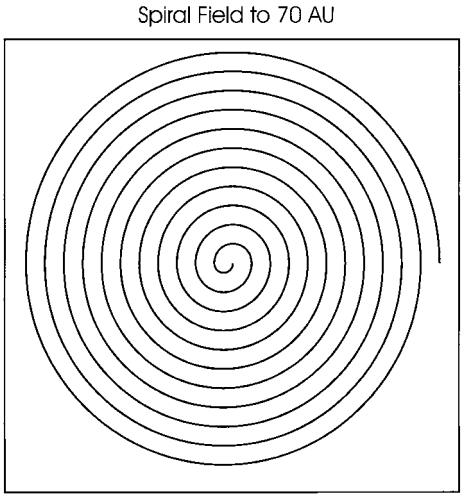

Figure 1. A spiral magnetic field line from the Sun to 70 AU according to Parker's model of the interplanetary magnetic field.

$$B_r(R,\theta,\phi) = B_r(R_1,\theta,\phi - R\Omega/V)(R_1/R)^2 \quad (1)$$

$$B_\theta(R,\theta,\phi) = 0 \quad (2)$$

$$B_\phi(R,\theta,\phi) = B_r(R_1,\theta,\phi - R\Omega/V)(R_1\Omega/V)(R_1/R)\cos\theta. \quad (3)$$

Here R_1 is a reference radius (typically either 1 AU or a few solar radii), and B_r is related to the strength of the magnetic field near the Sun. Thus, the radial component of $\boldsymbol{B}$ decreases as R^{-2}, the azimuthal component decreases as R^{-1}, and the meridional component is zero.

From the components of the magnetic field vector given above, one can calculate that a magnetic field line in the solar equatorial plane has the form of an Archimedes spiral, which is the shape of a rope coiled around itself on a surface. This is illustrated in figure 1 for a magnetic field line extending from the Sun to 70 AU in the solar equatorial plane. The angle between the magnetic field and the radial direction in the equatorial plane is determined by $\arctan(B_\varphi/B_r)$. Near the Sun, the heliospheric magnetic field is approximately radial. At the orbit of Earth (1 AU) the magnetic field line makes an angle of 45° with the radial direction. Far from the Sun the spiral is tightly wound and the magnetic field is nearly orthogonal to the radial direction. A magnetic field line at a heliographic latitude θ has the form of a spiral wrapped on a cone whose axis is the solar rotation axis and whose angular half-width is $90^\circ - \theta$. Over the poles of the Sun, $B_\phi \ll B_r$, unless R becomes very large. The magnetic field wraps around the same degrees of longitude regardless of the latitude.

Observations in the interplanetary medium from the Sun to Pluto and within $\approx \pm 30^\circ$ of the ecliptic have confirmed the spiral pattern predicted by Parker.

However, the observations by the Ulysses spacecraft (which surveyed latitudes between $\pm 80^\circ$ at relatively low levels of solar activity) suggest that the magnetic field lines might not be wrapped on cones of constant latitude, but rather extend from the polar regions toward the equatorial regions (see SOLAR WIND: ULYSSES). This model was introduced to explain the observations that (a) the radial component of the magnetic field did not vary with latitude along the trajectory of Ulysses, and (b) energetic particles that were presumably accelerated by shocks at low latitudes and large distances were observed at high latitudes closer to the Sun. The new model should be regarded as preliminary, and its applicability to periods of high solar activity and to large distances remains to be determined.

Sector structure and the heliospheric current sheet

Measurements of the direction of the magnetic field in the solar wind at a point near the orbit of Earth often show the field pointing away from the Sun (positive magnetic polarity) for approximately half a solar rotation and pointing toward the Sun (negative polarity) for the remaining part of the solar rotation. Each interval of uniform (positive or negative) magnetic polarity is called a 'sector', and the magnetic polarity pattern observed during one or more solar rotations is called the 'sector pattern'. The 'two-sector pattern' just described is typically observed during the period of declining solar activity. Near solar minimum, a 'four-sector pattern' is frequently measured during a solar rotation. The four-sector pattern consists of four sectors of alternating positive and negative polarity, each passing the spacecraft in approximately one-quarter solar rotation. Since the solar rotation period is approximately 27 days as seen by a spacecraft near the orbit of Earth, the duration of a sector is approximately 14 days and 7 days for a two-sector and four-sector pattern respectively. Near solar maximum the polarity pattern of the magnetic field is complex, and a sector pattern is not always present.

Assuming that the solar wind is stationary, the temporal pattern of magnetic polarities observed at a given location during a solar rotation is equivalent to a spatial pattern of magnetic polarities. Figure 2 illustrates the spatial configuration of a four-sector pattern. Each sector is a region of uniform polarity in the ecliptic plane (the plane in which the planets move), extending from the Sun to at least the orbit of Earth and bounded by Archimedes spirals. Thus, each sector in the ecliptic is topologically equivalent to the shape of a piece of a pie, hence the name sector.

The origin of the sector pattern is ultimately related to the large-scale pattern of the magnetic field at the Sun. The two-sector pattern is related to a dipolar magnetic field configuration and the four-sector pattern is related to a quadrupole component. Consider the singular case of a magnetic dipole whose axis is exactly along the solar rotation axis. The solar wind draws the field lines of the dipole into spiral field lines, but the polarity of the field

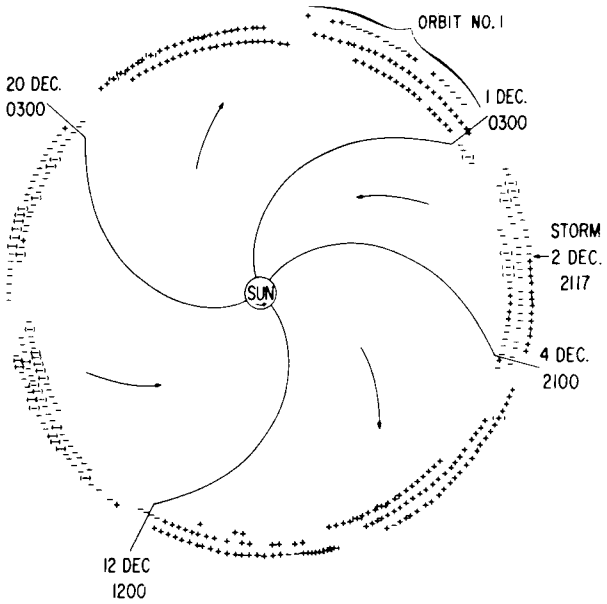

Figure 2. The four-sector pattern of the polarity of the interplanetary magnetic field.

lines is preserved in this process. Consider a SOLAR CYCLE for which the magnetic fields in the northern hemisphere have positive magnetic polarity. Then the heliospheric magnetic fields above the solar equatorial plane would have positive magnetic polarity and those below the solar equatorial plane would have negative polarity. The solar equatorial plane in this idealization is a singular surface at which the magnetic field strength is zero and across which the magnetic field polarity changes.

The Sun's rotation axis is tilted 7.5° with respect to the ecliptic, so that the solar equatorial plane is inclined relative to the ecliptic plane. Since the solar equatorial plane rotates with the Sun, an observer in the ecliptic plane will be below the solar equatorial plane for half a solar rotation and above it during the second half of the solar rotation. When the dipole axis coincides with the rotation axis, an observer in the ecliptic will alternately observe positive and negative magnetic polarities; he will measure a two-sector pattern. An observer located at heliographic latitudes $>7.5^\circ$ or $<-7.5^\circ$ would observe a uniform magnetic polarity. The sector structure would not be observed above or below the zone within $\pm 7.5^\circ$ of the solar equator, the 'sector zone'.

A second model for the sector pattern was discussed in the early literature on sectors. In this model, the sectors extend from pole to pole, like the pieces of an orange. According to this model, an observer would see a sector pattern at all latitudes.

In both models described above, the sectors are bounded by surfaces, which are planes in the region near the Sun. In the dipole model, the plane is the solar equatorial plane. In the orange model, the plane passes

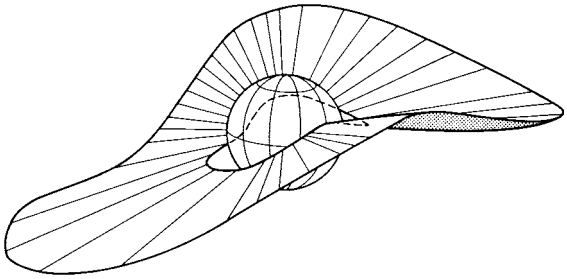

Figure 3. The shape of the heliospheric current sheet in the region within several solar radii of the Sun.

through the dipole axis. Obviously, these two models are diametrically opposed and mutually exclusive.

A third model of the heliospheric sector structure, which avoids the extreme and singular assumptions of the two models described above while retaining some features of each, was proposed many years ago. This model focuses on the form of the surface separating the positive and negative sectors, the 'heliospheric current sheet' or 'HCS'. According to this 'HCS model' the structure of the HCS can vary with the phase of the solar cycle. Near solar minimum and close to the Sun, the surface is approximately a plane that is basically the equatorial plane of the solar magnetic dipole. However, the surface can be distorted by an additional quadrupole component of the solar magnetic field such that it has folds near the Sun (figure 3). A four-sector pattern (see figure 2) can be produced by such a warped surface. The northern and southern extent of the sector pattern can exceed 7.5° when the dipole axis is tilted with respect to the solar rotation axis and when the quadrupole distortion of the HCS is large. The northern extent can differ from the southern extent; i.e. an asymmetry in the sector pattern can also be produced by quadrupole components of the solar magnetic field.

The heliospheric current sheet model has been confirmed by measurements at various latitudes. When a spacecraft is at sufficiently high latitude during the period of decreasing solar activity and near solar minimum, it will observe a single magnetic polarity, while a spacecraft in the sector zone at lower latitudes will observe a sector pattern at the same time. This result has been demonstrated by observations from HELIOS 1 and 2, PIONEER 11, VOYAGER 1 and 2, and Ulysses. For example, figure 4 shows a situation in which Voyager 1 was above the sector zone and Voyager 2 was in it. Voyager 1 observed a single magnetic polarity above the sector zone, while Voyager 2 observed both positive and negative magnetic polarities within the sector zone. This figure illustrates a hypothetical meridional cross section of the HCS, which appears as a wavy line. In reality periodic crossings of the HCS are not observed at large distances, owing to dynamical interactions in the outer heliosphere that distort the HCS. However, the latitudinal extent of the HCS, marked by the dotted lines in figure 4, does not change greatly with increasing distance, since the solar wind expansion is approximately

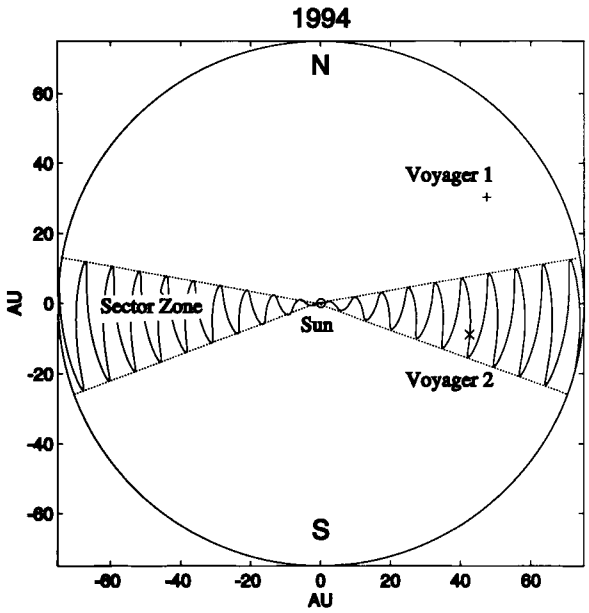

Figure 4. The sector zone illustrated here is the region in which both positive and negative polarity regions (sectors) are observed, not necessarily periodically as suggested in the idealized sketch here. Above the sector zone the polarity is positive (negative), and below the sector zone the polarity is negative (positive).

radial. Thus, the sector zone is well defined even when a periodicity of the sector pattern is not observed.

The foot-points of the heliospheric current sheet on an imaginary surface centered on the Sun and with a radius of a few solar radii (the 'source surface') can be calculated by extending the measurements of the photospheric field to the source surface. There are various ways to do this, but the simplest procedure assumes that the magnetic field is radial on a spherical source surface, and that there are no electric currents in the region between the photosphere and the source surface. Then one can use the photospheric magnetic field measurements to calculate a curve on this surface where the magnetic polarity changes from positive to negative. This curve is called the 'neutral line', and it corresponds to the foot-points of the HCS on the source surface.

Solar cycle dependence

Magnetic field strength

The strength of the interplanetary magnetic field varies with the solar activity, being weakest near solar minimum and strongest near solar maximum. This is illustrated in figure 5. The middle panel of figure 5 shows the SUNSPOT number, which is a measure of solar activity, as a function of time from 1977 to 1996. The bottom panel of figure 5 shows yearly averages of the magnetic field strength measured by spacecraft at 1 AU as a function of time. The magnetic field strength varies approximately sinusoidally (as illustrated by the dashed curve), from

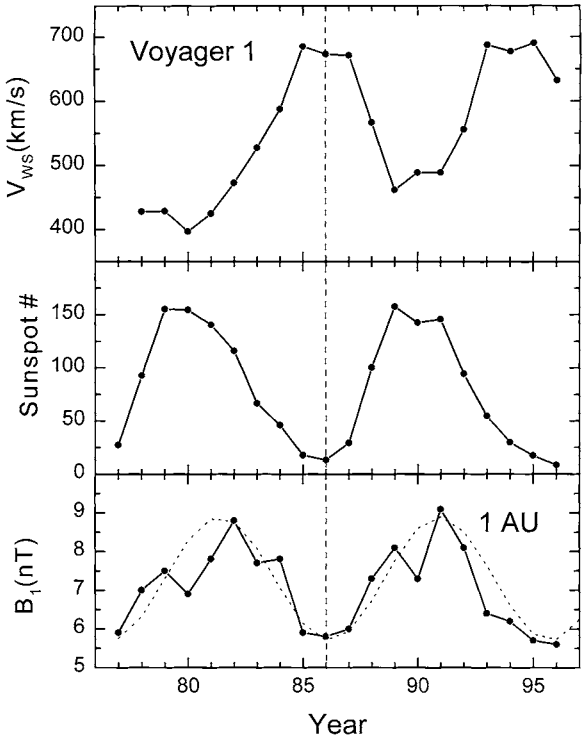

Figure 5. The Sunspot number versus time (middle panel) illustrating the solar activity cycle. The magnetic field strength at 1 AU (bottom panel), which is a measure of the solar magnetic field strength, varies with the solar activity cycle. The estimated solar wind speed along the trajectory of Voyager 1 (top panel) also shows a solar cycle variation.

≈6 nT near solar minimum to ≈9 nT near solar maximum. Thus, the strength of the magnetic field varies by 50% relative to its minimum value during the course of the solar cycle.

The solar cycle variation of the heliospheric magnetic field could be a consequence of two factors. First the quasi-stationary, large-scale magnetic field (e.g. the dipole and quadrupole components) might vary with solar activity. Second, transient ejecta have relatively strong magnetic fields and are more frequent when the Sun is more active, so that they will contribute to the variation in the magnetic field strength over the solar cycle.

Sector structure

Both the calculations based on the source surface model and the *in situ* observations show that the amplitude of the excursions of the neutral line on the source surface, and hence that of the HCS, increase with solar activity. Near solar minimum, the HCS is close to the solar equatorial plane. The maximum deviation of the HCS from the equatorial plane increases as solar activity increases. In other words, the width of the sector zone increases with increasing solar activity.

The sectors and the sector structure are less well defined and less persistent when solar activity is more intense. Intrusions of 'foreign' magnetic polarity are produced by ejecta from the Sun, which are associated with dynamical solar processes such as SOLAR FLARES and CORONAL MASS EJECTIONS. For example, there are often regions of negative polarity in positive sectors when the Sun is active, often making it difficult to identify a given sector or sector boundary. Nevertheless, an observer in the sector zone will typically measure a polarity distribution with two distinct peaks corresponding to positive and negative polarities at the spiral field directions even when the Sun is active.

Two possible sources for the magnetic fields in the sectors were considered in the early literature: (*a*) compact local sources (nozzles) and (*b*) the entire surface of the Sun. It is now known that the truth is somewhere between these extremes. The quasi-steady streams of uniform magnetic polarity, which often fill most of the heliosphere, originate in CORONAL HOLES, which are regions where the magnetic field lines are open to the heliosphere and the density is low. The coronal holes do not occupy the entire surface of the Sun, and the fraction of the solar surface that they occupy decreases with increasing solar activity. However, coronal holes do cover the polar caps during most of the solar cycle, they can extend from the polar regions to the equatorial regions over a limited range of longitudes in each hemisphere, and isolated coronal holes are occasionally observed near the solar equator. The origin of the magnetic field lines in the slow solar wind is not completely understood.

Elevation angles of $\boldsymbol{B}$

The elevation angle $\delta = \arctan[B_\theta/(B_r^2+B_\phi^2)^{1/2}]$ is the angle between the magnetic field vector and its projection on the $\boldsymbol{r}-\varphi$ plane. For a spacecraft in the solar equatorial plane, δ is the elevation angle of the magnetic field with respect to that plane, positive for a northward directed magnetic field. According to Parker's model, $\delta = 0$ at all latitudes because $B_\theta = 0$. However, there are always fluctuations in the magnetic field direction. The elevation angles of $\boldsymbol{B}$ have a Gaussian distribution, but the average and the most probable values of the distribution are zero at any epoch of the solar cycle.

Transient ejecta from the Sun carry magnetic fields whose configuration is not that of a Parker spiral. There is a class of ejecta called magnetic clouds for which the magnetic field direction rotates smoothly through a large angle, and in many cases the rotation tends to be from either south to north or vice versa. For most ejecta, the magnetic field configuration is more complex, but there is generally a relatively large meridional component B_θ of the magnetic field. When the Sun is active, there are many ejecta in the heliosphere and the distribution of elevation angles is relatively broad. The width of the distribution of elevation angles varies with the solar cycle, being smallest at solar minimum and largest at solar maximum. It is likely that this variation is primarily the result of a solar cycle variation in the frequency with which ejecta leave the Sun.

Magnetic field strength

Parker's model

According to Parker's model, the strength B of the magnetic field at any point in the heliosphere should be the square root of the sum of the squares of the components of $\boldsymbol{B}$ given by equations (1) to (3) above. Thus, Parker's model can be used to describe the large-scale heliospheric magnetic field strength to lowest order. In this case, one considers averages of the magnetic field over one or more solar rotations, and the ϕ dependence drops out of the equations. The source-field strength might change with both the time t throughout the solar cycle and the heliographic latitude θ. Similarly, the solar wind speed V changes with time t and θ. Thus, according to Parker's model, the strength of the magnetic field varies as

$$B_p(R,t,\theta) = B_{r1}(t,\theta)R^{-2}[1 + (419.5R\cos(\theta)/V(t,\theta))^2]^{1/2} \quad (4)$$

when the rotation period of the Sun is assumed to be 26 days independent of latitude, and the units of θ, V and R are degrees, km s^{-1} and AU respectively. Here, the factor $B_{r1}(t,\theta)$ is the radial component of the magnetic field at 1 AU as a function of θ and time, which we measure in units of a year. The first term in the brackets on the right-hand side of (4) is from the radial component of the magnetic field, which decreases as R^{-2}, and the second term is from the tangential component B_ϕ, which varies as R^{-1}.

Since the Ulysses data indicate no latitude dependence of the radial component of the magnetic field during the high-latitude passes, we shall assume that there is no latitude dependence in the source term at all phases of the solar cycle, i.e. we take $B_{r1}(t,\theta) = B_{r1}(t)$. From (4) with $R = 1$ and $\theta = 0$ we obtain $B_{r1} = B_1(t)\alpha(t)$, where $\alpha(t) \equiv [1+(419.5/V_1(t))^2]^{-1/2}$. $V_1(t)$ and $B_1(t)$ are the speed and magnetic field strength respectively, measured at 1 AU over the course of a solar cycle. Thus, in the absence of a latitude dependence of B_{r1}, Parker's equation (4) becomes

$$B_p(R,t,\theta) = \{B_1(t)[1 + (419.5/V_1(t))^2]^{-1/2}\} \times R^{-2}[1 + (419.5R\cos(\theta)/V(t,\theta))^2]^{1/2}. \quad (5)$$

Note that (5) has no free parameters, since $B_1(t)$, $V_1(t)$ and $V(t,\theta)$ can be determined from measurements, as discussed below.

Beyond a few AU, (5) has the simple form

$$B_p(R,t,\theta) = B_1(t)\alpha R(t)^{-1}\cos(\theta)(419.5/V(t,\theta)). \quad (6)$$

In particular, beyond 5 AU the difference between (6) and (5) is only 2% at $\theta = 0$. This means that beyond several AU the radial component of the magnetic field is negligible and the magnetic field strength is determined by the azimuthal component of the field. The magnetic field strength would vary with heliocentric distance as R^{-1}, if all other factors were constant. In general, however, the magnetic field strength at a spacecraft such as Voyager 1 will vary with time t (in particular, with the solar cycle) and with θ, because it is proportional to the source term $B_1(t)$ and inversely proportional to the solar wind speed $V(t,\theta)$ at the spacecraft.

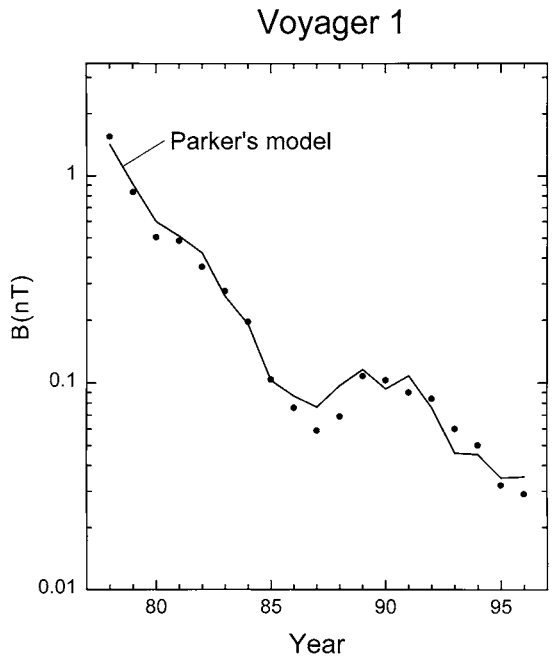

Figure 6. The variation of the heliospheric field strength measured by Voyager 1 (full circles) between 3 AU and 65 AU from 1978 to 1996 is described by Parker's model (solid curve).

The results for B_p presented in the following paragraph are based on equation (5), but essentially the same results were obtained from (6) with $\alpha = 0.72 \pm 0.02$. This value of α is obtained with $\langle V1\rangle = 446 \pm 32$ km s^{-1} which is computed using measurements of speed at 1 AU from 1978 through 1996. The value $\alpha = 0.72$ is consistent with a spiral angle of 45° at 1 AU. The small uncertainty in α indicates that it is not sensitive to variations of $V_1(t)$, which is why (6) is an excellent approximation to (5).

Measurements of the variation of the magnetic field strength by Voyager 1 as it moved from ≈3 AU to ≈65 AU are shown in figure 6. The measurements were made from 1978 to 1996. If the magnetic field strength at 1 AU did not vary with the solar cycle, and if the speed were constant with time and latitude, then one would expect from (6) that B would decrease monotonically with increasing time as the spacecraft moved away from the Sun. The bottom panel of figure 5 shows that the magnetic field at 1 AU does vary with the solar cycle. The top panel of figure 5 shows that the speed at Voyager 1 also varied with time, as a result of the increasing latitude of the spacecraft and the solar cycle variation of the speed. When these variations are considered, Parker's model (6) predicts the result shown by the solid curve in figure 6. Parker's model, which was introduced 40 years ago, provides an explanation for the observed magnetic field strength out to at least 60 AU.

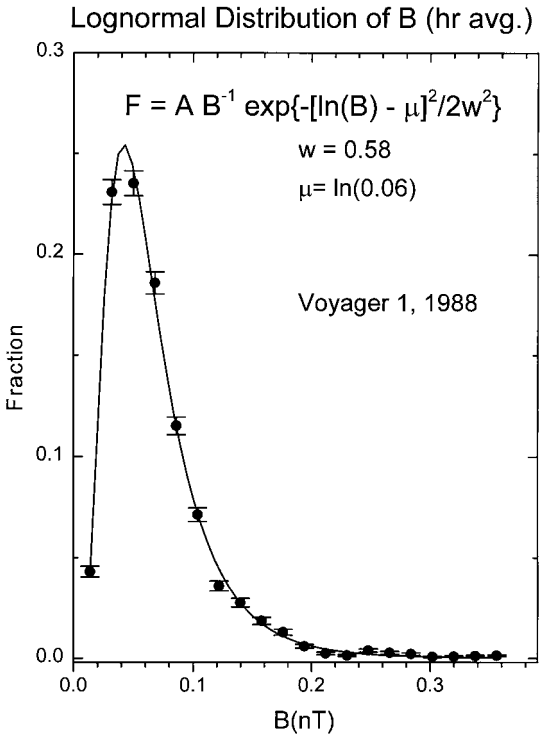

Figure 7. The distribution of hour averages of the magnetic field strength (full circles) is generally a log-normal distribution (solid curve).

Magnetic field strength fluctuations

The heliospheric magnetic field strength is highly variable over a large range of scales. To a first approximation the distribution of hour averages of the magnetic field strengths observed during a given year is log-normal, i.e. the distribution of $\ln B$ is a normal distribution. This result is illustrated for the distribution of hour averages measured by Voyager 1 during 1988, shown in figure 7, where the points are the observations and the curve is a best fit to a log-normal distribution. A log-normal distribution of B implies that relatively strong magnetic fields are observed far more frequently than one would expect for a normal distribution. The strongest magnetic fields are produced by the compressions of the front of streams, by shocks and by the ejection of plasmas carrying strong fields from solar disturbances. Log-normal distributions of the hour averages of B have been observed from 1 AU to 65 AU, from -20° to 30° in heliographic latitude, and at all phases of the solar cycle. The variance of the log-normal distribution of B relative to the mean magnetic field for a given year tends to be constant, independent of solar activity and position in the heliosphere. This means that near solar maximum, when the heliospheric magnetic field strength tends to be high, the variance in the log-normal distribution of B is also high. It implies that the intervals with the strongest magnetic fields occur near solar maximum, when transient ejecta are most abundant and when departures of the elevation angle of the magnetic field from Parker's model are greatest.

The distribution of magnetic field strength generally shows a scaling symmetry that is described by a multifractal distribution over a large range of scales. This means that the magnetic field strength has a fractal pattern in various parts of the structures carried by the solar wind, but the fractal dimension can vary within these structures. The situation is analogous to a landscape containing mountains and river basins. The fluctuations in altitude can vary greatly from place to place, much more so than one would expect from a Gaussian distribution of elevations such as one sees on the surface of a lake. Yet the shape of some large regions resembles the shape of smaller regions, etc. The dynamical causes for these invariant properties of the magnetic field strength distributions throughout the heliosphere are not yet known.

Solar Wind: Manifestations of Solar Activity

The Sun's outer atmosphere, the corona, is continually heated and expands to create the solar wind. Solar activity waxes and wanes with the 11 yr cycle of the Sun's magnetic field, and these activity changes also affect the solar wind. The brightest structures in the corona are a bright belt of streamers, the source of the slowest solar wind. These streamers are occasionally disrupted as coronal mass ejections (CMEs) which spew large amounts of gas and magnetic fields into the solar wind. CMEs appear to be a fundamental way in which the Sun loses mass and releases the magnetic flux and field twist built up during the cycle.

The solar magnetic field and the solar wind

The Sun's magnetic field controls much of its surface activity which evolves with an 11 yr period. The field tends to simplify with height in the corona, but the corona, and its outward expansion as the solar wind, also evolves on time scales related to the evolution of the surface field. The simplest magnetic configuration of the Sun occurs during activity minimum. At this time the Sun's magnetic field can be approximated as a dipole whose axis is tilted slightly with respect to the axis of rotation. Large CORONAL HOLES cover the Sun's polar regions and extend toward the equator. These open-field regions are of opposite magnetic polarity. The polar holes are separated by a wide band centered over the heliomagnetic equator within which lie the magnetically closed structures near the surface, i.e. active regions and sunspots. CORONAL STREAMERS extend over these regions forming a bright band around the Sun. The high-speed wind flowing from the polar holes constricts the oppositely directed fields over the streamers to a narrow current sheet which has the appearance of a ballerina's skirt (figure 1). This rotating, warped heliospheric current sheet (HCS) appears as a sector boundary crossing at Earth, such that during one solar rotation the Earth will be immersed in a minimum of two large sectors of opposite polarity each with the relatively high-speed wind of its parent hole. During the solar cycle new magnetic flux emerges at higher solar latitudes leading to a more complex and disturbed corona. The streamer belt and heliomagnetic equator become more complicated and more inclined to the rotation axis, and the magnetic sector structure observed in the solar wind is more chaotic. Near maximum activity a simple, single current sheet surrounding the Sun may not even exist.

On a global scale the slow solar wind is confined to the streamer belt and the HCS (see SOLAR WIND: GLOBAL PROPERTIES). It now appears that this band is the source of most transient activity which affects the heliosphere, except possibly near sunspot maximum. Near the solar surface most activity occurs on smaller scales within regions of strong magnetic fields (see ACTIVE REGIONS) in the form of flares and active region loop expansions. However, in the corona the most rapid, dramatic and energetic form of evolution occurs in large events called CMEs. Most CMEs tend to cluster within $\sim 30^\circ$ of the coronal base of the HCS over the cycle. Thus, there is a close relationship among coronal streamers, the HCS and CMEs and their evolution. Since CMEs dominate the transient activity in the solar wind, they are the focus of this article.

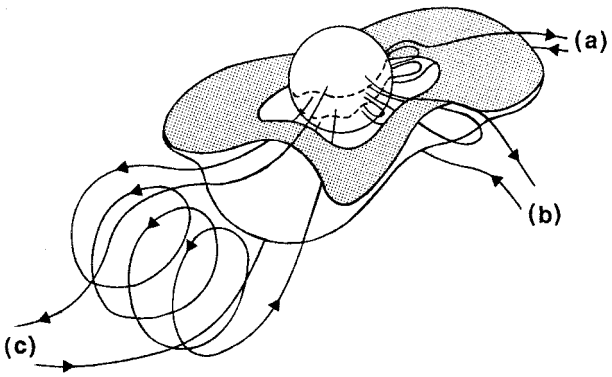

Figure 1. Schematic model of the coronal streamer belt as a disk of variable thickness forming a conduit for transient outflow from (*a*) steady-state helmet streamers, (*b*) small-scale ejections and (*c*) large-scale CMEs, some with flux rope structure. After Crooker *et al* (1993).

CMEs are immense structures of plasma and magnetic fields that are expelled from the Sun into the heliosphere. As such they are the nearest example on a large scale of the common process of magnetohydrodynamic (MHD) expulsion of material from objects throughout the universe. Although the range of CME speeds is large, even the slowest CMEs (slower than the in-ecliptic solar wind) never fall back to the Sun. This suggests that their internal magnetic fields control the dynamical evolution of CMEs near the Sun. CMEs can cause large geomagnetic storms at Earth and their attendant effects, such as auroral displays. Faster CMEs drive transient interplanetary shocks, which in turn can accelerate solar energetic particle (SEP) events. At the Sun the onset of CMEs can be associated with both flares and filament eruptions, but most flares occur without CMEs and some CMEs cannot be associated with any surface activity. Other articles discussing the origins and early evolution of CMEs are SOLAR CORONAL MASS EJECTION: OBSERVATIONS, SOLAR CORONAL MASS EJECTION: THEORY, SOLAR PROMINENCE ERUPTION and SOLAR FLARES: RELATION TO CORONAL MASS EJECTIONS.

CMEs near the Sun

CMEs are best viewed in white light from space-borne coronagraphs; these reveal that, even near the Sun, a CME can dwarf the solar disk. CMEs often appear to have a bright leading looplike structure followed by a dark cavity and a bright core of denser material, suggesting the eruption of a pre-existing prominence, its overlying coronal cavity and the ambient corona (figure 2). Prominences are elongated regions of dense, cooler

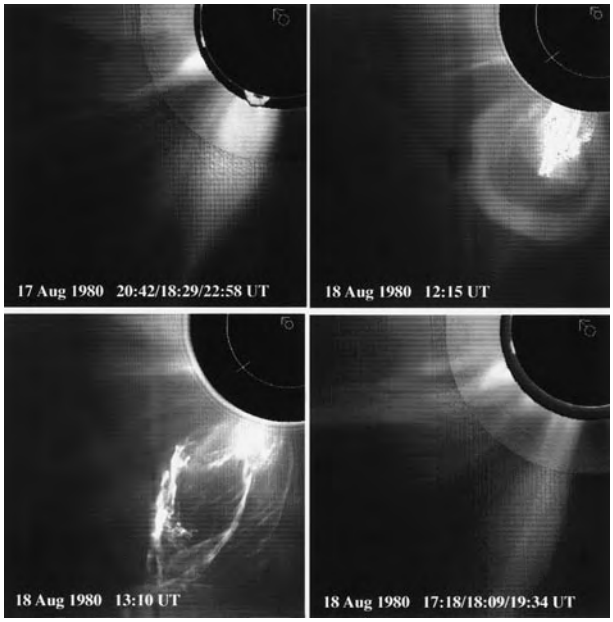

Figure 2. A CME and prominence eruption on 17–18 August 1980. The first and fourth panels are composites of an Hα (inner) image from Mauna Loa Observatory showing the prominence, an MLO K-coronameter image of the mid white light corona from 1.2 to 1.8 solar radii, and a solar maximum mission (SMM) coronagraph image of the white light corona from 2 to 5 solar radii. The second and third panels show only SMM data. The inner circle on each panel marks the solar limb and the arrow points to solar north. From Hundhausen (1997).

material suspended in the low corona in helical magnetic fields (see SOLAR PROMINENCE MODELS). Large prominences are surrounded by dark voids called cavities which have less coronal material but may be shaped by strong, helical magnetic fields (discussed later). There is a large range in the basic properties of CMEs. Their speeds, masses and energies range over 2–3 orders of magnitude, and their widths exceed by factors of 3–10 the sizes of flares and active regions. Occurrence rates of CMEs vary in phase and amplitude with the sunspot cycle.

CMEs arise in large-scale, closed structures, such as coronal streamers, where the magnetic field is strong enough to prevent the plasma from expanding outward. The temporal and latitudinal distributions of streamers and prominences are similar to those of CMEs, being confined to low latitudes about the current sheet near sunspot minimum and becoming broadly distributed near maximum. This evolution is very different from that of active regions, flares or sunspots, which migrate from mid to low latitudes during the solar cycle. Many energetic CMEs result from the disruption of a pre-existing streamer, which increases in brightness and size for days before erupting as a CME (figure 2). Possible causes of such disruptions include the emergence through the surface of new magnetic flux, the dynamical evolution of arcades and the shearing of field lines.

Signatures of CMEs in the solar wind

The CME's plasma is entrained on magnetic field lines and transported into the solar wind, where it can be detected by remotely measuring the plasma along the line of sight or by measuring directly its properties as the material passes over a spacecraft. CME plasma in the solar wind has been remotely detected by white light photometers on the Helios spacecraft and by measurements of interplanetary scintillation (IPS) of galactic radio sources from the ground.

The two Helios spacecraft were placed into highly elliptical solar orbits ranging from 0.3 to 1 AU from the Sun and operated from 1974 to 1983. The on-board photometers were able to produce crude images of $\approx$200 CMEs out to the orbit of Earth. The occurrence rates, widths and speeds of these CMEs were consistent with those of the coronagraph observations within 30° of the Sun. In these views of CMEs in the inner heliosphere, the CMEs are obviously expanding but otherwise their shapes are unchanged, with two brighter 'legs' behind and flanking a tenuous leading front. The interplanetary (IP) masses and energies of the Helios CMEs were factors of 2–10 higher than those determined by the earlier coronagraphs. However, the more sensitive measurements from the SOHO LASCO coronagraphs now indicate that mass flows out of the corona behind the leading edges of CMEs for a prolonged period of time, yielding higher masses consistent with the Helios observations. CMEs can contribute a sizable fraction of the total mass and energy flux of the solar wind, especially at solar maximum and in or near the ecliptic. The mass contribution ranges from a few percent at minimum to possibly as much as 40% at maximum.

The IPS technique detects transient disturbances in the solar wind as enhanced scintillation of distant astronomical sources in the sky along the line of sight. The scintillation is caused by small-scale turbulence in the wind due to the enhanced density of a transient such as a CME. By observing daily changes in the scintillation of a large number of sources distributed over the sky, crude maps of IP transients can be produced. A related technique involves the tracking and analysis of signals from deep-space spacecraft such as Pioneer Venus, Ulysses and Galileo as the extended solar corona transits between the spacecraft and the Earth. This technique is particularly sensitive to the enhanced density and density fluctuations in the compressed plasma between a CME and a shock if there is one and in the CME itself. However, these techniques have poor spatial and/or temporal coverage and are most useful when combined with other data sets on a particular event.

Most of our understanding of CMEs in the solar wind has come from direct measurements of the plasma and magnetic fields as the CME material passes over a spacecraft which is situated outside of the Earth's magnetosphere. A variety of signatures have been proposed as identifiers of CME ejecta in the solar wind. Table 1 summarizes those signatures which

Table 1. Signatures of CMEs in the solar wind.

Transient interplanetary shock waves
He abundance enhancements
Unusual ionization states (e.g. He^+)
Brief density enhancements and longer-duration density decreases
Proton and electron temperature depressions
Bidirectional field-aligned flows of halo electrons and/or low-energy protons
Magnetic field variations usually associated with magnetic 'clouds' or flux ropes:
Strong magnetic field
Smooth field rotation
Low plasma β
Low field strength variance

are different from the normal solar wind and usually observed for at least several hours. These include shock waves, density changes, depressed temperatures, flows with enhanced helium abundances and magnetic field structures consistent with looplike topologies. Although the front and sides of a CME are visible near the Sun because they are denser than the ambient solar wind, expansion of the CME can yield lower than average densities further from the Sun. Many of these signatures were first identified in the plasma which followed an IP shock by several hours and was considered to be the piston (CME) driving the shock (see figure 3). Some signatures can also be observed elsewhere in the solar wind where they may identify relatively slower CMEs not driving shocks.

More sensitive instruments show that the abundances and charge state compositions of elements and ions are systematically different in CME flows as compared with other kinds of solar wind (see SOLAR WIND COMPOSITION). As the solar wind–corona expands outward from the Sun, the electron density decreases so rapidly that the plasma becomes collisionless and the relative ionization states become constant, thus reflecting the conditions in the corona where this occurs. The charge states of so-called 'minor ions' ($Z > 2$) in CME flows usually suggest slightly hotter than normal coronal conditions at their origin (i.e. >2 MK). However, mixtures of charge states and, therefore, ionization temperatures are also found. In addition, transient flows often exhibit element and ion abundances (especially He and Fe) that are enhanced relative to the nominal solar wind. The coronal composition of transient flows are also seen in the systematic enhancement of elements with low first ionization potentials (FIPs) (see TRANSITION REGION: FIP EFFECT). Abundances of elements with FIPs <10 eV are enhanced by a factor of ∼4 relative to those high-FIP elements, an effect which is typical of coronal, not photospheric material. Finally, the Ulysses spacecraft (see SOLAR WIND: ULYSSES) showed not only that is there a latitude dependence on the speed of IP CMEs but also that their compositional dependence is different. The He and minor

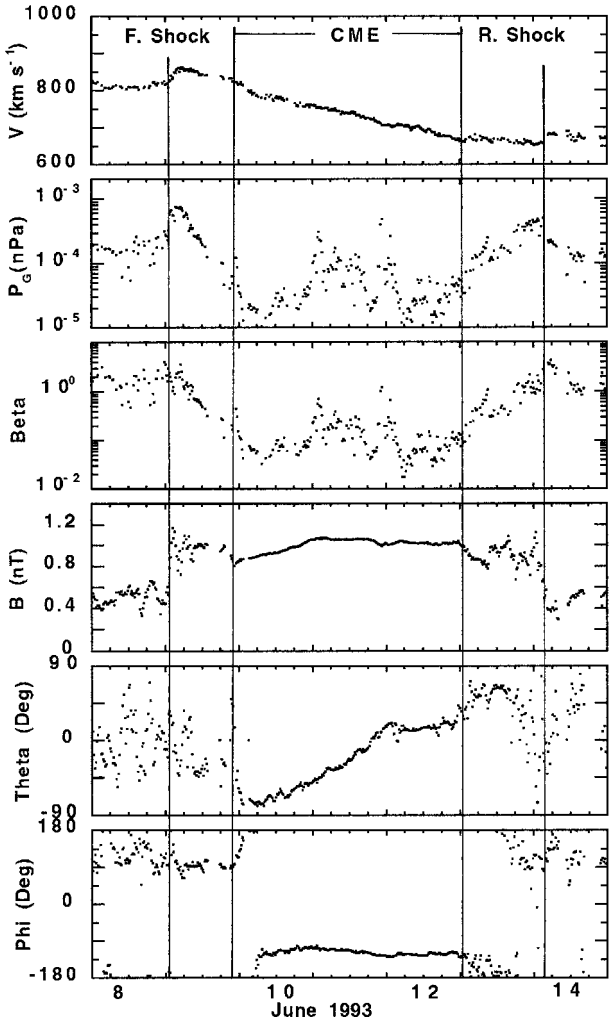

Figure 3. Ulysses plasma and magnetic field observations of an expanding CME–magnetic flux rope in the solar wind. From top to bottom the parameters plotted are bulk flow speed, plasma pressure (ions plus electrons), plasma β, magnetic field strength, field polar angle and field azimuthal angle. The bar marked 'CME' defines the region of bidirectional electron streaming. Ulysses was at 4.6 AU from the Sun and at a heliographic latitude of S33°. From Gosling (1996).

ion abundances and charge states become more and more similar to coronal hole flows the higher the ecliptic latitude.

Infrequently, unusually low ionization states of He and minor ions such as O, Fe and C are detected in CME flows. Although rarely observed before this decade, enhanced He^+ flows have been detected in at least four Earth-directed CMEs with the SOHO and WIND spacecraft during 1997–1998. In each of these events an erupting filament–CME could be associated with an unusually dense and narrow 'plug' of cool plasma at WIND in the trailing edge of a magnetic cloud. It is likely that such material is the solar wind signature of the filament itself and, therefore, is chromospheric in origin.

Although the speeds of the leading edges of CMEs near the Sun exhibit a wide range from ∼50 to >2000 km s^{-1}, the average speed is slightly less than the typical solar wind speed in the ecliptic. The speeds of most CMEs beyond several solar radii appear constant, indicating that they are rapidly accelerated low in the atmosphere. In the ecliptic within 1 AU of the Sun it appears that the fastest CMEs decelerate as they interact with the slower ambient plasma, while the slowest CMEs are accelerated, possibly by the same forces acting on the normal solar wind. At high heliographic latitudes the speed profiles of CMEs are different. Using bidirectionally streaming events observed at Ulysses as CME proxies, the speeds of high-latitude CMEs (730 km s^{-1} on average) were much higher than in the ecliptic plane and comparable to the surrounding solar wind flow characteristic of polar coronal holes (figure 3). This again suggests that CMEs are accelerated along with the surrounding solar wind.

In a hydrodynamic plasma regime, a dense region moving through a uniform, background flow at a sufficiently faster speed will produce a shock wave which stands out ahead of the driver (see SOLAR WIND SHOCK WAVES AND DISCONTINUITIES). Such shocks are frequently observed throughout the universe, but our detailed understanding of them comes from direct measurements of their properties made in the interplanetary medium and in Earth's bow shock. Within 1 AU of the Sun the strongest shocks are driven by CMEs whose leading edges are often a few hundred km s^{-1} faster than the normal wind speed. A spacecraft sees a forward-moving shock as a discontinuous increase, or jump, in most plasma and magnetic field parameters. In figure 3 a shock at Ulysses is encountered first (left) and stands off from the leading edge of the CME driver by about 20 h. Between the shock and the CME lies a turbulent region where the ambient solar wind plasma and interplanetary magnetic field (IMF) are compressed ahead of the CME. Depending on the signatures used, approximately 1/3–1/2 of all ejecta in the solar wind within 1 AU follow IP shock waves. When these shocks first develop is unclear, but there is evidence that most CMEs moving outward in the low corona with speeds greater than the local Alfvén speed (∼400 km s^{-1}) are associated with coronal shock waves. Coronal shocks are remotely detected as Moreton waves at the surface and metric radio type II bursts in the corona. At heights and densities typical of the solar wind, shocks can be tracked outward at kilometric wavelengths (see SOLAR WIND: INTERPLANETARY RADIO BURSTS).

Simple hydrodynamic model simulations have been successful in reproducing the basic speed and pressure profiles of shocks and CMEs even out to large distances from the Sun. Usually a simple pressure pulse of appropriate duration and amplitude is initiated into a uniform ambient flow with characteristic solar wind parameters. As the front of the faster CME overtakes the slower wind, a strong gradient develops and pressure waves eventually steepen into a forward shock propagating into the ambient wind ahead and, occasionally, a reverse shock that propagates back through the CME towards the source (the Sun). Because of its interaction with the ambient plasma, the CME slows until it eventually 'rides along' at the solar wind speed. This may not occur until several AU from the Sun. A different class of forward–reverse shock pairs was observed by Ulysses at high latitudes. In the event shown in figure 3, the speed declined from the front to the rear of the CME and the pressure was maximum immediately downstream from the shocks. Since the CME was not traveling faster than the solar wind ahead of it, the shocks were not caused by the relative motions between the CME and ambient wind but by expansion of the CME due to its high internal pressure. Simulations show that such features can be reproduced by the ejection of a dense CME into a uniform, high-speed solar wind. Initial propagation pressure waves steepen into shocks at a distance of about 3 AU.

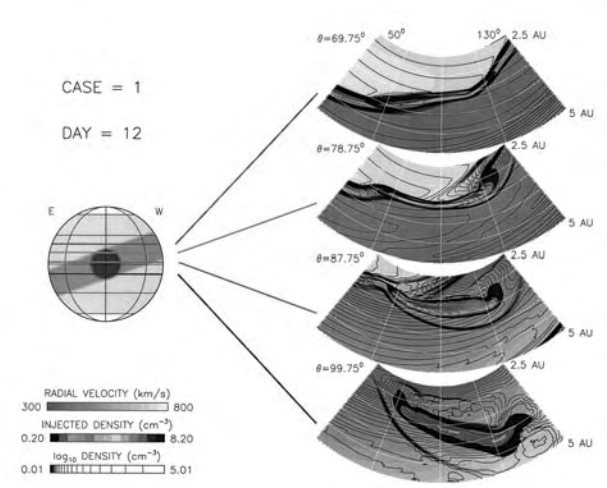

Figure 4. Results of a 3D simulation of a CME moving through a typical ambient solar wind. Here the CME is injected in the center of the HCS–streamer belt (left), specified as a high-density, low-temperature, slow-speed structure tilted to the solar rotation axis. The CME is represented as a 30° wide, 12 h duration pressure pulse. The resulting CME interaction with the solar wind flow is shown as the slices in heliolongitude and at distances 2.5–5 AU from the Sun 12 days after launch. The slices are through four different heliolatitudes and show that the CME's shape, pressure and speed will vary significantly depending on the characteristics of the ambient medium it encounters. Courtesy V Pizzo, NOAA Space Environment Center.

In recent two-dimensional (2D) and 3D hydrodynamic simulations attempts are being made to include more realistic solar wind conditions in which to inject the transient. For example, if an initially large but homogeneous CME is injected into a more realistic, latitudinally inhomogeneous solar wind, it will evolve very differently in the fast and slow wind regimes. Figure 4 demonstrates one such 3D simulation wherein a pressure-pulse CME is injected into a bimodal solar wind which is slow and dense

at low latitudes and fast and tenuous at higher latitudes. The CME extends across the boundary between the two regimes and is distorted into two sections. The parts separate radially owing to the strong velocity shear between the slow and fast ambient wind and latitudinally as a result of pressure gradients associated with rarefaction regions as the CME moves outward. This simulation also incorporates features of the wavy 'ballerina skirt' HCS which adds to the complexity of the interaction in the longitudinal direction. Full 3D MHD simulations using the observed photospheric magnetic field as an inner boundary condition have been successful in replicating gross coronal structure near the Sun, as well as the initiation of transients by shearing of the magnetic footpoints. However, none of these efforts is as yet sufficiently developed to reproduce the complex magnetic and plasma structure of the actual solar wind or the transients that flow through it.

Adding to the complexity of the real solar wind are interactions which occur between the transient flows, including their shock waves, and pre-existing faster or slower flows and the interaction regions bounding them. For example, a fast CME can overtake a slower CME or a fast flow can overtake a slow CME. In the inner heliosphere these interactions produce compound streams. These systems can continue to evolve and merge with other CMEs and shocks as they move outward. Eventually, well beyond the 5 AU orbit of Jupiter, such structures can form what are called merged interaction regions. These regions can become very extensive, sometimes essentially encircling the Sun like a distant belt. Such regions can diminish the flux of high-energy particles which continually stream into the heliosphere, called galactic COSMIC RAYS, causing solar-cycle-dependent decreases in their flux.

Energetic particle events associated with solar activity (SEPs) are also commonly associated with IP shocks (see SOLAR WIND: ENERGETIC PARTICLES). Solar activity produces two classes of SEPs, gradual and impulsive, depending on their energy versus time profiles. About 10 gradual events occur per year near maximum and each can last for several days. Although flares were once considered the source of SEP events, we now know that most of these particles are accelerated directly from the coronal and solar wind population by CME-driven IP shocks. Impulsive events are much more frequent, ∼100 per year near maximum, but last for only a few hours. They are generally much weaker than the gradual events and are only observed in space when a spacecraft or Earth intersects the pre-existing field lines which connect back to the flare–active region site. These are also called ^{3}He-rich events because the ^{3}He/^{4}He ratio in them is much higher than in the normal solar wind. During impulsive events is about the only time we can sample flare material and its associated accelerated particles in the solar wind.

The magnetic field topology of CMEs

Recent research has focused on those solar wind signatures indicative of the topology of the ejected magnetic fields.

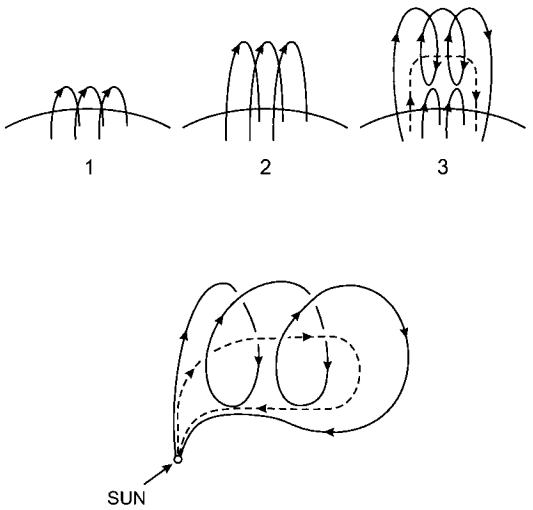

Figure 5. Schematic diagram of a reconnection model of magnetic flux rope formation at the Sun. In the top row from left to right rising, sheared field lines reconnect to form a rising flux rope and a closed arcade at the surface. Bottom: the flux rope structure as it would appear later and further out in the solar wind. Adaptation courtesy of J Gosling.

Most such studies involve observations and modeling of magnetic clouds and bidirectionally streaming particle flows (see below). Magnetic clouds are long-lived solar wind flows having enhanced field strengths which exhibit smooth, coherent rotations. Figure 3 shows an example of such a cloud embedded in an expanding CME; note the strong and smooth magnetic field strength, B, the smooth rotation of the polar field angle, θ and the low plasma β (ratio of plasma to magnetic pressure). Such a structure can be modeled as a force-free flux rope, which is a series of helical field lines, like the coils of a spring (figures $1(c), 5$) with pitch angles increasing towards the outer edge.

Some magnetic clouds have been associated with solar filament disappearances. Since filament plasma is embedded in helical, horizontal magnetic fields, the close association of CMEs with filament eruptions and shearing fields near the surface has led to the modeling of CMEs as flux ropes. One idea is that the interior fields of a rising, sheared CME reconnect, resulting in an ejected flux rope and new, closed coronal loops at the Sun (figure 5). (Magnetic reconnection is a dynamic plasma process whereby field line systems interact, resulting in a change in their topology.) At least 1/3 of all CMEs in the solar wind appear to be flux ropes but this fraction may be higher considering the limited sampling available from a single spacecraft. In several studies magnetic clouds have been found to have the same orientation and polarity as associated erupting filaments at the Sun. Furthermore, larger filaments always have twist in the same sense in a given hemisphere, even though the hemispherical polarity reverses every solar cycle. These suggest that the sign of the magnetic helicity (or sense of twist) of the erupted structure in the solar wind can be predicted from a given

solar filament eruption. Filament eruptions and CMEs may be important ways that the Sun sheds magnetic helicity as well as flux built up over the solar magnetic cycle.

Although CMEs clearly involve the ejection of magnetic fields from the Sun, our understanding of the strength and topology of these structures is poor. Partly this is because instruments such as coronagraphs view the optically thin coronal material in projection against the sky. The circular CME structures we see (figure 2) are likely to be 2D projections of 3D structures such as arcades, flux ropes or shells. A prominence and its associated helmet streamer can be modeled as a dual flux system, one part of which is a flux rope and its surrounding coronal cavity which may help to drive the eruption once the streamer is disrupted. It appears that the prominence itself may be only a small part of this system, lagging the bulk of the CME–flux rope in the solar wind. This seems to be supported by the recent WIND observations.

In the normal solar wind field lines are 'open', i.e. connected to the hot corona at only one end. This results in an outward flux of hot electrons from the Sun streaming along the IMF. Bidirectional flows of these electrons are occasionally observed in which the electrons flow in both directions along the field lines. These are interpreted as evidence that the associated transient field lines are closed with both footpoints connected either to the Sun (a bottle) or to each other (a plasmoid) and, thus, a good proxy for CMEs in the solar wind. Bidirectional proton flows have also been detected, often but not always in association with shocks and ejecta flows. Although both magnetic clouds–flux ropes and bidirectional flows are usually considered good evidence for closed structures and CMEs, it is still difficult to ascertain the field topology of a given structure, i.e. entirely closed (bottle or plasmoid), entirely open or a hybrid (flux rope).

Reconnection of magnetic field lines is thought to be an important energy release and heating process near the surface of the Sun, especially in flares. The disconnection from the Sun of the field lines stretched outward during CMEs and their associated reconnection in the low corona may also be fundamental to the ejection process. In a popular eruptive flare model, field lines stretched open during the eruption of a prominence and CME reconnect near the surface to form a magnetic arcade, accounting for the long-duration optical and x-ray events commonly associated with CMEs (e.g. figure 5). Other observations, such as the ejection of plasmoid-like structures and evidence for newly forming streamers beneath CMEs, support this concept. Some degree of disconnection–reconnection of transient field lines seems necessary to prevent a continual increase of the net IP magnetic flux, which is not observed. For instance, it has been estimated that, in the absence of any reconnection, CMEs should double the field magnitude in the ecliptic every 9 months. There are several ways of alleviating this problem. First, recent LASCO observations suggest that the occurrence of structures within CMEs having a concave outward appearance is much greater than recorded with older, less sensitive coronagraphs. Nearly half of LASCO CMEs show evidence for such features, which are prime candidates for loops disconnecting from the Sun. (However, in some CMEs these structures could be the projection of a rising pre-existing cavity–flux rope in the skyplane which would, therefore, not require reconnection–disconnection.) Second, there are a few observations and a model of outward-moving 'U-shaped' structures suggesting the disconnection of *previously open* field regions at the top of streamers, resulting in the expulsion of a detached structure open to the heliosphere. These might be associated with so-called 'heat flux dropout' events, intervals in the solar wind devoid of the normal halo electron flux. Third, it is evident that the bidirectional streaming signature is not always present throughout all parts of an IP CME, or can be missing entirely from CMEs identified by other signatures such as a magnetic cloud. This suggests that some field lines within the CME may be 'open' in the sense that they do not have both ends connected back to the Sun. Although the CME may begin at the Sun as a pre-existing flux rope connected to the surface at two ends, continual small-scale reconnection associated with the CME may produce a mixture of closed, open and disconnected field lines as it moves through the solar wind.

As mentioned earlier, CMEs tend to arise in coronal streamers which form a belt that encircles the Sun and is the base of the HCS. The HCS is essentially the heliomagnetic equator of the Sun, separating the opposite-polarity fields in the northern and southern hemispheres. A recent model suggests that the base of the HCS may often be broad, encompassing multiple helmet streamers and their current sheets. Most CMEs might then be spatially associated with the HCS (figure 1). In this view the HCS and its associated plasma are more dynamic than previously thought, acting as a conduit for a range of activity from slowly evolving streamers to large CMEs.

Indeed, it appears that in many, if not most, cases, CME–flux ropes in the solar wind expand through the current sheet in such a way that they carry the sector boundary, or polarity change, in the form of a large-scale rotation rather than a radially expanding current sheet (figure 1(*c*)). Reconnection near the Sun then re-establishes the current sheet behind the CME. In the solar wind following transients at sector boundaries there is evidence of small intertwined flux ropes which might result from disconnection and distension of the fields. In addition, quiet, radially aligned fields are often found in the trailing portions of CMEs and may be the legs of magnetic structures carried out by the CME. The Helios photometer images and the bidirectional electron data also indicate that the closed-field regions of CMEs can extend well beyond the magnetic cloud portion.

Finally, such transient activity can also compress, amplify and align pre-existing magnetic discontinuities in the HCS and at the leading edge of high-speed streams. In addition, since the closed fields of a CME effectively

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

isolate its interior from the surrounding solar wind, the ambient IP field and its associated plasma will be deflected around the oncoming CME. This interaction causes the ambient field to be compressed and to drape about the CME, much as a moving body in a fluid pushes the ambient medium aside. Compression will increase the ambient field strength and draping can reorient its direction, especially ahead of a fast CME.

The effects of CMEs on the solar wind also help explain why CMEs cause the largest geomagnetic storms. Geomagnetic storm indices are well correlated with the speed of the solar wind and the strength and direction (southward) of the IMF (see MAGNETOSPHERE OF EARTH: GEOMAGNETIC STORMS AND SOLAR WIND ORIGINS) parameters, which are also enhanced during the passage of CMEs. For example, compression and draping of magnetic fields at the leading edge of CMEs and of the ambient IP field are prime causes of strong southward fields. Good associations are also found between storms and other IP proxies of CMEs, in particular strong southward fields in magnetic clouds and compound streams (formed by faster streams overtaking slower ones), rapid decreases in the galactic cosmic ray flux, enhanced He abundance events and filament disappearances which can be isolated from flares. Storms are often preceded by sudden commencements which are well correlated with the IP shocks driven by faster CMEs. In general, CMEs which are associated with storms are among the largest and fastest structures in the solar wind. Since the occurrence rate of CMEs follows the solar activity cycle so that they are much more frequent around activity maximum, it is not surprising that geomagnetic storms are also more frequent and stronger during maximum.

Other sources of transient activity in the solar wind

Finally, we briefly mention several other kinds of solar activity that may have an influence on the solar wind. There is some evidence, although controversial, from global IPS measurements that solar active regions provide a source of small-scale density variations in the quiet solar wind. If they directly add denser-than-ambient plasma to the flow, then active regions can contribute to the mass flux of the solar wind. Previously, active regions had been thought to be small-scale, entirely closed magnetic structures with no direct access to the solar wind. The revisionist view is supported by x-ray images from the YOHKOH satellite showing that loops overlying active regions are continually expanding outward in the corona. There is also some evidence that open field lines overlie some active regions and could act as conduits for mass flow into the wind. Although it is well known that most of the material in the slow component of the quiescent solar wind originates from the vicinity of the coronal streamer belt, the details of where this material comes from and how it is transported outward are unknown. Recent results from LASCO, IPS and total solar eclipse data suggest that the streamer belt is very filamentary and highly structured. Blobs of material can now be observed being ejected from the cusps of streamers, probably through a quasi-steady reconnection process. Although the fast component of the solar wind, known to originate from the open fields of coronal holes, has low density, it does contain small-scale plasma structures whose source is not known. It has long been conjectured that the source of this material might be POLAR PLUMES, bright, radially elongated structures that emanate over polar coronal holes. Plumes often, but not always, have bipolar magnetic fields at their base, suggesting that reconnections with the prevailing open fields drive plasmoid-like structures into the wind. Recent observations from SOHO show upward motions of plasma in plumes, supporting this view.

Solar Wind: Radio Techniques for Probing

The solar wind is a complex magnetized plasma containing large-scale magnetohydrodynamic (MHD) structures, waves and turbulence (see SOLAR WIND PLASMA WAVES and SOLAR WIND TURBULENCE). The structure of the solar wind is modulated in both time and space by solar variability. The solar activity cycle modulates the structure of the solar wind over a time scale of years while transient energetic phenomena such as coronal mass ejections (see SOLAR CORONAL MASS EJECTION: OBSERVATIONS) can strongly perturb the solar wind on short time scales.

Many direct and remote sensing techniques are available for exploring the basic structure of the solar wind and its variation in time and space. Direct sensing techniques require *in situ* measurements by instrumentation on board spacecraft located outside of the Earth's magnetosphere. Remote sensing techniques employ a variety of ground-based and/or space-based instrumentation. A powerful class of remote sensing techniques exploits the use of radio waves to probe the solar wind. Beginning in the early-1960s, observations of radio waves from natural radio sources (e.g. quasars), spacecraft radio beacons and radar signals have been used to deduce the solar wind velocity and constrain its acceleration profile, to map three-dimensional MHD structures in the heliosphere, to determine the spatial spectrum of electron density inhomogeneities and to place constraints on the magnetic field in the inner heliosphere.

Scattering of radio waves in the solar wind

The solar wind is a plasma composed of electrons and ions, the bulk of the ion population being protons. The propagation of radio waves in the solar wind is determined by the refractive index of the medium, μ. For rarefied plasmas such as the solar wind and the wavelengths typical of radio experiments designed to study the solar wind, the refractive index $\mu(\boldsymbol{r})$ at position $\boldsymbol{r}$ is $\mu(\boldsymbol{r}) = 1 - r_e\lambda^2 N_e(\boldsymbol{r})/2\pi$, where $N_e(\boldsymbol{r})$ is the electron number density, λ is the wavelength of the radio radiation and r_e is the classical electron radius. In addition to the overall decline in electron density with distance from the Sun, there are variations in the plasma density due to large-scale MHD disturbances and turbulence which cause fluctuations in the refractive index: $\delta\mu(\boldsymbol{r}) \propto \lambda^2\delta N_e(\boldsymbol{r})$. The mean radial gradient in N_e can cause significant refraction of radio waves. Fluctuations in the refractive index $\delta\mu$ cause a variety of additional effects that are generally referred to as 'scattering'.

Scattering phenomena depend on $\delta\mu^2$. The mean density of the solar wind declines nearly as $N_e(\boldsymbol{r}) \propto r^{-2}$. With $\delta N_e(\boldsymbol{r}) \propto N_e(\boldsymbol{r})$ we have $\delta\mu^2 \propto r^{-4}$. Hence radio waves propagating through the solar wind are most strongly affected when they are closest to the Sun, as illustrated in figure 1. It is therefore useful to think of the solar wind as a thin scattering screen between the radio source and the observer. Consider a distant background source of radio waves—a QUASAR, for example. The radio waves incident on the thin screen are plane waves. The effect of density inhomogeneities in the plasma screen is to change the phase ϕ of the incident wave in a position-dependent manner: $\phi(x, y) = k\int \mu(x, y, z)\,\mathrm{d}z$, where $k = 2\pi/\lambda$. The magnitude of the phase change therefore depends on the nature of the electron density inhomogeneities from location to location in the screen. The wave emerging from such a screen is no longer planar, but is instead 'rumpled' owing to the phase changes imposed by the plasma screen. In other words, the wave now propagates into a range of directions—it has been scattered into an *angular spectrum*.

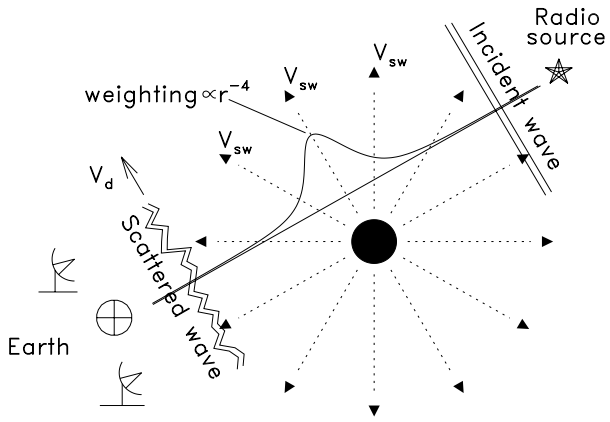

Figure 1. Radio emission from a natural or man-made source passes through the solar wind and is detected by ground-based radio telescopes. The spectrum of electron density inhomogeneities impresses position-dependent phase changes in the incident wave front. These yield both angular broadening and scintillation.

A useful statistic of the scattering medium is the *wave structure function*. Consider a Cartesian coordinate system where the scattering screen lies in the x–y plane at $z = 0$ and an observer is located at a distance L along the z-axis in the x–y plane. Let $\boldsymbol{r} = (x, y, L)$ and $\boldsymbol{s} = (x, y, 0)$. The wave structure function is $D(\boldsymbol{r}) = \langle[\phi(\boldsymbol{r}) - \phi(\boldsymbol{r} + \boldsymbol{s})]^2\rangle$, where $\phi(\boldsymbol{r}) = r_e\lambda\int N_e(\boldsymbol{r})\,\mathrm{d}z$ is the phase deviation along a straight-line path from the source to the observer. The *spatial spectrum* of electron density fluctuations $\Phi_{N_e}(q)$ (where $q = 2\pi/s$) is the Fourier transform of the spatial correlation function of the electron number density fluctuations $\langle\delta N_e(\boldsymbol{r})\delta N_e(\boldsymbol{r} + \boldsymbol{s})\rangle$. Generally speaking, the spatial spectrum of electron density fluctuations describes the nature of electron density inhomogeneities in the solar wind. Under certain simplifying assumptions, it can often be inferred from the wave structure function. A practical advantage of the wave structure function is that it is straightforward to measure.

The *diffractive scale*, r_{diff}, sometimes referred to as the *coherence scale*, is defined by $D(r_{diff}) = 1$, i.e. the transverse scale over which the phase varies by a radian or less. The angle into which the incident radiation is scattered by the solar wind is $\theta_c = 1/kr_{diff}$. The projected size of the source

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

on the scattering screen is a second spatial scale, commonly referred to as the *refractive scale*: $r_{ref} = L\theta_c = \lambda L/2\pi r_{diff}$. Note that a third scale can be identified. The Fresnel scale is $r_F = (\lambda L/2\pi)^{1/2}$ and we have $r_{diff} r_{ref} = r_F^2$. The Fresnel scale provides a convenient demarcation between two scattering regimes. When $r_F \ll r_{diff}$, we refer to the *weak scattering* regime; when $r_F \gg r_{diff}$, we refer to the *strong scattering* regime.

In weak scattering, inhomogeneities of a size comparable with r_F cause weak focusing and defocusing of the wave front, causing weak flux variations, or SCINTILLATIONS, on the ground. In strong scattering the wave will constructively and destructively interfere with itself as it propagates from the screen to the observer, producing a diffraction pattern on the ground. If the plasma screen were fixed, the diffraction pattern on the ground would be a fixed, random distribution of bright and dark patches. However, the solar wind moves away from the Sun with a speed of several hundred km s^{-1}. The electron density inhomogeneities being effectively 'frozen' into the solar wind plasma, the diffraction pattern sweeps across the ground at a similar speed and direction to the solar wind. An observer measuring the intensity of the background source at a fixed location on the ground therefore observes strong scintillations. Scintillations are often characterized by the scintillation index $m = \sigma_I/I$, the rms fractional intensity fluctuation. In weak scattering $m \ll 1$; in strong scattering $m \sim 1$. Radio scintillations have an analog in the visible part of the spectrum: stars twinkle as a result of their light being scattered in the Earth's atmosphere.

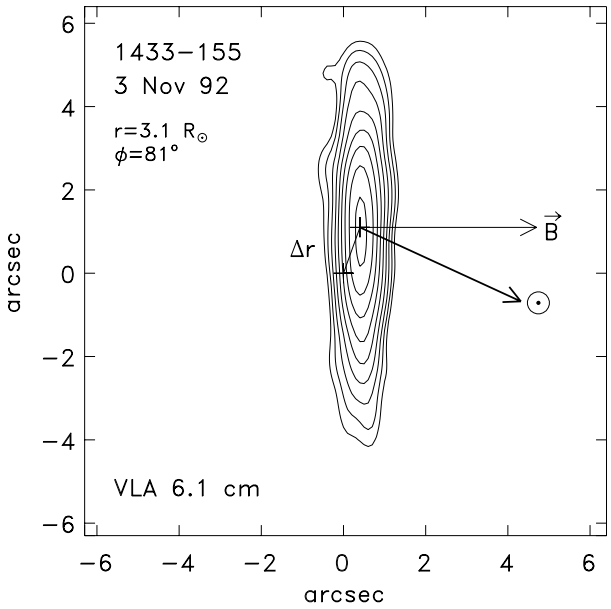

Figure 2. An observation of 1433–155 with the Very Large Array radio telescope at a wavelength $\lambda = 6.1$ cm. The radial distance of the source from the Sun and its position angle are as indicated. Note that the source is displaced by a fraction of an arcsec from its nominal position due to refraction. The heavy arrow indicates the direction toward the center of the Sun, while the lighter arrow indicates the direction of the electron density inhomogeneities, presumed to be aligned with the local magnetic field.

The use of cosmic radio sources

There are many cosmic sources of radio emission (e.g. quasars, radio galaxies, pulsars; see also RADIO EMISSION FROM BINARY STARS) that are spatially coherent—that is, point like—which lend themselves as probes of the foreground solar wind. As the Earth orbits the Sun, these sources are viewed at various elongations from the Sun. A variety of experiments can be performed which exploit natural sources of radio emission. One of the simplest is to measure the apparent angular size of the source. As discussed in the previous section, radio waves are scattered into an angular spectrum. As measured on the ground, the source is broadened in its angular extent. Since the source is, in the absence of the foreground solar wind, a point source, any angular broadening is solely the result of scattering in the solar wind. The spatial coherence of radio sources is measured using interferometric techniques. A RADIO INTERFEROMETER measures the *mutual coherence function*, $\Gamma(\boldsymbol{s}) = \langle E(\boldsymbol{r})E^*(\boldsymbol{r}+\boldsymbol{s})\rangle/\langle|E^2|\rangle$, of the incident radiation, where $E(\boldsymbol{r})$ is the electric field at location $\boldsymbol{r}$. The mutual coherence function is related in a particularly simple way to the wave structure function when observing a distant, point-like source of radio emission: $\Gamma(\boldsymbol{s}) = \exp[-D(\boldsymbol{s})/2]$. As discussed in the previous section, the angular width of the scatter-broadened source is conveniently expressed as $\theta_c = 1/kr_{diff}$, i.e. where $\Gamma(s) = \Gamma(r_{diff}) = \exp(-1)$. It is worth mentioning that the Van Cittert–Zernicke theorem shows that the inverse Fourier transform of the mutual coherence function (suitably normalized) yields the radio brightness distribution on the sky. This is the underlying basis of Fourier synthesis telescopes such as the VERY LARGE ARRAY NATIONAL RADIO ASTRONOMY OBSERVATORY. An example of an observation of a scatter-broadened source made by the Very Large Array is shown in figure 2. The image is anisotropic, and hence the scattering is anisotropic, implying that the electron density inhomogeneities are themselves highly anisotropic near the Sun.

Other experiments exploit the fact that, since the radio flux of many cosmic sources is constant over timescales of days to months, any short-term variation in the radio flux density is due to the passage of the radiation through the solar wind, i.e. scintillations. Scintillations are commonly exploited in three ways. First, scintillation is caused by the movement of the diffraction pattern of the incident radiation across the ground as the solar wind travels outward from the Sun. The intensity fluctuations can be measured by a single antenna and the autocorrelation of a time series of such measurements can be formed. The Fourier transform of the autocorrelation function of the intensity fluctuations is the power spectrum $P(f)$ of the intensity fluctuations at the location of the antenna. In the weak scattering regime, $P(f) \propto \Phi_{N_e}(q)$, the spatial spectrum of electron density fluctuations, where

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

$q = 2\pi f/V_{SW}$. Hence, single-station measurements of scintillations of background radio sources can be used to constrain $\Phi_{N_e}(q)$ at various elongations from the Sun.

A second way in which scintillations are exploited is to use them as a passive tracer of solar wind velocity. In a procedure similar to that outlined above for one antenna, the temporal cross-spectrum $P_c(f)$ can be measured by each pair of antennas and the diffraction pattern velocity vector can be extracted from the cross-correlation function (the Fourier transform of the cross-spectrum), or the cross-correlation function can be measured directly. As the background source changes in solar elongation, V_{sw} can be measured as a function of elongation and its acceleration profile can be inferred. While conceptually simple, complications enter into such measurements in practice. One of the main complications is the fact that the solar wind is composed of both slow-speed and high-speed streams. In addition, the electron density inhomogeneities are anisotropic.

A third use of scintillation in the weak scattering regime is to observe a grid of background cosmic sources and to compute the scintillation index m and its mean value $\langle m \rangle$ in each case. The Cambridge disturbance factor is then computed as $G = m/\langle m \rangle$. Typically, hundreds of measurements are made each day to provide a dense sampling of the scintillation properties of the IPM in the form of a 'G map'. Lines of sight along which enhanced regions of electron density occur yield enhanced values of G. Coherent density structures in the IPM can be mapped out using G maps and their evolution in time can be tracked by forming daily G maps. For example, heliospheric structures that corotate with the Sun have been observed using this technique. Recently, tomographic techniques have been exploited to infer the three-dimensional structure of such disturbances (figure 3).

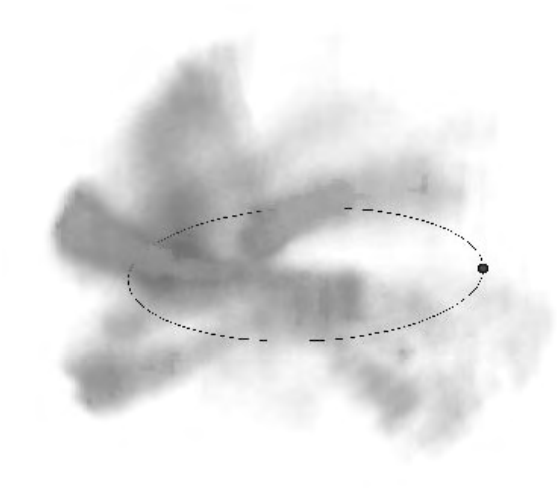

Figure 3. An example of a tomographic reconstruction of the inner heliosphere, to a distance of 1.5 AU, which was derived from a combination of IPS intensity level data and velocity data obtained over one solar rotation period (23 June 1994 to 20 July 1994, Carrington Rotation 1884). Earth's orbit is as indicated. The technique is described in detail by Jackson *et al* (1998).

The use of artificial radio beacons

Radio beacons on the ground (radar) or on board spacecraft offer another means of probing the solar wind. Temporally coherent radio signals—that is, those which are sufficiently narrow band to be regarded as monochromatic—have been used to exploit the phenomena of spectral broadening and phase scintillation to study the solar wind. When a spacecraft is in opposition to the Earth, onboard transmitters can be employed as beacons to study the effect of the solar wind on the signal as it passes through the solar wind. Radar experiments have used VENUS as a passive reflector. As Venus moves into opposition behind the Sun, a radio signal can be transmitted from Earth to Venus. There, the signal is reflected and returns to Earth, where it is detected and spectrum analysed. Both spacecraft signals and reflections from Venus are sufficiently local that the wavefronts involved are no longer planar. Furthermore, in the case of radar experiments, the wave makes a double pass through the solar wind (see VENUS: INTERACTION WITH SOLAR WIND). These complications aside, radar and spacecraft signals have been successfully employed for a variety of studies.

Spectral broadening of a monochromatic signal emitted by a spacecraft is caused by differential Doppler shifts from angular scattering on electron density inhomogeneities in the solar wind. A ground-based receiver can measure the power spectrum of the signal emitted by spacecraft. The Fourier transform of the power spectrum can then be related to the spatial spectrum, $\Phi_{N_e}(q)$, of the solar wind turbulence. In addition, such measurements can be used to constrain the solar wind velocity. Similar analyses are employed for a radar signal reflected from a planet.

It is possible to infer $\Phi_{N_e}(q)$ by measuring the phase variations (phase scintillation) of the incoming radio signal directly. In practice, observations are made at two separate radio frequencies in order to recover both the free space and plasma contributions to the phase. The temporal structure function of the phase is then constructed as $D(\tau) = \langle [\phi(t) - \phi(t+\tau)]^2 \rangle$. The temporal phase structure function is then transformed to the spatial structure to the spatial structure structure function using $D(s = \tau V_{SW})$.

Future prospects

While *in situ* measurements of the solar wind plasma have been made in the ecliptic plane for decades, and more recently at high latitudes by *Ulysses* (see SOLAR WIND: ULYSSES), such measurements have only been possible at distances of ∼1 AU or more from the Sun. Remote sensing

techniques at radio wavelengths offer the only means of probing the inner heliosphere at present. Although a future satellite mission designed to probe the outer corona and inner heliosphere directly is in the planning stages, high-quality synoptic measurements of the solar wind at critical distances from the Sun will continue to rely on remote sensing techniques. With improvements to the sensitivity of groundbased RADIO TELESCOPES, greater numbers of cosmic background sources will be available for routine monitoring of the solar wind.

Solar Wind: Theory

The supersonic outflow of electrically charged particles, mainly electrons and protons from the solar CORONA, is called the SOLAR WIND. The solar wind was described theoretically by E N PARKER, in 1958. Parker's theory was verified experimentally by *in situ* observations by Soviet and American spaceprobes. On its way to Venus, in 1962, the MARINER II spacecraft observed the solar wind for 104 days. The average flow speed was more than 500 km s^{-1}. This observation showed that the coronal plasma expands into a supersonic solar wind as Parker had predicted.

Parker's solar wind theory

Parker was familiar with the work on comet tails that had been carried out in Germany in the late 1940s and early 1950s under the leadership of LUDWIG BIERMANN (see COMETARY TAILS). The 'ionic' comet tails were observed to be pointing radially out from the Sun. This required a radial force much larger than the force that the photons from the Sun can provide, and Biermann concluded that the 'corpuscular' radiation from the Sun may play an important role in forming the radially pointing comet tails.

Parker based his solar wind theory on the fact that the solar corona has a temperature of more than a million kelvin. He argued that the electron density and the pressure in such a hot atmosphere decrease rather slowly, and the pressure, far from the Sun, is orders of magnitude larger than the pressure of the interstellar gas surrounding the solar system. According to Parker, this imbalance between the pressure in the outer corona and the local interstellar medium would lead to an expansion of the coronal gas into a supersonic solar wind.

The coronal gas, at a temperature of one million kelvin or more, is fully ionized; the number of neutral atoms is very small. However, the thermal energy of the plasma is not large enough to overcome the gravitation field and escape from the Sun. In the inner corona the pressure decrease is determined by gravity, so the gas is in static equilibrium. However, an ionized gas at a temperature of more than a million kelvin is a good conductor of heat. Hence, the coronal temperature does not decrease significantly with increasing distance from the Sun. The thermal energy of the plasma is almost constant whereas the energy needed to overcome the gravitational field decreases. In the outer corona the thermal energy is larger than the escape energy, and the gas can escape.

In Parker's solar wind model, the energy transport (in the form of heat conduction) from the inner corona plays an important role for supplying the energy needed to bring the plasma out of the solar gravitational field. The electrons are much better at conducting this heat than are the ions, owing to their smaller mass, but most of the energy flux goes into increasing the energy of the ions. This transfer of energy from electrons to ions is achieved through an electric field. This electric field must be consistent with the force and energy balance in the flow.

Parker described the coronal gas as a fluid. This allowed him to take into account the coupling of electrons and ions, without calculating the electric field explicitly. In his first study he assumed that the heat conductivity is so high that the coronal plasma has a constant temperature. On the basis of this assumption he could illustrate how the coronal plasma reaches supersonic speed around 5 solar radii from the Sun, and expands into interplanetary space with a steadily increasing flow speed. The equations also allow for subsonic flow, but the pressure far from the Sun in such solutions is almost the same as the pressure in a static, isothermal corona. Hence, the subsonic solutions do not describe an outflow that is in force balance with the local interstellar medium.

In the supersonic flow the flow speed is larger than the thermal motion in the gas, and the dynamic pressure (associated with the directed motion) is larger than the thermal pressure (associated with the random motion). The dynamic pressure of the spherically expanding solar wind decreases with distance from the Sun. At a distance where the dynamic solar wind pressure is equal to the pressure of the interstellar gas a shock is formed: the flow speed is reduced, the density increases and most of the flow energy is transferred into thermal energy. The solar wind termination shock, at 100 AU or so (1 AU = Sun–Earth distance), has not yet been observed, but the Voyager 1 and 2 spacecraft may cross this boundary in a not too distant future.

Parker's solar wind theory has formed the basis for our understanding of the expanding solar corona as well as the outflow of ionized gas from galaxies and stars, and other celestial bodies, and the outflow of light ions from the polar regions of the Earth (the polar wind).

History

Studies of the Sun have a long history in many cultures, but it was the studies of aurora and geomagnetic storms that led to the studies of the solar wind.

The AURORA was part of the mythology and the life of peoples living in the Arctic, but when Celsius and Hiorter in Uppsala, Sweden, started systematic observations of the 'the magnetic needle', in the 1740s, the correlation between aurora and fluctuations in the geomagnetic field was first found. Their collaboration with Graham in London showed that geomagnetic fluctuations occurred both in London and in Uppsala when aurora was seen in Sweden. These findings seem to be the first to establish the link between aurora and GEOMAGNETIC STORMS.

It took some time to find the common cause of aurora and geomagnetic disturbances. The 11 year SUNSPOT CYCLE was noticed by the German amateur astronomer Schwabe in 1843, and several investigations showed a correlation between auroral and geomagnetic activity, and sunspot number. In the 1850s Broun found that geomagnetic storms had a tendency to recur after 27 days, a time close to the rotation period of the Sun, seen from the Earth. On 1 September 1859, a large solar flare was observed by Carrington and by Hodgson, and approximately 18 h later

there was a large geomagnetic storm with aurora at very low latitudes. This event served as an indication that there is a connection between solar 'storms' and geomagnetic storms (see MAGNETOSPHERE OF EARTH: GEOMAGNETIC STORMS AND SOLAR WIND ORIGINS). Throughout the last part of the 19th century there were several studies of the possible link between solar activity and geomagnetic storms. 'At the end of the century it was established that aurora and geomagnetic storms should be regarded as manifestations of an unknown cosmic agent of solar origin', Kristian Birkeland wrote in 1908.

One hundred years ago Birkeland set up an impressive research program in Norway to investigate the effects of charged particles from the Sun on the near Earth environment. Together with his assistants he carried out laboratory experiments, observations from field stations around the world and theoretical studies. This was the first comprehensive research effort in solar–terrestrial physics. (Birkeland financed the research program with money he earned from working with industry.)

Birkeland is best known for his Terella experiments, where cathode rays interact with a magnetized sphere, placed in a low-density gas. The experiment showed that the cathode rays impacted on the sphere in regions around the two poles, much like the auroral zones at high latitudes. However, what is less known is that Birkeland also used his magnetized sphere as a cathode to study the emission of 'electric corpuscules' from the Sun. On the basis of observations of continuous geomagnetic activity at stations in the Arctic, Birkeland concluded that there is a continuous flow of charged particles from the Sun. These particles interact with all bodies in interplanetary space, and the interaction with comets leads to the formation of comet tails. To study this process in the laboratory he let cathode rays impinge upon an anode of coal. On the basis of many years of studies of the Sun and of geomagnetic activity he was convinced that all stars, in the course of their evolution, emit electrons and ions into space, and he went on to speculate that most of the mass in the universe is not in stars and nebulae but in 'empty' space.

At the time when Birkeland carried out his work it was not known that the outer solar atmosphere, the corona, is hot. It was first in the 1930s that the picture of a corona with a temperature of more than a million kelvin began to emerge. This was made possible by the development of the CORONAGRAPH by BERNARD LYOT. By shielding the solar disk with a circular plate it was possible to carry out observations of the corona on a regular basis. Previously, such observations could be made only during eclipses. Lyot measured the width of the green line (5303 Å) to 0.9 Å (1 Å $= 10^{-10}$ m). He suggested that the broadening could be due to thermal motions, but the element emitting the line was not known, so a temperature could not be determined.

Grotrian argued, from the early 1930s, that the corona is hot, but it was the identification of coronal lines, as emission lines from highly ionized elements, that established that the corona is hot. Edlén identified the green line (5303 Å) as an emission line from iron atoms that have lost 13 electrons, Fe XIV, and he showed that many of the other coronal lines were emitted by highly ionized elements. These elements cannot exist in the corona unless the temperature is a million kelvin or more. With such a high temperature one could describe the relatively slow electron density fall-off and the widths of the coronal spectral lines. However, it was not easy to understand how it is possible to maintain a hot corona overlaying a 'cold' CHROMOSPHERE. The rapid increase in temperature from the chromosphere to the corona is consistent with a heat conductive energy loss from the corona. This energy loss must be balanced by coronal heating. Biermann and Schwarzschild claimed that acoustic waves could transport energy into the corona from the lower layers in the solar atmosphere, whereas ALFVÉN suggested that MAGNETOHYDRODYNAMIC WAVES (later called Alfvén waves) may carry the energy necessary to heat the corona.

Already in 1941, Alfvén had published a model of a hot static corona, extending out to 10 solar radii, and in the early 1950s there were indications that the solar corona extends even further into interplanetary space. Hewish and Vitkevich observed fluctuations in radio signals that pass through interplanetary space relatively close to the Sun. They found electron density irregularities extending out to at least 20 solar radii and that the 'super corona' changed over the sunspot cycle. Latitude variations were also observed. These observations, together with Biermann's observations of ionic comet tails and Forbush's observations of the variations of the low energy cosmic ray intensity over the sunspot cycle, were known when Parker formulated his solar wind theory.

The solar wind

In 1958 Parker published a paper on the 'dynamics of the interplanetary gas and magnetic field' in the *Astrophysical Journal*. In this paper he presents a model of an expanding solar corona; the coronal gas is allowed to flow out from the Sun in the form of a solar wind. With this model Parker could describe the transition from a quasi-static inner corona to a supersonic solar wind with speeds of several hundred kilometers per second at the orbit of Earth. Parker used hydrodynamic equations, and he considered an isothermal, spherically symmetric, radial flow. This model suffers from several shortcomings, where the most severe may be that the energy balance in the flow is not addressed. However, with this very simple model, Parker could illustrate how the hot coronal gas expands and expels the interstellar gas from interplanetary space. Parker's solar wind model bears some similarities to Bondi's and McCrea's models of accretion of interstellar gas onto a central object. Formally, the two problems are identical, but the physics of Parker's solar wind model is more difficult to understand than the physics of the accretion flow.

The simplicity of the model invited criticism. Chamberlain pointed out that the temperature in the flow is determined by degradation of the heat conductive flux

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

and adiabatic cooling, whereas in the Parker model it was taken to be constant. This also implied that the energy per unit mass in Parker's model is infinite. Chamberlain argued that the energy per unit mass should be set to zero. This assumption led to a low-speed 'breeze' solution of the fluid equations. Parker included the energy balance in the flow in his model and showed how heat is conducted outward from the inner corona and converted into flow energy by the pressure gradient force. This model could also describe the supersonic solar wind.

Opponents argued that a fluid treatment of the coronal gas is not valid, and that a kinetic approach should be used. During the 1960s there were several attempts to construct exospheric solar wind models. Many of these studies gave results in better agreement with the breeze solution than with the supersonic wind solution. One reason some of the exospheric models gave low flow speeds is that the electric field in the models was too small. This electric field is set up by the plasma to balance the pressure gradient force in the electron gas. In the fluid model the electric field does not appear explicitly. In the kinetic models this is not the case. Many of the exospheric models used the electric field of a static corona. This is smaller than the field in a subsonic–supersonic solar wind and gives rise to a smaller acceleration of the protons than is found in the hydrodynamic model.

In Parker's model the solar magnetic field is 'dragged out' by the solar wind. Because of the high electric conductivity the electric field in the expanding gas is small. As a consequence, the magnetic field is connected to the source region at the Sun. When the Sun rotates, the gas emitted from one region in the corona is situated on a spiralling field line, and the direction of the field depends on the polarity in the corona. In the ECLIPTIC, the average magnetic field is in the ecliptic plane, and the angle between the average field and the radial direction is around 45° at the orbit of Earth.

It took only a few years before the solar wind 'controversy' could be settled. *In situ* observations of the interplanetary plasma were carried out by the Soviet spacecraft Lunik 2 and the American spaceprobe Explorer 10. However, it was not until the fall of 1962, after the Mariner II observations of the solar wind, that Parker's solar wind model was accepted. On route to Venus, Mariner II obtained 104 days of observations. It measured an average solar wind flow speed of 504 km s^{-1}. The proton density was around 5 cm^{-3}, much lower than the density in a static corona. The average interplanetary magnetic field showed a spiral structure very similar to the model proposed by Parker.

The Mariner II flight took place during the declining phase of the sunspot cycle. There were several high-speed solar wind streams, with a recurrence period of 27 days (seen from the Earth), during the mission, that gave rise to recurrent geomagnetic storms with the same period. Thus, the source of recurrent geomagnetic storms could be identified as high-speed solar wind streams, but the solar source regions of these streams, often called M-regions, were not identified. It was 10 years later that 'coronal holes', were first identified as the source regions of quasi-steady high-speed solar wind; coronal holes are regions in the corona, with unipolar magnetic field and low electron density. During the declining part of the sunspot cycle the polar regions develop into large coronal holes, and the high-speed solar wind from these regions fills up a large fraction of interplanetary space.

Solar wind from a given corona

When Parker formulated his solar wind theory he took the inner solar corona to be a reservoir of particles and energy for the outflowing solar wind. Therefore it can be argued that he made the assumption that the energy balance in the corona is between coronal heating and inward heat conductive energy loss and that the energy loss in the solar wind is not large enough to significantly change the structure of the inner corona.

This model can describe the basic dynamics of the corona–solar wind system quite well, i.e. the expansion of the coronal gas into a supersonic solar wind. However, Parker realized that the model could not describe the quasi-steady high-speed solar wind streams that were observed, mainly during the declining phase of the sunspot cycle. He found that energy has to be added beyond the inner boundary to speed up the flow. Many years later Leer and Holzer showed that this energy has to be deposited in the supersonic region of the flow; energy deposition close to the Sun increases the solar wind particle flux whereas energy deposition in the supersonic flow increases the energy per unit mass in the flow and therefore the flow speed.

There are several problems with a model where the electron density and temperature in the inner corona are taken to be independent of the solar wind outflow. If we assume that the electron (proton) density at the inner boundary is fixed, and let the temperature increase, the solar wind proton flux increases rapidly. By varying the temperature from one to two million kelvin the solar wind proton flux changes by a factor of 100 or so. However, the solar wind proton flux is observed to be fairly constant whereas the coronal temperature shows considerable variation. This inconsistency cannot be resolved in a reasonable manner within the framework of a traditional solar wind model. In order to obtain a more complete description of the solar wind we must include the coronal energy balance in the model.

Formation of the corona and acceleration of the solar wind

In Parker's theory the solar wind is a consequence of the coronal heating process, so the inclusion of the coronal energy balance would be a natural extension of his model. This can be done by moving the inner boundary from the corona into the upper chromosphere. A significant energy flux is needed to balance the radiative losses from the chromosphere, but the energy flux deposited in the outermost part of the solar atmosphere, where the electron

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

density is very small, is not radiated away locally. The temperature increases until some other loss mechanism balances the heat input. In magnetically closed regions, where the coronal plasma is trapped by the magnetic field, inward heat conduction is the most significant energy loss, whereas in regions where the magnetic field extends into interplanetary space, and the coronal plasma is free to escape, energy may also be lost in the solar wind. How much of the energy that is lost as inward heat flux and as solar wind energy flux may depend on the amplitude of the energy flux and how and where this energy flux is deposited in the corona.

Energy balance in a static corona

Let us first consider the energy balance in magnetically closed regions, where the energy deposited as heat is lost as inward heat conduction. To make the problem as simple as possible we can consider a spherically symmetric corona, with a 'lid' on it. This outer boundary does not allow transport of either plasma or energy.

If this static corona is heated by an energy flux from the Sun, say 100 W m^{-2} at the solar surface, and this energy flux is deposited in the corona over a length scale comparable with a solar radius, we find a coronal temperature in the range 1.5–2.0 million K; a corona at this temperature will lose 100 W m^{-2} into the TRANSITION REGION in the form of an electron heat flux. However, the heat conductive loss from the corona depends sensitively on the coronal temperature; a corona at 0.5 million K loses only 1 W m^{-2} as inward heat flux. Because of the very strong temperature dependence of the heat conduction in an ionized gas we find that a small heat input is sufficient to maintain a rather hot corona.

In a corona where the electron (proton) density is so low that the electrons and protons are not thermally coupled, the proton heating must be balanced by heat conduction in the proton gas. As there is no reason to expect that the protons are heated less than the electrons, the lower heat conductivity in the protons leads to a proton temperature that is higher than the electron temperature.

The electron density in the inner corona is determined by the pressure in the chromosphere–corona transition region, and this pressure is determined by the heat conductive flux from the corona. If we assume that the radiative losses from the transition region are balanced by the heat flux from the corona, we find that an inward heat flux of 100 W m^{-2} corresponds to a transition region pressure of $p_{TR} = 7 \times 10^{-3}$ N m^{-2}. The pressure is proportional to the heat flux, so a heat flux of 10 W m^{-2} corresponds to 7×10^{-4} N m^{-2}. A large inward heat flux leads to a high transition region pressure, a large electron density in the inner corona and strong collisional coupling between electrons and protons. A small inward heat flux is consistent with a low pressure in the transition region and a low electron density in the corona.

Energy balance in coronal holes

In magnetically open regions the energy that is deposited in the corona can be lost as inward heat flux and as solar wind energy flux. Which of these two loss mechanisms is the most important one may depend on how and where energy is transferred to the coronal plasma. If most of the energy is added to the electrons, as heat, a large fraction may be lost as inward heat flux. However, if most of the energy is added to the ions the inward heat flux may be reduced significantly.

In order to investigate the energy balance of coronal hole regions we can construct mathematical models extending from the upper chromosphere, through the transition region and corona, and far into interplanetary space. The heating of the corona is specified through the amplitude of the energy flux and how and where this energy flux is deposited. These types of studies show that heating of the very inner corona leads to a large inward heat flux, whereas only a small fraction of the energy flux is lost in the solar wind. Heating further out from the Sun leads to a larger solar wind energy loss, but there is a significant difference between models with electron and proton heating.

In models with extended electron heating the inward heat flux is a significant fraction of the energy flux, and because of the high heat conductivity in the electrons the temperature in the corona does not exceed 1.5 million K for a reasonable heat input. The large inward heat flux is consistent with a large transition region pressure and a quite large electron density in the inner corona. The solar wind emanating from such a corona does not reach a high flow speed far from the Sun. A typical value is 300 km s^{-1}. In these models, where the electrons are heated, a large fraction of the outward energy flux from the corona is carried as electron heat conduction. This energy is transferred to the ions via the polarization electric field. This model has many similarities to the 'classical' solar wind model, where electron heat conduction from the inner corona supplies the energy flux that is needed to drive the solar wind.

If most of the energy is added to the protons, the inward heat flux is much smaller, the transition region pressure is low, the electron density in the inner corona is low, the thermal coupling may be weak and the coronal proton temperature may be quite high. In models with extended proton heating most of the energy deposited in the corona is lost in the solar wind. The density in the corona and the solar wind proton flux are small, so the energy per unit mass in the flow, and the flow speed far from the Sun, can be quite large. In order to obtain flow speeds of 800 km s^{-1}, measured in the high-speed wind by the Ulysses spacecraft, a large fraction of the energy must be deposited in the outer corona where the proton density is so low that the heat cannot be conducted away. Then, the heating leads to a high proton temperature and rapid acceleration of the flow.

This type of model study of the corona–solar wind system is limited by the assumptions made, but some

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

general results seem to emerge. High-speed solar wind streams cannot be found in models where most of the energy is deposited in the very inner corona. In models with significant electron heating the inward heat flux is too large, the coronal electron density is too high and the coronal temperature is too low to generate high-speed wind. The high-speed streams can be obtained in models where most of the energy is deposited in the protons. The energy may be deposited as heat or it may go into direct acceleration of the flow, but none of these processes will lead to a large flow speed unless the energy is deposited sufficiently far out in the corona. Most of the energy flux deposited in the corona, in these models, is lost in the solar wind. As the asymptotic flow speed is comparable with the escape speed of the Sun, the solar wind mass flux is proportional to the the energy flux deposited in the corona.

Ulysses and SOHO

In the 1990s there have been two successful space missions that have contributed significantly to our understanding of the solar wind. The Ulysses spacecraft has observed the solar wind at all solar latitudes (see SOLAR WIND: ULYSSES). The first orbital period was during the declining phase of the sunspot cycle. The observations showed a fast and steady solar wind at latitudes larger than 20°. Close to the ecliptic the flow speed was lower and more variable. The solar wind mass flux showed little variation with latitude.

The fast solar wind streams originate in large coronal holes. Observations of spectral lines from large polar coronal holes, with instruments on board the Solar and Heliospheric Observatory (SOHO), show that heavy ions are warmer than protons which themselves are warmer than the electrons. These observations support a model of high-speed wind, with significant energy deposition in the protons and not in electrons. The fact that we observe heavy ions in the corona may be taken as an indication that their temperature is high. If the temperature of heavy ions were equal to the proton temperature, the density of heavy ions would fall off so rapidly with heliocentric distance that it would be difficult to see them in the corona. However, does a high temperature tell us that a heavy ion is preferentially heated?

Particle escape seems to be the most important energy loss process for protons and heavy ions in coronal holes. As the flux of escaping particles is an exponential function of the thermal energy over the escape energy a modest heating of heavy ions leads to a high temperature. If the energy input per unit mass is the same for protons and heavy ions the temperature should be proportional to mass. However, if the ion temperature increases with mass, more rapidly than proportional to mass, we can conclude that the heavy ions are preferentially heated. So far, only a few ion temperatures have been measured in large coronal holes with the Ultraviolet Coronagraph and Spectrograph (UVCS) on board SOHO, but observations of spectral lines from oxygen atoms that have lost 5 electrons, O VI, seem to indicate that there are heavy ions in the corona that are preferentially heated.

Summary

Parker's solar wind theory forms the basis for our understanding of the interplanetary plasma. The dynamics of the solar wind is described by models developed more than 40 years ago. The extension of these models, which includes the coronal energy balance, has led to a fairly good understanding of the acceleration of the solar wind.

The solar wind is driven by the energy deposited in the corona. This process is not understood. In the future the emphasis will therefore be on trying to understand coronal heating. A better understanding of how energy is transported into the corona and transferred to the gas will also give us a deeper understanding of how the solar wind is accelerated.

Solar Wind: Ulysses

Ulysses is the first space mission in a polar orbit around the Sun, and the first to make observations in the previously unvisited regions of the heliosphere over the polar regions at high heliolatitudes. The objective of the Ulysses space mission, launched on 6 October 1990, is the exploration of the dependence on heliolatitude of the heliospheric medium and its relationship with the Sun's coronal structure and dynamics. The heliosphere is the large, three-dimensional region of space around the Sun filled with the SOLAR WIND and the remnant of the SOLAR MAGNETIC FIELD carried in it. The outer boundary of the heliosphere is determined by the interaction between the solar wind and the local interstellar medium.

The properties of the heliospheric medium and their dependence on solar and coronal phenomena have been studied since the early 1960s by numerous spacecraft in Earth orbit, by planetary probes during their cruise to the target planets and by dedicated interplanetary missions. Most of the direct, *in situ* observations have been confined to the vicinity of the ecliptic plane (the plane of the Earth's orbital motion around the Sun). In heliographic coordinates, this corresponds to a range of $\pm 7.25^\circ$ in heliolatitude, the angle between the ecliptic plane and the solar equatorial plane. Solar observations from the ground clearly show that solar and coronal phenomena strongly depend on heliolatitude. In particular, observations during solar ECLIPSES make clear that the CORONA usually has an appearance and structure in the polar regions very different from those near the Sun's equator. As the solar wind, which forms the heliospheric medium, is a result of the expansion of the solar corona into space, its properties are also expected to depend strongly on heliolatitude. This dependence of the heliospheric medium on heliolatitude had been recognized, but, prior to Ulysses, no space mission had been undertaken to study the heliospheric medium in three dimensions.

This delay was due, in part, to the difficulties involved in placing a spacecraft into an orbit out of the ecliptic plane. Ulysses' unique orbit was achieved by first targeting the spacecraft to Jupiter and using gravity assist (the maneuver which allows, during the close flyby of a planet, use of the gravitational potential of the planet to modify the orbit of a spacecraft) to deflect the trajectory of Ulysses out of the ecliptic plane. The Jupiter flyby took place in February 1992, and since then Ulysses has been in a nearly polar orbit around the Sun. Its orbital plane makes an angle of about 80° with the solar equatorial plane, its aphelion (the furthest distance from the Sun) is at 5.4 astronomical units (AU, the mean distance between the Sun and the Earth), its perihelion (closest approach to the Sun) is at 1.4 AU. The orbital period of Ulysses is 6.2 years; its first complete polar orbit is shown in figure 1. Ulysses is equipped with a comprehensive payload to make observations in the solar wind. Instruments to measure the speed, density, temperature and composition of the solar wind plasma are complemented by instruments to measure the magnetic field, radio and plasma waves, as well as energetic particles from the Sun and COSMIC RAYS.

Following the Jupiter flyby, the spacecraft first explored the region of the heliosphere over the south pole of the Sun, in 1993–4. It then moved relatively rapidly, between September 1994 and August 1995, from the southern polar regions to the northern polar regions. This passage from south to north allowed a unique survey of the latitudinal dependence of the solar wind. Ulysses completed its first full solar polar orbit in March 1998. The timing of the mission during the declining and minimum phases of the SOLAR CYCLE, with the polar passes taking place in 1994 and 1995, has yielded a unique set of observations of the configuration of the heliosphere and the properties of the heliospheric medium at solar minimum activity.

The key results of Ulysses are:

(a) The confirmation of the very nearly uniformly high solar wind velocities (>750 km s^{-1}) from the polar coronal holes.
(b) The significant over-expansion of the polar solar wind when compared with the areas occupied by coronal holes.
(c) The clear differentiation, as determined by ion composition and freezing in temperature measurements, between the characteristics of fast and slow solar wind streams.
(d) The latitudinal independence of the radial component of the magnetic field, constraining solar wind models.
(e) The high levels of mostly Alfvénic, transverse fluctuations associated with high-speed wind streams.
(f) The slower evolution of the turbulence in the uniform solar wind in the polar regions when compared with the near-ecliptic regions of the heliosphere.
(g) The less than expected latitudinal gradient of cosmic rays, calling into question established cosmic ray modulation models.

These findings of Ulysses are described in more detail in the following paragraphs.

It has been known from previous solar and interplanetary observations that there are two kinds of solar wind. The slow solar wind, with speeds not exceeding about 450 km s^{-1}, originates from above coronal regions in which magnetic fields lines are generally closed in large-scale loops. The fast solar wind, with speeds in excess of 550 km s^{-1}, but usually about 750 km s^{-1} or more, originates from regions of the solar corona, the so-called CORONAL HOLES, in which magnetic field lines rooted in the solar surface at one end spread out into the heliosphere. The configuration of the solar corona around solar minimum is dominated by two large coronal holes in the polar regions and a belt of closed magnetic fields in the equatorial region. This was the coronal configuration during the polar passes of Ulysses in 1994 to 1996. The observations of the solar wind onboard Ulysses confirmed that the polar regions of the heliosphere were filled with fast solar wind, carrying magnetic field lines of opposite

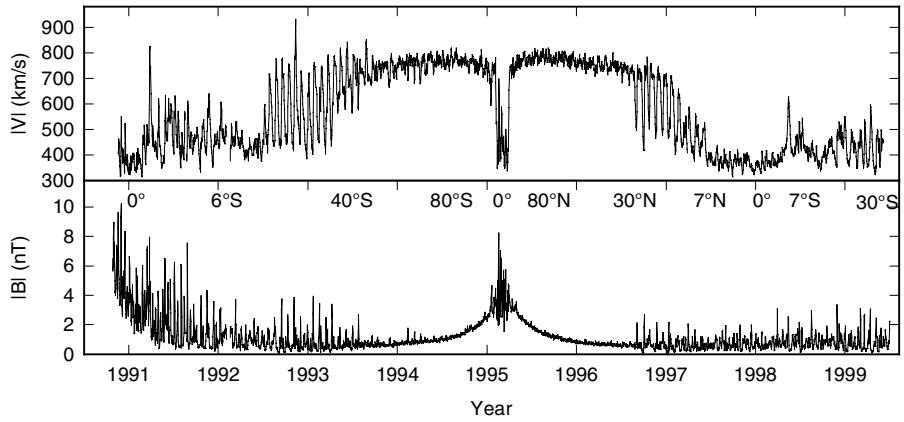

Figure 2. The solar wind speed (upper panel) and the magnitude of the magnetic (lower panel) observed by Ulysses from launch through its first orbit.

polarity from the two polar coronal holes. When Ulysses was close to the solar equator, at latitudes less than 35° south in 1993 and about 25° north in 1996, the solar wind reached the spacecraft both from the equatorial band of solar streamers (the heliospheric extension of the regions above the closed magnetic regions in the corona) and from the equatorward extensions of the polar coronal holes. This was due to the small inclination and warping of the band of slow solar wind with respect to the equatorial plane, so that as the Sun rotated, Ulysses was immersed alternately in slow and fast solar wind in each period of solar rotation. When Ulysses passed poleward of the equatorial region, the speed of the solar wind was found to be uniform, at about 750 km s^{-1}, in a very large volume of space over the two solar poles. Only small variations in this high speed were found, explained by small-scale dynamic effects ('microstreams') and by the effect of very large-amplitude, long-wavelength Alfvén waves which dominated the large-scale fluctuations in the magnetic field. The overview of the two key parameters, the solar wind speed and the magnitude of the magnetic field measured by Ulysses since launch, is shown in figure 2.

The areas covered by coronal holes near the Sun's poles are relatively small, only about 20% of the solar surface at the base of the corona, yet Ulysses observed that more than 75% of space (measured in terms of solid angle) around the Sun was filled with solar wind originating from those coronal holes. This means that the solar wind does not simply expand radially in the corona but considerable expansion takes place in latitude, from the poles towards the equatorial regions, as the solar wind is accelerated away from the Sun. Several previous models of coronal expansions had considered this possibility, but only Ulysses' observations were able to establish this important aspect of the origin of the solar wind.

The composition of the solar wind is different in slow and fast streams, a result well established in observations made in the ecliptic plane. Partly because of its polar orbit, partly because of the instrumentation carried, Ulysses provided the first very strong and comprehensive

evidence that the compositional differences between the two kinds of solar wind represented the coronal conditions in which they originated. Slow solar wind originates in regions where the coronal plasma is very hot, about 1.5 MK or so, so that elements such as oxygen, iron or magnesium are highly ionized. But coronal holes are cooler and the lower temperature is reflected in the degree of ionization of the elements. Using ratios of the ionization states of elements (for example, the abundance ratio of O^{7+} and O^{6+}, respectively oxygen ions with 7 and 6 electrons stripped away) measured in the solar wind, it is possible to determine the temperature of the corona at the height where the ionization/recombination time scale of the ions (which is increasing with distance from the solar surface due to the decreasing density) overcomes the expansion time scale of the accelerating solar wind. This is the 'freezing-in' temperature which can be used to differentiate between the regions of origin of the solar wind. The major result from Ulysses is that the boundaries between slow and fast solar wind streams are extremely sharp in the corona; in addition, it appears that the fast solar wind is accelerated much lower in the corona (at heights less than four solar radii) than previous models suggested. This, together with more detailed elemental abundance data, provides strong constraints on the major unsolved question as to how the solar wind is accelerated.

Observations of the magnetic field carried in the solar wind, along the high-latitude orbit of Ulysses, yielded three results which had not been predicted. One of these is that the magnetic field does not depend on latitude, but remains constant over the whole polar region of the Sun. It had been assumed that however complex the coronal magnetic field may be, at large distances it will appear to be approximately like a dipole, with stronger fields near its axis. As this is not the case, the implication is that magnetic fields become more evenly distributed in latitude close to the Sun than the dipole model implies. This finding is related to the non-radial expansion of the fast solar wind from the coronal holes to lower latitudes and confirms the overall structure of the heliosphere at solar minimum.

Two other properties of the high-latitude heliospheric magnetic field differentiate it from the interplanetary magnetic field observed near the ecliptic. Fluctuations in the direction of the magnetic field in the high-speed solar winds from the polar coronal holes were found to be very much greater than at low latitudes; it is important to note that the magnitude (or strength) of the magnetic field was relatively constant, only varying as a function of distance from the Sun. The directional fluctuations were most pronounced perpendicular to the radial direction from the Sun. These large-scale directional fluctuations, transverse to the flow of the solar wind, were identified as Alfvén waves, driven by the tension of the magnetic field lines. Such waves had been first identified in low-latitude data in fast solar wind streams, and attributed to a population of waves which travelled in the solar wind from the corona far into interplanetary space. At high latitudes, however, the waves had much larger amplitudes and covered a significantly wider range of periods than previously seen. This property of the high-latitude heliosphere is the result of a considerably reduced rate at which long-wavelength waves decay with distance from the Sun. The heliospheric medium is fundamentally a turbulent flow, in which lower-frequency (longer-wavelength) waves decay to give rise to waves of higher frequency. Turbulent processes in the solar wind are not well understood. The results of Ulysses at high latitudes indicate, when compared with the turbulent decay of waves in the equatorial region, that the large speed differentials in the solar wind found at low latitudes are responsible for the faster decay rate observed there. In the more uniform (and faster) flow speed of the solar wind in the polar regions large-amplitude magnetic fluctuations remain a prominent feature of the medium over larger distances than near the ecliptic.

This result leads directly to another unexpected observation made by Ulysses. Before these observations were made, it had been thought that the intensity of cosmic rays would be significantly higher over the poles of the Sun than in the ecliptic. As cosmic rays (highly energetic ions and electrons originating elsewhere in the galaxy) follow the lines of force of the magnetic field, they were expected to find access to the inner solar system easier over the solar poles where the magnetic field lines are less wound up into spirals by the rotation of the Sun. However, the intensity of cosmic rays showed a much less pronounced increase than expected as Ulysses reached high heliolatitudes. It appears that the large amplitude magnetic fluctuations at high latitudes effectively act as barriers which impede the propagation of cosmic rays into the heliosphere. This conclusion was well supported by the cosmic ray observations during the period when Ulysses moved rapidly from the south to the north pole in 1994–5, when the dependence on heliolatitude was not significantly complicated by either temporal changes or by a dependence on heliocentric distance. A summary of the cosmic ray intensity, as a function of heliolatitude, measured on Ulysses, is shown in figure 3, together with the model predictions based on our knowledge before Ulysses. As a result of Ulysses' observations, models of cosmic ray propagation in the heliosphere need significant revisions (see COSMIC RAYS: PROPAGATION IN THE HELIOSPHERE).

Overall, the observations made at high heliolatitudes by Ulysses have provided the basis for a better understanding of the solar wind and the heliosphere. Many of the results were seen as welcome confirmation of models extrapolated from the observations near the ecliptic plane. However, there were enough unexpected results to provide an *a posteriori* justification for the mission. Ulysses remains in orbit around the Sun to explore the same regions that it visited during solar minimum, to observe the changes in the solar wind caused by the increased solar activity at high latitudes during the next solar maximum in 2000–1. It is likely that these observations, which are likely to remain unique as no similar space mission is being planned at present, will provide a data base for future, possibly more refined,

Solar X-ray Jets

X-ray jets have been discovered on the Sun by the soft x-ray telescope aboard the Japanese YOHKOH satellite as transitory x-ray enhancements in the solar CORONA with apparent collimated motion. They are associated with small flares (microflares or subflares), which occur in x-ray bright points (XBPs, see SOLAR CORONA: X-RAY BRIGHT POINTS), emerging flux regions (EFRs, see CHROMOSPHERE: EMERGING FLUX REGIONS) and ACTIVE REGIONS (ARs). Whereas many XBPs occur in quiet regions and CORONAL HOLES, x-ray jets occur throughout the solar corona. As the spatial resolution and exposure time of soft x-ray observations increased, more and more x-ray jets were found. Hence, it could be that the solar corona is full of tiny unresolved x-ray (coronal) jets which are responsible for coronal heating and acceleration of the high speed SOLAR WIND.

There is a lot of evidence for MAGNETIC RECONNECTION in x-ray jets. In this sense, x-ray jets are also useful for studying the basic physics of magnetic reconnection.

Figure 1 shows a typical example of an x-ray jet that occurred in active region NOAA 7001 on 11 January 1992. This x-ray jet is one of the largest observed so far and could be a prototype of many other, smaller jets.

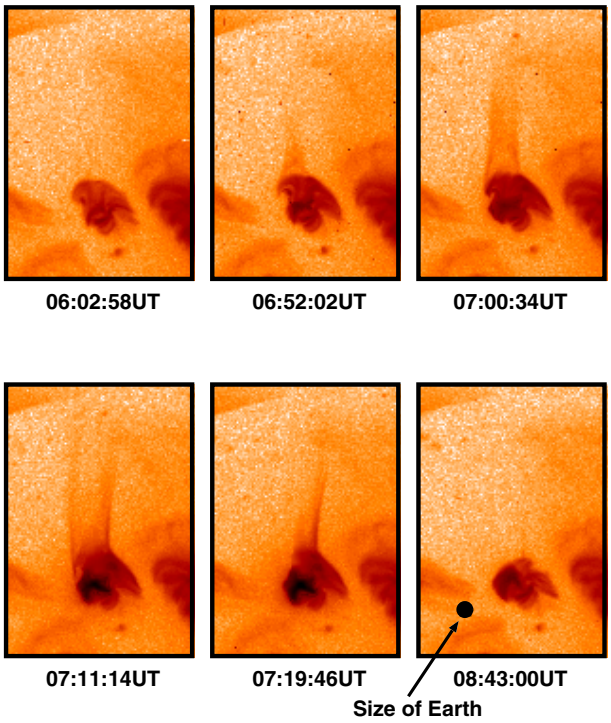

Figure 1. An x-ray jet occurred in NOAA7001 on 11 January 1992 (Shibata *et al* 1994 *Astrophys. J.* **431** L51). The size of each frame is 1200″ × 1040″ (≃ 8.6×10^5 km by 7.5×10^5 km). These are negative images. North is at the top and west is to the right. The maximum length of the jet was greater than 3×10^5 km and the width was about 7.5×10^4 km. The apparent velocity changed with time and was 90–230 km s^{-1}. The active region at the footpoint of the jet looks like a sea anemone, and so is called an *anemone-AR*. The surrounding region is a coronal hole. During the ejection of the jet, a bright loop appeared (as a result of a small flare) about 3×10^4 km south of the footpoint of the jet, while the loop system just below the jet disappeared at 0721 UT. The boundaries of the jet moved apart at a speed of ∼ 20 km s^{-1}, increasing the apparent width of the jet. The west boundary of the jet continued to move even after the east boundary had disappeared, giving an impression of whip-like motion.

Observed properties

Structure/morphology and dynamics

Most jets are associated with small SOLAR FLARES (microflares, subflares) at their footpoints. The length of the jets is a few 10^4–4×10^5 km (average ≃ 1.5×10^5 km), their width is 5×10^3–10^5 km (average 1.7×10^4 km), their aspect ratio (= length/width) is 3–27 (average ∼ 10), their apparent velocity is 10–1000 km s^{-1} (average ≃ 200 km s^{-1}) and their lifetime ranges from a few minutes to more than a few hours. The number of jets decreases as the length, the velocity or the lifetime increases. The histograms (figure 2) are similar to those of flares and EUV explosive events. Many jets (∼ 68%) appear in or near to active regions (ARs). Among the jets ejected from bright-point like features in ARs, most (∼ 86%) are observed to the *west* of the active region. The x-ray intensity distribution along an x-ray jet often shows an *exponential* decrease with distance from the footpoint.

Temperatures, densities and energies

The average temperatures of jets are ∼ 3–7 MK, which is comparable to that of the microflares at the footpoints of the jets, and the average electron densities are 0.3–4×10^9 cm^{-3}. The total thermal energy is 10^{26}–10^{28} erg, which is about 1/10 of the total (released) thermal energy of the footpoint flare. The masses of the jets are 10^{11}–10^{13} g and their kinetic energy is estimated to be 10^{25}–10^{27} erg.

Magnetic fields and evidence of reconnecting fields

Co-alignment of soft x-ray images with magnetograms (taken at ground-based observatories) revealed that 72% of jets occur in mixed polarity or satellite polarity regions. This gives direct evidence for the presence of neutral points (or current sheets) near the footpoint of jets. X-ray jets favor regions of evolving magnetic flux (increasing or decreasing). This suggests that x-ray jets are produced by magnetic reconnection.

There is much direct and indirect evidence for magnetic reconnection in jets:

(a) *Two types of interaction between emerging flux and coronal field*: There are two types of interaction (reconnection) between emerging flux and coronal field: the *anemone-jet* type and the *two-sided-loop/jets* type (figure 3). The former occurs when emerging flux appears in coronal holes. In this case, a jet is ejected in a vertical direction. On the other hand, the latter occurs when emerging flux appears in quiet regions, and two-sided loop brightenings (or jets) occur in the horizontal direction on both sides of the emerging flux.

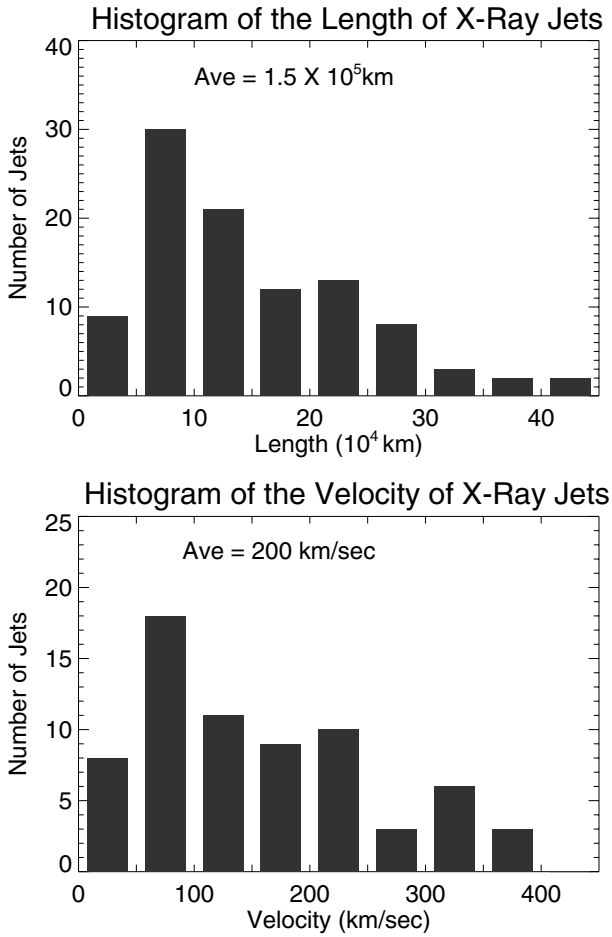

Figure 2. Histograms of velocity and length of x-ray jets (Shimojo *et al* 1996 *Publ. Astron. Soc. Japan* **48** 123).

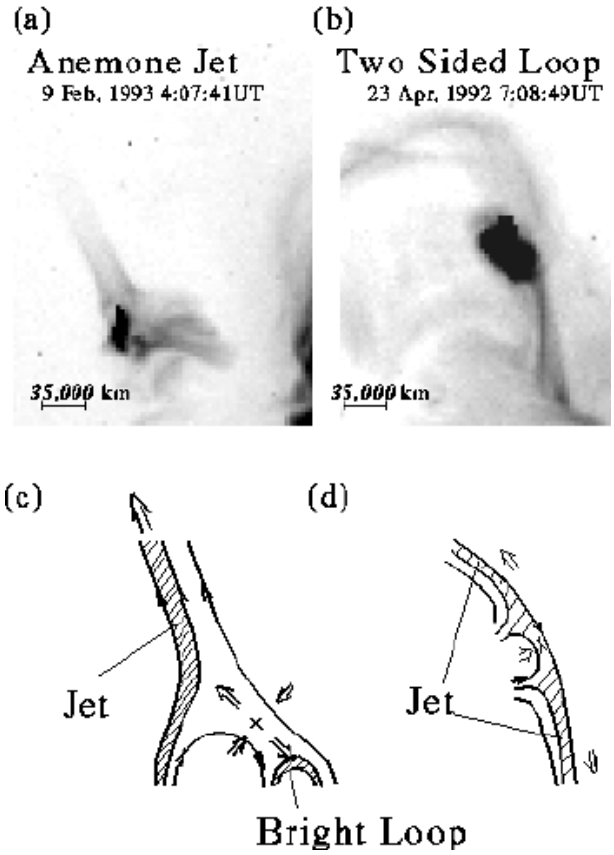

Figure 3. Soft X-ray Telescope images (from Yohkoh) of two types of interaction of emerging flux with overlying coronal magnetic fields. (*a*) *Anemone-Jet* type observed on 9 February 1993. (*b*) *Two-sided-loop* type observed on 23 April 1992. Schematic illustration of (*c*) *anemone-jet* type and (*d*) *two-sided-loop* type (Yokoyama and Shibata 1995 *Nature* **375** 42).

(b) *Converging shape of jets*: The width of the jets often decreases with height (i.e., *converging* shape), which is similar to the shape of Hα surges observed in emerging flux regions and EUV macrospicules. This shape suggests that the cross-section of the flux tube decreases with height, i.e., the field strength increases with height. Such situations arise if there is a neutral point near the footpoint of a jet as in the *anemone-jet* model in figure 3. This situation is expected also when the satellite spots appear in an opposite polarity region, and in fact such magnetic field properties have been confirmed by comparing magnetograms with soft x-ray images of many jets as discussed above (figure 4).

(c) *A gap between the footpoint of a jet and the brightest part of a footpoint flare*: Though the footpoints of jets roughly correspond to small flares, close examination of the footpoints has revealed that often small flares (or loop brightenings) occur separately (by more than a few thousand km) from the exact footpoints of jets. This characteristic is also seen in tiny XBP jets. Such a gap is expected for the magnetic reconnection mechanism, because the heated reconnected field lines are quickly ejected in opposite directions to form one bright loop and a separate jet in the other direction (figure 3).

(d) *Change of topology of a footpoint active region*: When the ARs at the footpoints of jets can be resolved well, their morphology changes substantially during the occurrence of a jet. For example, a loop system disappeared during the jet of 11 January 1992 (figure 1).

(e) *Whip-like motion of jet*: In some cases, a jet moves perpendicularly to the jet axis at a few 10 km s^{-1} during the ejection of the jet, which has been referred to as *whip-like motion* (figure 1). This might be evidence of a dynamical rearrangement of the magnetic field configuration as a result of reconnection.

Relation to other dynamic phenomena

Hα surges: Sometimes, x-ray jets are observed to be associated with Hα SURGES, nearly simultaneously and in nearly the same direction. There are also cases with no x-ray jet when Hα surges are observed. This is probably

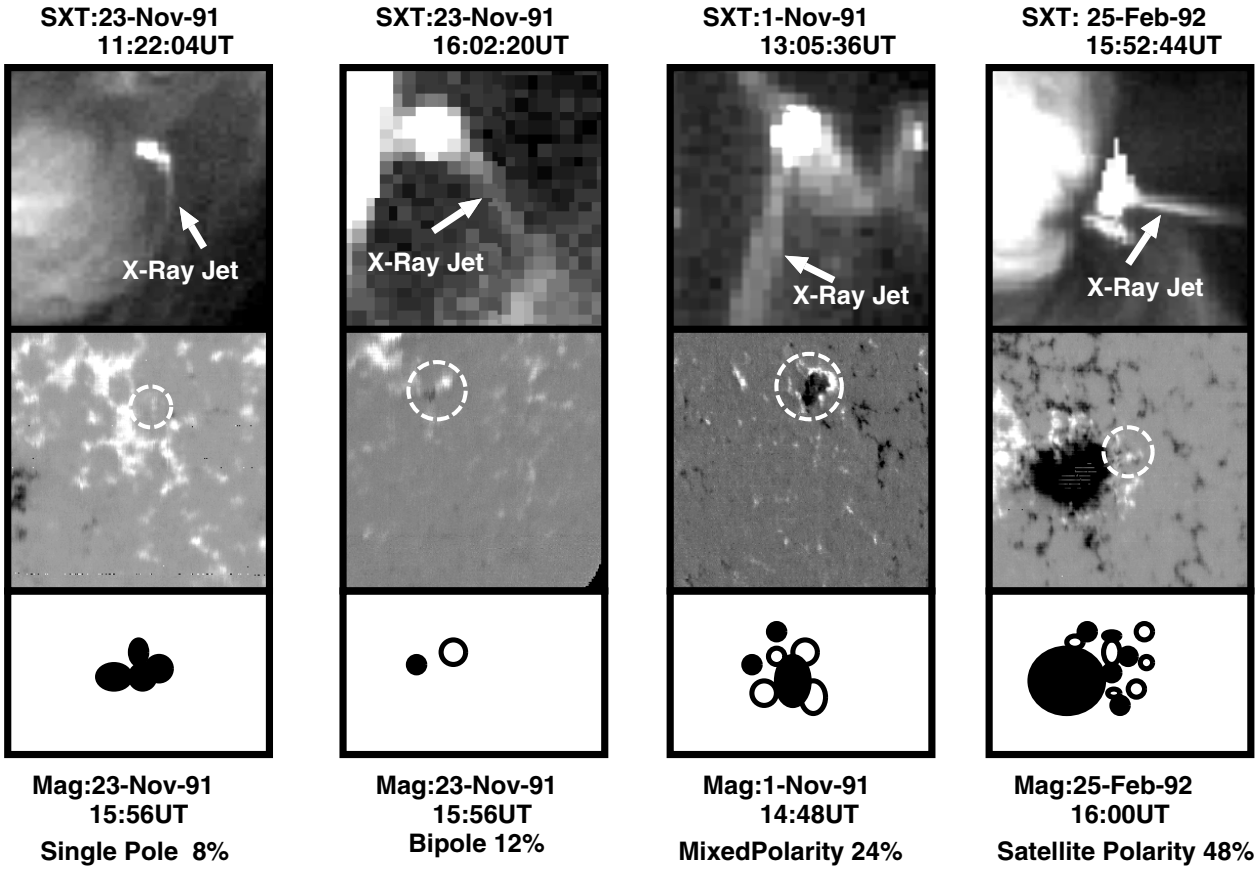

Figure 4. Examples of the magnetic field properties of x-ray jets (Shimojo *et al* 1998 *Solar Phys.* **178** 379). The first row shows x-ray jet images taken by the *Yohkoh* Soft X-ray Telescope. The second row are the corresponding magnetograms with white circles indicating the footpoint of the jets. The third row shows schematic illustrations of magnetic field configuration types.

because the density of the hot jet is too low to be observed by a soft x-ray telescope.

Type III bursts: Type III radio bursts (see SOLAR FLARES: RADIO BURSTS) are often associated with x-ray jets. This implies the existence of high-energy electrons in these small flares and jets, and supports the view that the generation mechanism of x-ray jets and microflares may be physically similar to that for larger flares.

Nanoflares: It was found that very faint transient soft x-ray brightenings occur in polar regions. The absolute soft x-ray intensity of these brightenings is two orders of magnitude smaller than those of active region transient brightenings, and fluctuates on a timescale of a few minutes. The total (released) energy is probably comparable to 10^{24} erg, i.e., that of nanoflares. The polar coronal holes are found to be very active and full of nanoflares, and tiny x-ray jets often occur from these nanoflares.

X-ray plasma ejections: The *Yohkoh* soft x-ray telescope has discovered another new ejection feature, *x-ray plasmoids* (or *x-ray plasma ejections*). X-ray plasmoids are blob-like hot plasma ejections, and are sometimes seen as an erupting x-ray loop. They are ejected not only from long duration flares but also from compact impulsive flares, so that they may be evidence for magnetic reconnection occurring above the soft x-ray loop. Although x-ray plasmoids are morphologically very different from x-ray jets, there are common properties in both hot plasma ejections. Table 1 summarizes the physical conditions of both x-ray jets and x-ray plasmoid ejections.

Coronal mass ejections: Some large jets have shapes intermediate between well-collimated jets and loop-like ejections which resemble a SOLAR CORONAL MASS EJECTION (CME).

The physics of x-ray jets/mechanisms of formation

Various observations suggest that magnetic reconnection is actually occurring during the ejection of x-ray jets. Hence the magnetic reconnection mechanism is a most promising energy release mechanism for x-ray jets. The current sheet for the magnetic reconnection mechanism is created in the following situations: (1) the current sheet is created between emerging flux and the coronal field (emerging flux model; see figure 5), (2) the current sheet is created between a horizontally moving bipole and the network field (converging flux model), (3) the current

Table 1. Physical quantities of x-ray jets and x-ray plasmoids (based on Ohyama *et al* 1997 *Adv. Space Res.* **19** 1849).

	X-ray jets	X-ray plasmoids
Temperature (10^6 K)	4–6	5–16
Density (cm^{-3})	3×10^8–4×10^9	10^9–10^{10}
Mass (g)	10^{11}–10^{13}	10^{13}–10^{14}
Thermal energy content (erg)	10^{26}–10^{28}	10^{28}–10^{29}
Kinetic energy (erg)	10^{25}–10^{27}	10^{27}–10^{28}
Thermal energy of flare (erg)	10^{27}–10^{29}	10^{29}–10^{30}
GOES class of flare	B–C class	M class

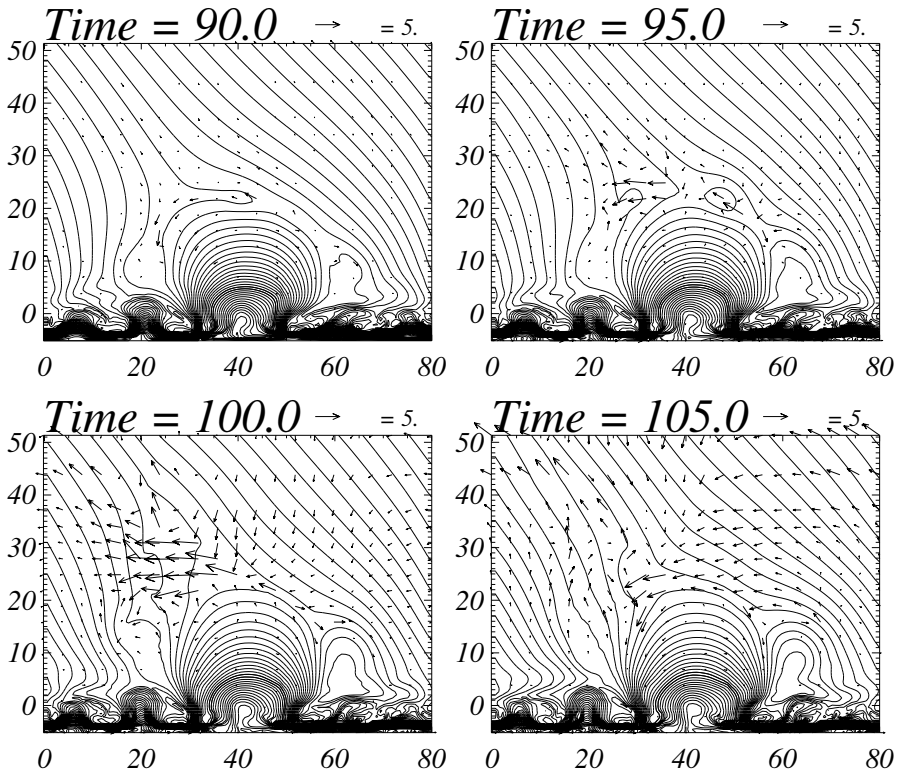

Figure 5. Emerging flux reconnection model of x-ray jets (from a 2D MHD numerical simulation of reconnection driven by emerging flux (Yokoyama and Shibata 1996 *Publ. Astron. Soc. Japan* **48** 353)).

sheet is created between sheared flux and pre-existing flux (sheared flux model).

There is no doubt that x-ray jets exist along magnetic field lines, and hence are collimated by a magnetic force. As for the acceleration mechanism of x-ray jets, there still remains a fundamental question: How are jets accelerated in the magnetic reconnection process described above? There are three possible processes.

Evaporation flow (jet)
An evaporation flow (jet) occurs as a result of a flare that is produced by the reconnection. In this case the jet is accelerated by the *gas pressure gradient force*, which is enhanced by sudden heating of plasmas in the upper chromosphere due to heat conduction flux or high energy electron beams propagating from the flare energy release site. The maximum velocity of an evaporation jet is of the order of

$$V_{\text{ev-jet,max}} \sim 3C_s \simeq 1500 \left(\frac{T}{10^7\ \text{K}}\right)^{1/2} \ \text{km s}^{-1} \qquad (1)$$

where C_s and T are the sound speed and temperature of the flaring plasma, respectively. The apparent velocity of the constant density part of the jet is about 30–300 km s^{-1}, if the density of the jet is 20–40% of that of the flare, consistent with the apparent velocities of many x-ray jets.

Magnetic twist
A magnetic-twist jet is accelerated by the *magnetic pressure force* in a relaxing magnetic twist as a result of reconnection

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills, Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

between a twisted loop and an untwisted loop. If the density of the jet is much higher than that of the ambient corona, the maximum velocity of the magnetic-twist jet becomes

$$V_{\text{mt-jet,max}} \sim 2v_A \simeq 2000 \frac{B}{10\ \text{G}} \left(\frac{n}{10^9\ \text{cm}^{-3}} \right)^{-1/2}\ \text{km s}^{-1} \quad (2)$$

where v_A is the Alfvén speed, B is the magnetic flux density and n is the hydrogen number density, but again the apparent velocity of the constant-density part of the jet is of the order of 15–300 km s^{-1} if the density of the jet is 20–40% of that of the flare.

Reconnection jet
A reconnection jet is accelerated (like a slingshot) by the *magnetic tension force* in the reconnection process. The velocity of the jet is of the order of the local Alfvén speed

$$V_{\text{rec-jet}} \sim v_A \simeq 1000 \frac{B}{10\ \text{G}} \left(\frac{n}{10^9\ \text{cm}^{-3}} \right)^{-1/2}\ \text{km s}^{-1}. \quad (3)$$

The velocity of magnetic islands (or plasmoids or expanding helical loops ejected from current sheet) is also comparable to the local Alfvén speed.

Since the observed velocities of many jets are within the range of possible speeds from the above mechanism, at present it is not possible to identify which jets belong to which type. We need more detailed theoretical modeling as well as finer observations such as Doppler shift measurements.

Solar–Stellar Connection

The solar–stellar connection refers to the complementarity of solar and stellar studies in general, and to those concerning dynamic phenomena in stellar outer atmospheres in particular. The most important agent in these phenomena is the stellar magnetic field, although wave motions associated with convection also play a role.

The Sun is the only star that offers the potential to observe its internal structure (through helioseismology) and the dynamic geometry of its (outer) atmosphere (SOLAR TELESCOPES AND INSTRUMENTS: GROUND, SPACE) in great detail. On the other hand, observations of stars like the Sun provide tests of our understanding of the physical processes that determine solar structure and dynamics because we can use the diversity of the stellar population to probe dependences on, for example, chemical composition, mass, rotation rate or binarity. In traditional astrophysics, the combined study of the quasi-steady properties of Sun and stars in general have deepened our understanding of the solar interior, of solar evolution and of radiative transfer in stellar atmospheres (SOLAR SPECTROSCOPY AND DIAGNOSTICS).

Whereas effects of solar magnetic activity have been studied ever since the discovery of sunspots by European observers in the early 17th century (although the phenomenon was already reported on at least 23 centuries ago), the study of the stellar equivalent had to wait until the second half of this century. Pioneering studies of stellar chromospheres, that is of the relatively warm layers immediately above the stellar surface, in the 1950s by Olin C WILSON at MOUNT WILSON OBSERVATORY, gave the study of stellar magnetic activity its initial momentum, which has continued to grow over the years. By now we know that stellar outer atmospheric processes that occur on time scales of up to centuries rather than millions of years are the result of the fact that most stars like the Sun have magnetic fields threading their surfaces.

Stellar magnetic activity is characterized by highly structured magnetic fields at the stellar surface that persist for times much longer than the local time scales for convection. The fields at the stellar surface lie beneath volumes within the outer atmosphere in which the temperatures significantly exceed that of the surface and which show up as bright at selected wavelengths. The details of the mechanisms heating those domains are still unclear, but models either rely on the dissipation of electric currents or on the damping of a variety of waves traveling through the magnetic field. The amount of energy involved and the way it is distributed over the different temperature domains in stellar outer atmospheres depends on the magnetic flux density at the surface, and appears to adhere to the same rules regardless of stellar structure: the Sun and almost all other cool stars define simple relationships between radiative losses from different domains in their outer atmospheres that are independent of stellar properties. The energies involved in any outer-atmospheric layer extend well beyond the range seen on the Sun, however.

Through the solar–stellar connection we have learned that the Sun is a rather inactive star, typical of its class. We now know that some stars show activity cycles, like the Sun, but that these actually form a minority. The levels of activity in cool stars cover an enormous range. The most active stars have more than 50% of a visible hemisphere covered by dark starspots, suggesting that most of their surface is in fact covered by a strong magnetic field, only part of which 'condenses' into dark spots. In inactive stars, the coverage by spots is insufficient to be detectable by current white-light instruments, but there the associated emissions from the hot outer atmosphere can be used as a measure of activity. Inactive giant stars have been observed for which the entire stellar corona, with temperatures exceeding 1 million kelvin, is dimmer than the darkest coronal regions on the Sun (the so-called coronal holes).

We have also learned that tidal interaction between companion stars in compact binary systems enhances activity, that stellar rotation is slowed over time by stellar winds flowing away from cool stars, that heating of the outer atmosphere occurs both because of the action of the magnetic field and because of the damping of purely acoustic waves, and that convection requires rotation to excite a globally functioning dynamo that can generate and maintain the stellar magnetic field. The following sections provide more information on each of these topics.

A brief historical perspective

Signatures of stellar magnetic activity have been observed for almost a century now through the white-light modulation caused by the stellar equivalent of large sunspots, or clusters of these, rotating onto and off stellar disks. Early this century, emission components were discovered in the cores of the chromospheric H and K resonance lines of singly ionized calcium in the spectra of many stars of spectral type G and cooler (the solar spectral type is G2V). The discovery paper by Karl SCHWARZSCHILD and Eberhard, published in 1913, was followed by a stream of usually brief papers publishing results on one or a few stars. In the early 1950s, a vigorous study of the Ca II H and K resonance lines in stellar spectra was started by Olin C Wilson at Mount Wilson Observatory. This research has continued to date, and has resulted in records of stellar chromospheric activity, with frequent if not daily observations spanning more than two decades for about 100 stars in the solar neighborhood.

In the last two decades of the twentieth century, a series of spacecraft were launched to observe the (extreme) ultraviolet and (soft) x-ray signatures of stellar activity. The HEAO-B EINSTEIN Observatory and the INTERNATIONAL ULTRAVIOLET EXPLORER were the first to observe extensive samples of cool stars at these short wavelengths with low but useful spectral resolution. Later the spectroscopic capabilities of the EXTREME ULTRAVIOLET EXPLORER and of instruments on the HUBBLE SPACE TELESCOPE

provided much more detailed spectral information from which atmospheric densities and temperatures could be derived.

Convection and acoustic phenomena

As we work down in mass from heavier (hotter) to lighter (cooler) stars on the main sequence (generally referred to as dwarf stars or even simply as dwarfs), near-surface convection sets in around a surface effective temperature of ≈9000 K (Sun: 5770 K) and persists down to the coolest red dwarf. For evolved (sub-)giant stars, in which the hydrogen in the core is exhausted, the convection sets in at progressively lower surface temperatures with decreasing surface gravity. Stars with a surface temperature below this onset temperature are referred to as cool stars. For main-sequence stars, the ratio of the depth of the convective envelope to the stellar radius increases with decreasing effective temperature; the coolest main-sequence stars are entirely convective. In absolute terms, however, the depth of the convective envelope is about the same for all of these stars cooler than the Sun, but the stellar radius decreases with surface temperature. For giant stars, the convective envelope deepens steadily with decreasing temperature, and therefore with age, at least during the initial phases of post-main-sequence evolution; for these evolved stars, the convective envelopes become very deep as the stars expand, reading depths up to ten times the solar radius.

Stars with masses $M_* \lesssim 1.3\,M_\odot$, where $M_\odot$ is the solar mass, maintain a convective envelope throughout their main-sequence and post-main-sequence evolution up to the giant branch, i.e. as long as nuclear fusion persists. In contrast, more massive stars have no convective envelope on the main sequence or in the early post-main-sequence phase, but develop one after crossing the dividing line for convective envelopes in the HERTZSPRUNG–RUSSELL DIAGRAM.

Convective motions generate sound waves. This happens most efficiently just below the stellar surface where the plasma velocities are largest in order to be able to transport the stellar luminosity despite the low specific heat of the plasma at the low densities there. With the velocity, the wave power increases with decreasing surface gravity, and of course with increasing luminosity. Waves that are reflected near the surface (either directly or after being deflected upward after traveling inward) are used in helioseismology. Waves with a frequency above the acoustic cut-off frequency penetrate into the outer atmosphere, i.e. into the part of the atmosphere above the layers emitting the bulk of the stellar luminosity.

In the outer atmosphere, the density decreases rapidly within the first few hundred kilometers above the surface as a consequence of the strong stratification: the pressure scale height is only of the order of 100 km in main-sequence stars. Energy conservation results in a dramatic increase in the amplitude of the sound waves as they travel upward, until the waves develop into rapidly dissipated shock waves. The chain of processes involved, from radiation damping in the stellar photosphere to the dispersive and dissipative behavior of weak shocks, strongly reduces the dependence of acoustic energy deposition on surface gravity. Complementary solar and stellar observations suggest that sound waves result in a so-called basal emission from, primarily, the chromosphere. The basal emission depends on surface temperature, but little on gravity or chemical composition. The basal atmosphere consists of rapidly evolving, localized, fluctuating brightenings that recur a few times as trains of shock waves travel by.

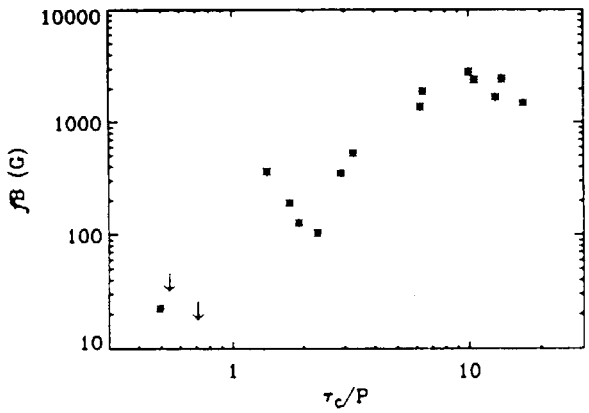

Figure 1. The measured average surface flux density of magnetic field versus the Rossby number in a sample of main-sequence stars. The Rossby number is the ratio of the convective turnover time scale τ_c for convection at the bottom of the convective envelope to the stellar rotation period P, and thus a measure for the effectiveness of Coriolis forces in affecting the circulation of mass. The figure shows how magnetic activity increases with rotation rate.

The basal emission was discovered initially in stellar data through the comparison of radiative losses from different temperature domains in the outer atmospheres of cool stars. It found subsequent empirical support in solar data with spatial and temporal resolution that demonstrated the absence of intrinsically strong magnetic fields at those locations from which this basal, pulsating chromospheric emission originates.

Solar and stellar magnetic fields

Magnetic field at the stellar surface

Cool stars other than the Sun have similar magnetic fields, but attempts to measure these fields by means of the polarization of Zeeman components in spectral lines necessarily fail, because the polarities of the field are strongly mixed, so the net polarization signals from neighboring unipolar patches cancel almost entirely (see SOLAR MAGNETIC FIELD: ZEEMAN AND HANLE EFFECTS). Strong fields with sufficiently large filling factors are detectable, however, by a broadening of Zeeman-sensitive spectral lines even in the unpolarized intensity spectrum. Note that measurements in the visual spectrum severely underestimate the contributions of starspots to the total magnetic flux because of their relative darkness.

Moderately active stars of spectral types G and early K have intrinsic field strengths B ranging from 1.0 to 1.9 kG, and fractional surface coverage (or surface filling factor) f ranging from about 1.5% to 35% (see figure 1). The very active Ke and Me stars (i.e. stars with chromospheric lines in emission over the nearby continuum) exhibit B up to 4.2 kG and f up to 70%. These field strengths are compatible with predictions from stellar atmospheric models based on the solar example, which have the field strength dictated by a balance between gas and magnetic pressures. For evolved giant stars, B decreases from $B \simeq 650$ G for early G-type giants to 400 G at K5 III, in accord with the decreasing gas pressure at the surface.

Starspots and stellar active regions

As stars rotate, their outer atmospheric signal as detected on Earth is modulated, because of the inhomogeneous coverage of their surface by magnetic field. This causes the observed signal to change as regions rotate into and out of view. The resulting signal is too confusing to interpret for stars with rotation rates like that of the Sun. For much more active stars, such as the rapidly rotating tidally interacting binaries, the signal is less ambiguous. Their active regions, the regions of strong, bipolar magnetic activity, can be very different from solar ones. Observations of one such binary, AR Lac, for example, show that the surface filling factor for active regions varied from 2% to 20% over the years. The associated mean radiative flux density from its active regions in the chromospheric Mg II resonance lines somewhat exceeds the very top of the flux range observed for stars as a whole, as one would expect. It is, however, three times larger than the flux from the brightest non-flaring parts of SOLAR ACTIVE REGIONS, while for the areas surrounding these bright regions, a flux density was inferred comparable to the flux density for an average solar active region. Clearly, the activity of this binary star is not reflected by a solar counterpart.

Modeling light curves of spot-studded stars is often the only way to obtain information on active regions on stars, but the derived information can be ambiguous. The observed signals may show reasonably large amplitudes, with long-term coherence, so that simple light-curve analyses require only a few, typically two, spot groups to match much of the modulation curve. Yet many more spots or spot regions may exist that would result in a similar light curve. What is abundantly clear, however, is that these spots or spot complexes can be very substantial. XX Tri and II Peg are extreme examples, with amplitudes in the visible of 0.6 and 0.5 magnitudes, or factors of 1.7 and 1.6 respectively. For II Peg this amounts to a spot coverage of 60% of one hemisphere, whereas for the Sun the spot filling factor never exceeds 0.2%. Spot temperatures (generally taken to be the same for all spots on a star, averaging over the dark umbrae and the less dark, more horizontally structured penumbrae) appear to lie some 500 K to 2000 K below the ambient surface temperature, with an average temperature difference of the order of 1000 K.

For sufficiently rapidly rotating stars, emissions from various features on stellar disks are subject to Doppler shifts associated with the line-of-sight component of the rotational velocity. These shifts can be used to make crude Doppler maps of the surface. In two thirds of the active stars for which such surface maps have been made, indications have been found for spots at high latitude or even at the rotational poles. This set of stars is dominated by tidally interacting RS CVn binaries, but also includes young T Tauri stars, single rapidly rotating FK Comae stars, and W Uma (near-)contact systems. No clear correlation has been found between stellar class and the occurrence of polar starspots. The existence of high-latitude starspots in rapidly rotating stars may be the consequence of strong Coriolis forces on flux rising from deep within the star, which are expected to deflect rising flux bundles towards latitudes of up to 60°. Truly polar spots could result either from flux eruption originating very deep in stars with relatively small radiative interiors, or by a pole-ward slip of the previously anchored deep segments of flux rings following an earlier eruption of flux at mid latitudes elsewhere on that ring.

The distribution of sizes and lifetimes of stellar active regions have not yet been determined, leaving the Sun as the only star for which this information is known. A lower limit to the lifetimes of stellar active regions is probably given by the lifetimes of (clusters of) starspots, but even these are difficult to determine. The most active stars, the tidally interacting RS CVn binaries, have had spots reported that appear to live from a few months up to several years, although significant changes from one rotation to the next have been reported, suggesting that small-scale changes to the spots, or more likely to spot groups or nests, occur on a time scale of no more than weeks.

For the Sun, the size distribution of active regions is a monotonically decreasing function of region size, extending from the smallest ephemeral regions up to the largest active regions. For regions larger than ephemeral regions, that distribution is independent of the phase of the solar cycle, only changing by a multiplicative factor. Lifetimes increase from only hours for ephemeral regions to about two weeks for the largest active regions, before the flux is effectively distributed into the surrounding quiet regions.

Atmospheric structure

Diagrams relating the radiative losses from the different temperature domains in the outer atmospheres of cool stars show a remarkably high degree of correlation (figure 2). It appears that the radiative flux densities are related through power-laws, such that two flux densities $F_{i,j}$ are related through $F_j \propto F_j^{\beta_{ij}}$. These power-law relationships are independent of the stellar effective temperature or surface gravity, provided that the basal emission component is removed. The relationships then hold for stars ranging from early F-type where convection sets in, to mid M-type stars, and from main-sequence

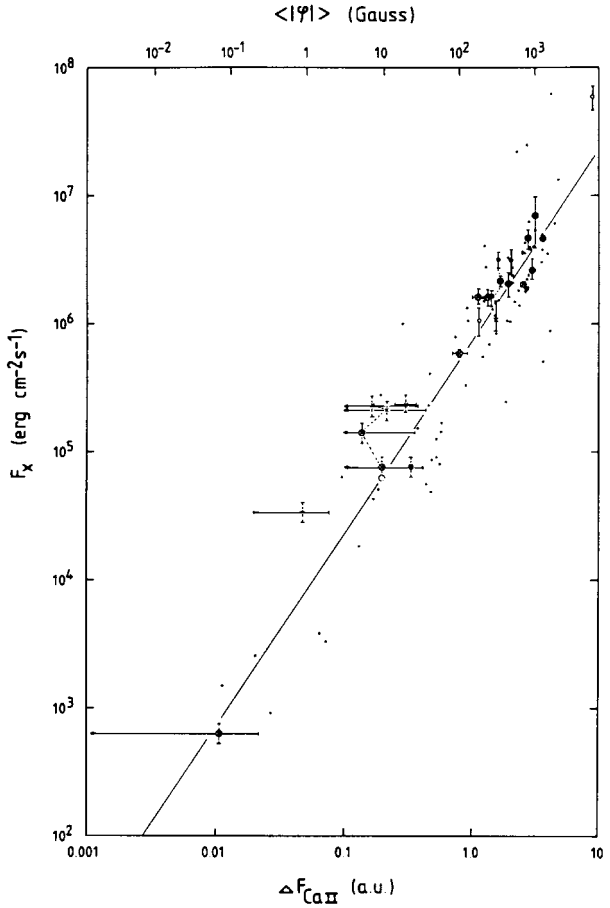

Figure 2. Relationship between the soft x-ray flux density, F_X (0.05–2 keV; observed with EXOSAT's CMA/L1 assembly), and the Ca II H+K excess flux density ΔF_{CaII} (one unit equals 1.3×10^6 erg cm^{-2} s^{-1}). The line is a power-law with slope 1.5. EXOSAT and Mount Wilson Ca II H+K measurements were obtained within three days for 13 of the stars, and within three months for the others. Small dots are used for the comparison of Einstein IPC and Mount Wilson Ca II H + K flux densities that were measured up to several years apart. The scale at the top of the diagram translates the Ca II H + K emission to the equivalent average magnetic flux density.

stars up to at least luminosity class II–III of the semi-bright giants; the only exception is formed by the M-type main-sequence stars beyond $B - V \approx 1.3$. The scatter about the mean relationships is caused by measurement uncertainties, intrinsic stellar variability, and differential limb darkening. The steepness of these relationships increases as the difference in the formation temperature of the two diagnostics used increases, with the most extreme cases being close to quadratic relationships.

Solar data observed with moderate spatial resolution of several thousand km up to about 10 000 km exhibit the same relationships as the disk-integrated signal for stars. Surprisingly, stellar power-law relationships extend beyond the range of flux densities seen in spatially resolved solar data: in the coronal soft x-ray emission, the stellar relationship spans more than five orders of magnitude, ranging from an order of magnitude dimmer than a solar coronal hole, to more than two orders of magnitude brighter than an average solar active region. The combination with solar data has allowed a calibration of the stellar radiative losses in terms of magnetic fields (figure 2), showing that chromospheric losses scale roughly as the square root of the magnetic flux density, and coronal soft x-rays scale roughly linearly.

The agreement of the solar and stellar relationships between radiative losses is surprising given their nonlinear character. After all, simply increasing the number of active features on a stellar disk should have resulted in linear scaling relationships for stars, even if the locally valid relationships are nonlinear. The analysis of solar information has shown that the distribution of magnetic flux over the solar surface is the key behind this invariance of relationships: the histogram of flux densities over the solar and (by inference) stellar surfaces is such that it preserves the nonlinear character upon integration over the visible hemisphere. The requirements this puts on the dynamo and the surface dispersal of flux have yet to be explored.

Chromospheric modeling for stars is complicated because of the high degree of structure and the effects this has on radiative transfer. A comprehensive atmospheric model is hampered by the fact that for a star like the Sun, the chromospheric emission is dominated by the relatively quiet regions, while the coronal emission is dominated by the active regions, thus making it impossible to develop a consistent model in the absence of knowledge of the detailed surface distribution of magnetic field.

Main-sequence stars of moderate activity show a dominant coronal emission component at about 2–4 MK, which is generally assumed to be directly comparable to the most common component in the quiescent solar corona, i.e. a combination of relatively stable active-region and quiet-region magnetic arches or loops. A hotter component exists on more active dwarf stars, and on evolved stars in general, even in the absence of obvious large-scale flaring. The peak contribution of this component lies between about 7 MK and 15 MK.

The determination of dimensions of coronal magnetic loops in stellar coronae can be made if the characteristic mean coronal electron density within the loops contributing most to the observed spectrum is known. For the handful of stars for which coronal density diagnostics have been measured, the characteristic densities estimated from diagnostics for coronal components around 3 MK are typically about three orders of magnitude lower than those found for the hotter components around 10–15 MK. The associated high volume emission measure (proportional to the square of the electron density) of the hotter component implies that the volume filling factors of the hotter components are several orders of magnitude smaller than those associated with the 3 MK component. Perhaps we

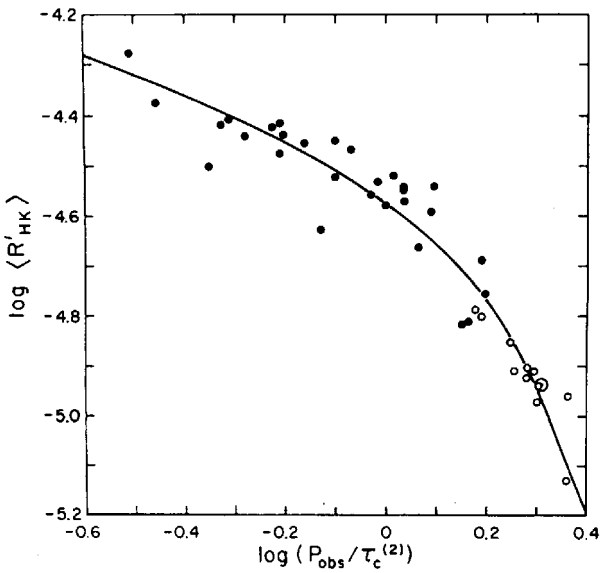

Figure 3. The ratio $R'_{\rm HK}$ of the emission from the chromosphere in the cores of the Ca II H and K lines, after subtraction of a photospheric contribution (including the basal flux), to the total bolometric emission of these main-sequences stars versus the ratio of the rotation period to a color-dependent scaling function $\tau_{\rm c}^{(2)}$ that resembles the convective turnover time at the bottom of the convective envelope for a mixing-length model with a mixing length of two pressure scale heights. Open and closed circles indicate stars below and above the so-called Vaughan–Preston gap, respectively, separating stars with predominantly regular cycles below the gap from those with irregular cycles or non-cyclic behavior above it.

are looking at the signature of a multitude of small, compact, short-lived brightenings occurring over a substantial part of the stellar surface but with a small volume filling factor.

The magnetic dynamo

The outer-atmospheric activity in cool stars has its roots in what is referred to as the dynamo. No comprehensive theoretical model for stellar dynamos has yet been developed (see DYNAMO THEORY). Empirically, however, we have inferred a substantial body of information. For example, we know that a dynamo resulting in magnetic activity appears to operate in all rotating stars with a convection zone directly beneath the photosphere. In single stars, the dynamo strength is a continuous, and largely monotonic, function of rotation rate (figure 3), at least down to the intrinsic scatter associated with stellar variability. It also depends on some other stellar property or properties, but that dependence has not yet been unambiguously determined.

Atmospheric radiative losses associated with magnetic activity observed for main-sequence stars of a given rotation period—and by inference also the dynamo efficiency—increase rapidly with increasing depth of the convective envelope from the onset of convection up to about $B - V \approx 0.6$. A similar increase is inferred for (sub)giants.

A globally functioning dynamo requires only vigorous envelope convection and rotation, but not necessarily a boundary layer between a radiative interior and a convective envelope, because even the fully convective M-type dwarf stars exhibit magnetic activity.

Among the cool main-sequence stars, there is a variety of patterns of variability in their activity; only a minority fraction of these stars show cyclic variations that resemble that of the Sun. For main-sequences stars with moderate to low rotation rates, activity tends to be cyclic, but no clear trend of cycle period with stellar parameters has been found. For truly active stars, various variability patterns exist, but generally no unambiguous activity cycle is seen. The relatively active stars never reach low states of activity on the timescale of years to decades; perhaps multiple sunspot cycles are present on the surface (i.e. a more extreme overlap of successive cycles than seen for the solar cycle), or perhaps the dynamo merely varies around an average state of quasi-permanent activity.

The atmospheric radiative losses appear to 'saturate' for stars with rotation periods below about one or two days, but it remains unclear whether this reflects (i) a saturation in the dynamo action, (ii) in the heating mechanism, or (iii) in the photospheric flux content through increased annihilation of opposite polarities.

The presence of a companion star enhances the dynamo action in cool components of tidally interacting binaries not only by enforcing rapid rotation through tidal interaction (see below), but presumably also by affecting the pattern of differential rotation.

Stellar winds

Measuring the properties of STELLAR WINDS that, like the solar wind, are at coronal temperatures of around a million degrees is difficult, because the tenuous material has little effect on the x-ray, UV and visible spectra emitted by the central star and its outer atmosphere. Winds may be detected through radio and near-IR free–free emission, but only with difficulty even in favorable cases. That mass loss occurs is primarily an inference based on the solar example and the observed effects on the stellar rotation rates.

Despite the existence of at least some potential diagnostics, only upper limits have been derived for mass loss rates of cool stars on the main sequence or in the early phases of post-main-sequence evolution. For late-A and early-F type stars and for a few M-type dwarfs, upper limits to the mass loss have been found of 10^{-10}–$10^{-9}\ M_\odot\ {\rm yr}^{-1}$, which may be far above actual values (the solar mass loss is $\approx 2 \times 10^{-14}\ M_\odot\ {\rm yr}^{-1}$).

For most stars well away from the main sequence, the mass loss rates are large, and the winds cool; in late-K and M-type (super-)giants, (much of) the wind is at chromospheric temperatures, which makes detecting signatures of the wind easier. One case for a cool main-sequence star is V741 Tauri, in which a white dwarf revolves around a K2V star. It has a wind at a velocity

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

of 600–800 km s^{-1}, a wind temperature of no more than a few times 10^4 K, and a mass loss rate of a few times $10^{-11}\,M_\odot\ \mathrm{yr}^{-1}$, i.e. a thousand times the solar mass loss rate, possibly dominated by coronal mass ejections rather than a steady outflow.

For the coolest giants and supergiants that have no detectable coronal emission in their outer atmospheres, the mass loss rates scale roughly with the surface area of the star, $\dot{M}_*/M_\odot \approx 2.5 \times 10^{-14}(R_*/R_\odot)^2$.

Indirect effects of winds: stellar spin down

Outer-atmospheric activity is accompanied by loss of stellar angular momentum, which in all stars up to and including at least giant stars is an important process in the deceleration of stellar rotation.

The rotational velocities of subgiants decrease strongly within a period of roughly 50 million years following the onset of deep envelope convection. During this phase of the stellar evolution, the moment of inertia of the envelope, I_{CE}, is less than 1% of the stellar value, I_*. As the stars evolve, the convective envelope deepens. If the wind torque would act only on the envelope with little interaction between envelope and interior, then the interior would be left rotating substantially faster than the envelope, and the deepening envelope in the evolving star would dredge up angular momentum from the radiative interior, and then spin up. Such a resurgence of rotation rate and associated activity is not observed, and so much of the interior's angular momentum must have been removed before I_{CE} reaches a substantial fraction of I_*, i.e. well before an effective temperature of about 5250 K (at about G2 III), requiring at least moderately strong coupling between most layers in the interior of the stars.

Stars are born with a broad range of initial rotation velocities. The rotational evolution of young stars can be studied particularly well using data on open clusters. By the age of the α Persei cluster, some 50 Myr, there is a substantial spread in rotation velocities, which narrows remarkably by the age of the Pleiades cluster, at only 70 Myr for the G and K-type stars. The swift change implies a spin-down time scale of the order of the age difference between these two clusters, i.e. only $\sim$20 Myr. By the age of the Hyades, some 600 Myr, the spread has been reduced strongly, and a reasonably well-defined, monotonically decreasing relationship exists between rotation rate and effective temperature, extending from about F0 down to late of K.

An important property of stellar rotational history is the convergence of rotation rates that occurs for ages beyond $\sim$1 Gyr: for stars of solar age, the details of the initial dispersion in rotation rates have been effectively lost, both where the surface rotation rate and where internal differential rotation are concerned. It is this reduction of the initial dispersion that allowed Skumanich to find the age–activity relationship for mature main-sequence stars $v_{\mathrm{eq}}(t) \propto t^{-1/2}$. This convergence now appears to be the consequence of the nonlinear response of angular-momentum loss to angular velocity.

An interesting side effect of the loss of stellar angular momentum through the magnetized stellar wind occurs in tidally interacting binaries. Let us start with a system in which the two component stars have been synchronized with the orbital motion. As one or both of the stars lose angular momentum, the tidal coupling will tend to keep the stars rotating at the orbital period. But that means that part of the orbital momentum is transferred into the rotational momentum. As a result the orbit shrinks. This leads to a higher rotation rate, higher activity and thus a more effective loss of angular momentum through the wind. The result is that the stars spiral in towards each other, until they ultimately merge. This has been proposed as the explanation for rapidly rotating, apparently single evolved FK Comae stars that should, had their evolution been that of a single star all the time, have only a very low amount of angular momentum left.

Solar–Stellar Connection: Activity and Brightness Changes of Solar-Type Stars

The surface and outer atmosphere of the Sun are dominated by the presence of localized magnetic fields. They influence the structure of and energy transport through the solar atmosphere and wind, outward to the distance of the heliopause (see SOLAR WIND: MAGNETIC FIELD). In addition, the occurrence of the magnetic features varies on characteristic time scales. Chief among them is the roughly 11 yr cycle of the number of sunspots, which has been recorded telescopically by Galileo and contemporaries since the early 17th century.

With the advent of satellite observations, changes of the total SOLAR IRRADIANCE on time scales of years have been recorded. The total solar irradiance varies with the 11-year activity cycle and by as much as 0.14% from minimum to maximum of the activity cycle; the irradiance is highest at solar maximum.

Any successful theory of the origin and nature of solar surface magnetism would require that similar phenomena be present on stars that are close in mass and age to the Sun, i.e. the solar-type or Sun-like stars. In recent decades it has become possible to measure changes in spectrophotometric and photometric fluxes that indicate changes in both surface magnetism and brightness of Sun-like stars over time scales of years. The characteristics of the observed variations in surface magnetism and brightness resemble those of the Sun and appear to be a universal feature of Sun-like stars.

Surface magnetism

On the sun, the disk-integrated Ca II H (396.8 nm) and K (393.4 nm) emission fluxes increase as coverage by surface magnetic features such as sunspots increases. The magnetic fields provide energy to the CHROMOSPHERE and other outer layers of the solar atmosphere; that energy is shed by emission lines such as Ca II formed in those regions. With the benefit of satellite-based observatories, many other emission lines similarly energized by the magnetic fields are available for study in the ultraviolet and x-ray spectrum regions. However, the Ca II H and K fluxes have historically provided much information on magnetic activity in lower main sequence stars because the spectrum features are accessible to ground-based instruments.

Measurements of Ca II H and K emission fluxes of stars are necessarily integrated over a star's visible hemisphere. It is assumed that the observed variations of the Ca II emission fluxes in Sun-like stars are caused by changes in surface coverage or magnetic field strength on the unresolved stellar disks, and therefore the Ca II fluxes contain information on stellar surface magnetism.

Two aspects of surface magnetism derived from spectroscopic indicators of magnetic activity in solar-type stars are the fluxes averaged on evolutionary time scales (i.e. a billion years or so) and their year-to-year variability. Both cross-sectional (time-averaged) and time serial studies have been made in order to investigate the origin and nature of magnetic activity in Sun-like stars.

Cross-sectional studies of surface magnetism

Olin C Wilson, working at the 100 in Hooker telescope at Mount Wilson Observatory, and other astronomers established four decades ago the basis of cross-sectional studies of average Ca II fluxes in lower main sequence stars.

The average surface magnetism, indicated by the time-average value of the Ca II fluxes, shows a dependence on axial rotation. In addition, rotation is observed to slow on long time scales, i.e. with increasing main sequence age.

The body of evidence suggests that, shortly after a solar-mass star arrives on the main sequence, its rotation rate and time-averaged flux of Ca II emission show similar values among stars close to it in age, and the values of those parameters decrease gradually with age. That means that the observed parameters of age, rotation and Ca II fluxes are closely coupled in Sun-like stars. A similar relation can be found among lower main sequence stars of different masses. In other words, the average Ca II emission and the rotation rate of a lower main sequence star, including the Sun, are determined primarily by the star's main sequence age and mass.

The problem of creating, maintaining and transforming magnetic fields by means of plasma fluid motions, which is relevant to planetary, solar, stellar and galactic magnetic fields, can be studied with the magnetohydrodynamic dynamo. Briefly, DYNAMO THEORY suggests that surface magnetism can be described by the dynamo number, D, which depends on mean helicity and differential rotation shear. In a lower main sequence star, those plasma motions may be linked to the observable parameters of mass (depth of the convection zone) and age (or axial rotation, which may be related to internal differential rotation). It is the concept of the dynamo number that leads to the expectation that stars close in mass and age (i.e. rotation) would show similar attributes in surface magnetic activity. In contrast, stars differing greatly in mass and age (i.e. rotation) should exhibit magnetic activity that is dissimilar.

The interpretation of the observational results is that the production of magnetic fields causes a star's surface angular momentum to decrease with age. The slowing of rotation with time is a sign of a gradual loss in angular momentum caused by the presence of a magnetized stellar wind, which presumably obtains throughout the star's main sequence lifetime. As a consequence of the production of magnetic activity, the dynamo's efficacy decreases with increasing age, and angular momentum is lost. The slowing rotation weakens the production of magnetic fields and the fluxes of emission lines that are driven by the presence of magnetic fields.

The coupling between Ca II emission, age and rotation is so close among lower main sequence stars that knowledge of any one parameter, along with an estimate

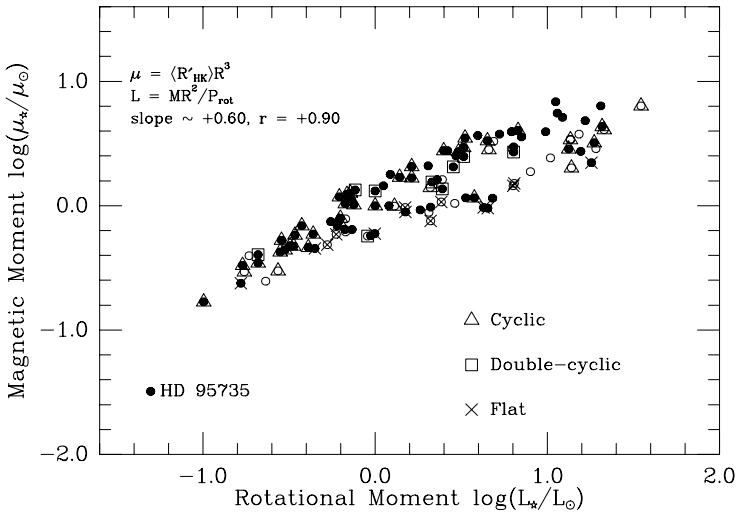

Figure 1. The magnetic moment is plotted against rotational moment, both values normalized to those of the Sun, for the Sun and 112 stars from Wilson's sample of stars on or near the lower main sequence. Measured rotational moments are denoted by filled circles; estimated rotational moments are denoted by open circles. The slope for the $\log(\mu)$–$\log(L)$ relation is $d \sim +0.60$ and the Pearson correlation coefficient is ∼+0.90. The three classes of variability in Ca II fluxes based on the 25 yr records discussed in Baliunas *et al* (1995) are also indicated. Points enclosed by triangles denote stars with a periodic cycle; points enclosed by squares denote stars with two distinct periods ('doubly cyclic'); points with crosses denote stars with little Ca II variability. (Reproduced from *The Astrophysical Journal* by permission of the authors.)

of a star's mass, leads to good estimates of the other two parameters. One of several possible depictions of the relation among those parameters in a sample of lower main sequence stars, whose spectral types extend from mid-F to late K, is illustrated in figure 1. There the magnetic moment, calculated from the Ca II emission fluxes, is seen to depend on the rotational moment. The existence of the close relation is tantamount to saying that the mechanism generating magnetic activity is affected by and affects a star's rotation. The process by which magnetic fields are produced influences angular momentum to the extent of erasing differences in rotation among lower main sequence stars of similar mass and age that surely must have held in the pre-main-sequence phase.

Decade-scale variations in Ca II fluxes

Between 1966 and 1978, Wilson carried out a program at Mount Wilson Observatory of monthly monitoring of the Ca II H and K emission fluxes in 91 lower main sequence stars. Variations of Ca II emission fluxes on time scales of years seen in the records of Sun-like stars are assumed to be produced by a mechanism similar to that causing the 11 yr solar activity cycle, e.g. the magnetohydrodynamic dynamo.

Wilson's purpose was to provide records on the counterpart of the solar activity cycle in lower main sequence stars. Since 1978, not only have the records of Wilson's sample been continued, but also the program has expanded in scope. The longest records now stretch back more than three decades. Monitoring of a much larger sample of nearly 150 Sun-like stars began in 1991.

At times, stars in the program have been observed as often as nearly every night. Such densely sampled records reveal axial rotation from the modulation of Ca II fluxes when magnetic surface features, asymmetrically distributed on the surface, persist for several weeks. Analysis of densely sampled records suggests the presence not only of surface differential rotation but also of features stable on time scales as long as several years, although not particularly for the stars close in mass and age to the Sun.

The three classes of magnetic variability

Across the sample of lower main sequence stars, Wilson found in the Ca II H and K records three broad classes of variations on time frames of years: (1) cyclic; (2) variable; (3) non-variable. The cyclic, or periodic, variations show a pronounced periodicity like the 11 yr solar cycle. The variable records display major fluctuations but no persistent periodicity. The non-variable records are essentially constant with time, to the limits of detection. Examples of each class of magnetic variability in Sun-like stars are shown in figure 2.

The cyclic records can be found among lower main sequence stars of nearly any age and mass. The variable records tend to occur in the younger stars. The flat records may be occurring only in the Sun-like stars.

Figure 2 may be interpreted as a crude evolution of surface magnetism in Sun-like stars. A young star (with an age less than 2 billion years or so) of about one solar mass is rapidly rotating and often presents a variable record (top panel). An older star (with an age beyond two billion years or so) near one solar mass, i.e. a sun-like star, shows either

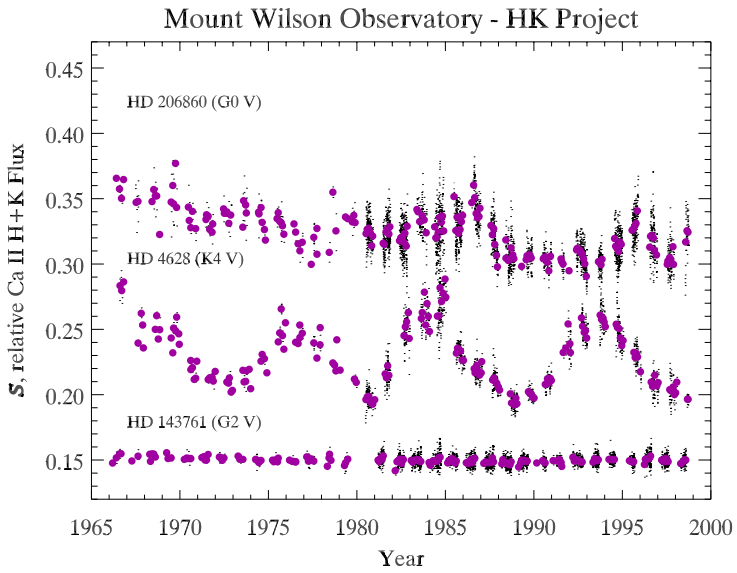

Figure 2. Records of Ca II H and K fluxes in three stars whose masses are similar to the Sun's. The record of a star whose age is about 1 billion years (upper panel) is usually variable with little indication of a preferred periodicity. The records of Sun-like stars—those close in mass and age to the Sun—are generally either cyclic (middle panel) or essentially non-variable (lower panel) to within the precision of the observations (∼1% rms over the length of the record).

a cyclic (middle panel) or a flat (bottom panel) record. The two patterns of records for the Sun-like stars may be the result of sampling relatively short intervals of solar-type variability on time scales of centuries. That is, the Sun shows cyclic magnetic changes a large part of the time. At other times, the Sun's magnetism decreases to a sustained state of little variability, similar to the Maunder minimum (ca 1640–1720 CE) and other periods of low surface magnetism revealed by the cosmogeochemical records of radiocarbon (^{14}C) and ^{10}Be.

At present the Sun is in the cyclic phase and exhibits an 11 yr period. The cyclic phase lasts roughly several centuries. Every few centuries or so, the Sun enters and remains in a low-magnetic state, with a low-amplitude, long-period cycle, if any, and low average flux. This state roughly lasts a century. The low-magnetic states are assumed to be similar to the essentially non-variable records of Ca II fluxes in Sun-like stars. An analysis of the statistics of the number of cyclic and flat records in the relatively short records (∼30 yr) of Sun-like stars suggests a comparable frequency and duration of cyclic and flat phases of surface magnetic variability.

It is still unclear whether, for main sequence stars much older than the Sun, further and more subtle changes in magnetic activity records would occur, for example an increase in the frequency or duration of the Maunder-minimum phase, along with a lengthening of the cycle period during the cyclic phase.

Explanation by the dynamo theory

The evolution of the Sun's magnetism may be further illuminated by dynamo theory. As mentioned above, the dynamo number, D, depends on the product of differential rotation shear and mean helicity. For the youngest solar-mass stars, which are rapidly rotating, the dynamo number is large, with the consequence that several dynamo modes may be simultaneously excited, producing surface magnetism that is variable, with no clear periodicity. As a solar-mass star ages and its rotation slows, the dynamo number diminishes and a characteristic periodicity, indicating a single excited mode, persists. At smaller dynamo numbers, a star's surface magnetism may have a cyclic periodicity combined with occasional periods of low surface magnetism and little variability. At greater ages, and slower rotation, still smaller dynamo numbers suggest that the dynamo may barely operate, and a star may show little variability in surface magnetism. For the smallest dynamo numbers, the dynamo may not be globally sustainable.

It remains difficult to compare results from dynamo theory with empirical results. One reason why comes from consideration of the common argument that the observed cycle period depends on the dynamo number through a power law, $P_{\rm cyc} \propto D^i$, where i is estimated from theoretical considerations. A comparison of various predictions yields a range of possible values for the parameter, i, from $-1.0 < i < +0.5$; that is, not even the sign of the dependence is reliably known. Furthermore, it is difficult to know which theoretical parameters are to be compared with which empirical parameters.

Correlation between magnetic changes and brightness changes

Satellite-based radiometry measurements of the Sun made over the last 20 yr (see SOLAR TELESCOPES AND INSTRUMENTS:

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills, Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

SPACE) show that, over the course of the 11 yr cycle, changes in magnetic activity are positively correlated with changes in total solar irradiance. The total solar irradiance variations arise from changes in the sum of the irradiances of individual surface features, each with a different irradiance, whose surface coverage varies with time. For example, consider just two varying components, visibly dark sunspots and bright faculae, at one phase, activity maximum. Sunspots are dark compared with the magnetically quieter surface and so subtract from the the total irradiance that would result in the absence of sunspots. However, faculae are bright. At activity maximum the area coverage by faculae is more extensive than by sunspots, and the positive irradiance contributions of the faculae more than compensate for the loss by sunspots. As a result, the net irradiance change over the sunspot cycle shows a positive correlation with surface magnetism.

Roughly analogous observations of Sun-like stars reveal a similarly positive correlation over their activity cycles. Techniques that emphasize highly precise differential photometry, e.g. rapid measurement of close-by, non-variable comparison stars, have been used to measure variations of Sun-like stars in the visible (e.g. *b* and *y* Stromgren passbands). The corresponding amplitude of solar brightness change over recent activity cycles is estimated to be roughly 0.1% in the visible spectrum. In Sun-like stars, the photometric brightness is observed to change with the Ca II fluxes over the activity cycle, i.e. the photometric brightness changes are positively correlated with surface magnetism through the activity cycle. Amplitudes of photometric brightness change over the activity cycle as low as the Sun's have been observed for Sun-like stars. Amplitudes several times larger than the Sun's have also been observed.

The existence of the positive correlation between brightness change and activity change over the activity cycle is another important aspect of the similarity of surface magnetism in Sun-like stars. The different amplitudes of observed photometric amplitudes seen among the Sun-like stars suggests that at times the Sun can vary substantially more during an activity cycle than it has during the limited period of recent satellite measurements. In other words, there may exist components of total solar irradiance change that occur on time scales of several decades or longer. Sustained observations of the total solar irradiance should reveal any long-term components of solar irradiance change. It may also be possible to study decades-long changes in one star, the Sun, by considering the cycles observed in a large sample of Sun-like stars, despite their relatively short records.

Applications to studies of extra-solar planets and terrestrial climate change

Studies of the variability of sun-like stars have been used in two topics removed from the study of the theory of surface magnetism. First, stars with little variability, because they are in a temporary or chronic state of low variability, are good candidates for searching for EXOPLANETS by techniques using Doppler or photometric variations. The reason is that the condition of little activity variability produces photometrically and spectrally quiet backgrounds against which to see the subtle planetary effects, if present. Second, if the records of a large sample of Sun-like stars can be considered as different phases of changes in the Sun on time scales of decades to centuries, then information can be obtained on the long-term variability of the Sun and its potential impact on terrestrial CLIMATE change.

Solar–Terrestrial Connection

Radiation from the Sun and the energy from the SOLAR WIND that crosses the magnetopause have a profound influence on the Earth and its surrounding atmosphere (see also MAGNETOSPHERE OF EARTH: MAGNETOPAUSE). The consequences range from the formation of ozone to the flickering aurorae in both polar regions. The most significant solar variations cause long-term changes in the Earth's atmosphere and intense storms in space. Such storms can damage spacecraft and power generation networks.

The Earth's atmosphere

The EARTH'S ATMOSPHERE is, to a first order, horizontally stratified largely through the effects of gravity. Its structure is best described by temperature (figure 1), which results from a balance between absorption of solar radiation and re-radiation, and horizontal and vertical transport. In the troposphere (0–12 km altitude), the temperature decreases by $\sim$7 K km^{-1}, the key radiatively active molecules being water vapor (H_2O), carbon dioxide (CO_2) and methane (CH_4). Above the troposphere lies the stratosphere where there is a modest rise in temperature owing to the absorption of ultraviolet radiation in the range 290–360 nm by ozone (O_3). Radiative cooling, particularly by nitric oxide (NO), causes a sharp reduction in temperature around 85 km altitude, which lies near the center of the mesosphere. This is the coldest part of the Earth's environment with temperatures of about 150 K. Above this altitude, extreme ultraviolet and x-rays are absorbed leading to temperatures that rise to about 1500 K at 300 km altitude, a region known as the thermosphere. Above 1000 km, the atmosphere remains at a constant temperature with altitude, because diffusion processes dominate. This regime is called the exosphere.

The pressure of the atmosphere, p, at an altitude z, is given by the following equation, where p_0 is the pressure at a reference height z_0, m is the mean molecular mass, T is the temperature, g is gravitational acceleration and k is Boltzmann's constant:

$$p = p_0 \exp\left[-\frac{mg}{kT}(z - z_0)\right]. \qquad (1)$$

The parameter kT/mg is known as the scale height. Typical values are about 7 km at the Earth's surface, 5 km in the mesosphere and 50 km at 300 km altitude.

The mean molecular mass of the atmosphere is constant below about 70 km, because the atmosphere is turbulent and mixing occurs. Above about 70 km, the scale height begins to change, because solar radiation causes molecules, especially oxygen (O_2), to dissociate. Then above about 115 km altitude, turbulence no longer dominates so that the gases begin to separate by diffusion, i.e. each gas responds according to its own atomic mass, as given in equation (1). Thus for a given temperature the scale height of hydrogen (H) is 28 times greater than that of molecular nitrogen (N_2). Above about 1500 km altitude, hydrogen is the dominant gas species.

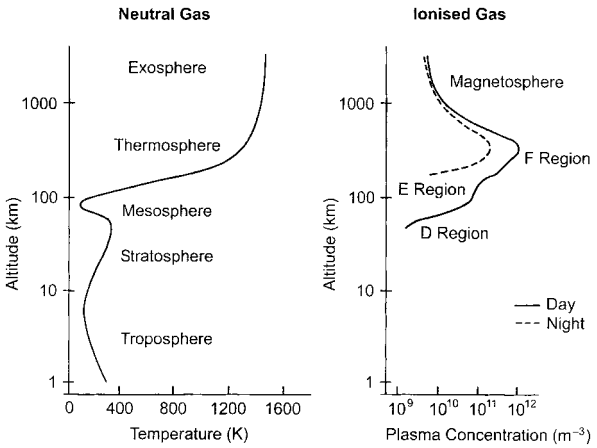

Figure 1. Left: The temperature of the Earth's atmosphere as a function of altitude, identifying the various spheres of the neutral atmosphere. Right: The vertical distribution of ionization both for daytime (full curve) and at night (broken curve). The D, E and F regions are identified. The region above about 1000 km altitude is the magnetosphere.

The ionized atmosphere

Solar radiation ionizes some of the neutral atmospheric constituents in the mesosphere and thermosphere leading to the formation of the ionosphere, which may be defined as the region where there are sufficient free electrons and ions to affect the propagation of radio waves. The ionosphere is embedded within the thermosphere, and it is only above 1000 km altitude that the concentration of the ionized atmosphere exceeds that of the neutral component, and this upper region is known as the magnetosphere (see MAGNETOSPHERE OF EARTH).

The plasma concentration in the ionosphere and magnetosphere may be described by the continuity equation (2), where q is the ionization rate of free electrons (N). The ionosphere and magnetosphere is an electrically neutral plasma, and hence the concentrations of electrons and ions are the same. The parameter, l, is loss rate due to recombination. The final term in equation (2) is a transport term due to the divergence of the flux ($N\boldsymbol{V}$) where $\boldsymbol{V}$ is the plasma velocity.

$$\partial N/\partial t = q - l(N) - \mathrm{div}(N\boldsymbol{V}). \qquad (2)$$

The ionosphere comprises three main regions, the D region (70–95 km), the E region (95–150 km) and the F region (>150 km). These names were chosen early in the 20th century in case additional layers were found at lower altitudes.

In the D and E regions, the electron concentration is dominated by local production and loss. The collision frequency of ions with the neutral particles is so high in these regions that, to a first order, the ions move with the neutral particles. The collision frequency of the electrons is much smaller, and thus they are free to move under the actions of electric fields. Therefore this leads to the

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

possibility of ions and electrons moving with respect to each other, which is in essence a current.

The production of plasma depends on the flux of x-rays and EUV, the solar zenith angle, the atmospheric composition and density, the last two parameters combining to form what is termed the optical depth. The height of maximum production is a balance between the increasing density of the atmosphere with decreasing altitude and the diminishing intensity as the ionizing fluxes are absorbed as they penetrate further into the atmosphere. The maximum photo-ionization occurs at different altitude for each wavelength. For example, the peak ion production occurs at about 105 km for $\lambda = 1$–14 nm, 115 km for $\lambda = 80$–103 nm and 150 km for $\lambda = 14$–80 nm. Integrating across all wavelengths the peak production occurs about 110 km for an overhead Sun. In general, the ionization in the D and E regions is dominated by molecular species (NO^+ and O_2^+), whereas in the F region O^+ is the dominant species.

Molecular ions are lost through dissociative recombination, a process whereby molecules break apart during recombination. The atomic ions are lost through radiative recombination, a process that requires the emission of a photon to conserve both momentum and energy. Radiative recombination is a much slower process than dissociative recombination, by a factor of 10^3. The typical lifetimes of ions (and hence electrons) at D, E and F region altitudes are approximately 1 s, 1 min and 1 h respectively. Because there is only a minute amount of photoionization at night from scattered Lyman α and β from the Earth's geocorona the plasma concentration in the D and E region is very low (figure 1).

The F region peak plasma concentration occurs where diffusion of plasma along the magnetic field line is approximately equal to the loss rate of plasma. Above the F region peak, diffusion dominates plasma processes. Equation (1) can be used to describe the plasma distribution but using the average ion and electron temperatures, $(T_i + T_e)/2$, rather than the neutral temperature, T. Above about 110 km for electrons and 300 km for ions, there are insufficient collisions to maintain thermal equilibrium with the neutral particles. Near the F region peak, the ion temperatures are 5–20% greater than the neutral temperatures, but the electrons are between 2 and 5 times greater. Therefore the scale height of the plasma in the ionosphere is considerably larger than that of the neutral atmosphere.

By chance, the ionization potentials of O^+ and H^+ are almost identical, and thus the charge exchange readily occurs ($O^+ + H \leftrightharpoons O + H^+$). The formation of H^+ contributes significantly to the increase of the plasma scale height and is a major reason for the ionosphere acting as a major source of plasma for the magnetosphere. During daytime, the upward fluxes through 1000 km altitude are $\sim 10^{12}$ m^{-2} s^{-1}. During the night, cooling occurs and some of the magnetospheric plasma falls back into the ionosphere, acting to maintain the F region concentration through the night.

During the day, the absorption of solar radiation causes the thermospheric temperature to rise by ~400 K, resulting in a large pressure bulge on the dayside of the Earth at F region altitudes compared with nighttime values. A major consequence is that winds blow at speeds of 100–400 m s^{-1} from the dayside to the nightside thermosphere. The expansion of the atmosphere at E region heights causes differential motion of the electrons and the ions, which causes current to flow, as discussed above. This current changes the intensity of the magnetic field at the Earth's surface by ~50 nT, and the associated dynamo electric field is about 10 mV m^{-1}.

Solar-induced variations in the neutral atmosphere

The total solar irradiance is remarkably constant, although there is about an 8% increase in the flux reaching the ground in January compared with June owing to an eccentricity in the Earth's orbit. Since space-based measurements of solar irradiance began in the 1970s, the variation has been less than 0.2%. Such measurements must be made from space to ensure that observations are not affected by the Earth's atmosphere. It is estimated that a 1% increase of solar irradiance is required to cause a 1 K increase in global temperature. Therefore the solar irradiance variation (~0.2%) is of minor importance in recent global climate change. However, there are over 2000 papers which show statistically significant correlations between tropospheric parameters (e.g. temperature and rainfall) and the 11 yr solar cycle. Therefore there must be less direct physical processes that have an impact on the troposphere (see SOLAR–TERRESTRIAL CONNECTION: LONG-TERM AND SHORT-TERM CLIMATE VARIABILITY).

The daily and seasonal changes in the temperature of the atmosphere are very large compared with those resulting from the increase of greenhouse gases. In the troposphere, models predict that a doubling of CO_2 will lead to a few K rise in surface temperature. The corresponding variation through a year at a given site is of the order of 20–30 K. The mesosphere would cool by ~10 K as a result of increased CO_2 owing to the additional radiative cooling. The natural seasonal variation is about 20 K. In the thermosphere, a 50 K reduction in temperature would occur, with a corresponding variability over a season of about 400 K. Therefore the effects of changes in greenhouse gas concentration are much smaller than the natural changes caused by normal diurnal and seasonal changes at each level in the atmosphere. These comparisons also show that the mesosphere is the best level in which to search for global change effects, because the predicted changes are comparable with the natural variability, whereas in other levels the predicted changes are a small fraction of the natural variations. Alas, mesospheric measurements are difficult as the mesosphere is too high for aircraft and balloon-borne measurements and too low for satellites, but new techniques using optical methods for remote sensing the mesosphere are being developed. The longest data series of the ionosphere

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

extend for only a few decades, short in comparison with meteorological data series. However, even these data sets are indicating a reduction in the altitude of the peak concentration in the F region of up to 1 km yr^{-1}. There is still considerable regional variability in the level of change, but the sense is consistent with increased CO_2 concentrations (Jarvis *et al* 1998).

Solar-radiation-induced variations in the ionized atmosphere

The intensity of the solar radiation in the wavelength range critical for the ionosphere and magnetosphere ($\sim$1–140 nm) varies on average by a factor of about 2.5 between sunspot maximum and minimum, although some specific lines may be enhanced by a factor of $>$100. The consequence for the ionosphere is that the electron concentration increases by approximately the same factor between sunspot minimum and maximum. Similarly, a 27 day modulation of solar flux can be detected in the ionospheric electron concentration both at E and F region altitudes. The 27 day modulation is difficult to identify owing to the large day-to-day variability in the ionosphere caused by geomagnetic storms and wave energy propagating upwards from the troposphere and stratosphere. Measurements of sunspot number and the intensity of the solar radio flux at 2800 MHz (λ = 10.7 cm) are often used in ionospheric models because these parameters are easy to determine at the Earth's surface. However, they are at best only a guide to the general level of activity, rather than a reliable indicator of EUV and x-ray fluxes. These fluxes must be known accurately if ionospheric concentrations are to be predicted reliably.

Solar flares last 1–100 min and release $\sim 10^{22}$–10^{25} J of energy. The largest flares, C class, give an energy flux at the Earth (1 AU) of 10^{-6}–10^{-5} W m^{-2} near 1 nm. This produces a corresponding increase of ionization in the D and E regions of the dayside ionosphere that has profound effects on radiowave propagation, as discussed later.

Solar-wind-induced variations in the ionized atmosphere

Typically 1% of the 10^{13} W of solar wind power that impinges upon the magnetopause is transferred into the magnetosphere when the interplanetary magnetic field (IMF) has a southward component. Under such conditions, reconnection is likely to occur, this being the major physical mechanism by which energy enters the magnetosphere–ionosphere system. When the IMF is northward the energy crossing the magnetopause falls by 2 orders of magnitude. The solar wind energy is redistributed in the magnetosphere by the effects of electric fields, currents, energetic particles and waves, which in turn have significant effects on the stratosphere, mesosphere, thermosphere, ionosphere and magnetosphere (see SOLAR–TERRESTRIAL CONNECTION: COUPLING BETWEEN SOLAR WIND, MAGNETOSPHERE, IONOSPHERE AND ATMOSPHERE). The resultant changes also have a major and increasing effect on human activities (see SPACE WEATHER PREDICTIONS).

The heliospheric current sheet is the boundary between the northern and southern lobes of the Sun's magnetic field. At the Earth, which lies close to the heliospheric equator, the current sheet is distorted and is often likened to a ballerina's skirt. These two factors combined mean that the north–south component of the IMF varies from northward to southward on average every $\frac{1}{2}$ h. Therefore reconnection at the dayside magnetopause is switched on and off frequently, thus the energy flow from the solar wind to the magnetosphere is highly irregular both in space and time.

There is still considerable uncertainty over some of the detailed response of the coupled magnetosphere–ionosphere system to southward turnings of the IMF and thus increased energy transfer. There is general agreement that the electric field across the magnetosphere and the currents that couple the ionosphere to the magnetosphere both increase within minutes. After about 1 h, there is a major reconfiguration of the geomagnetic tail, known as a substorm, which leads to majestic displays of the AURORA in the nightside ionosphere, among other phenomena. Intense currents (1 MA) are driven from the magnetosphere through the ionosphere, which results in enormous Joule (Ohmic) heating. These currents deposit $\sim 10^{11}$–10^{12} W in the ionosphere and thermosphere which is about twice as much as the energy deposited by the energetic particles that cause the aurora. Substorms typically last about $\frac{1}{2}$ h and recur on average every 3–5 h. Hence there are about 1500 substorms per annum. Energetic ions and electrons with high pitch angles injected during the substorm process drift around the Earth at (2–3.5) $\times$ 10^4 km altitude. Their motions are controled by the gradient and the curvature of the Earth's magnetic field and the azimuthal drift are in opposite directions for ions and electrons, hence the formation of the ring current (see MAGNETOSPHERE OF EARTH: RING CURRENT). Typically about 10^{11} W power is stored in the ring current, the energetic particles eventually being scattered by waves and ending up precipitated in the stratosphere, mesosphere and thermosphere.

The major exception to the continually oscillating IMF occurs during the passage of a coronal mass ejection (CME) event. Although CME events occur about twice per day on the Sun, only a small fraction of these impact upon the Earth's magnetosphere. When they occur, the IMF magnitude and direction change very slowly with time. Thus the IMF may have a northward component for 1 day, the consequence of which would be that the aurorae diminish markedly in intensity and move progressively poleward. Similarly the southward component of the IMF may last for 1 day also, and hence considerable energy is transferred to the magnetosphere. During these intervals, frequent and intense substorms usually occur, and their cumulative effect is known as a magnetic storm.

The occurrence of magnetic storms varies over the solar cycle. In general, storms are most frequent up to

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

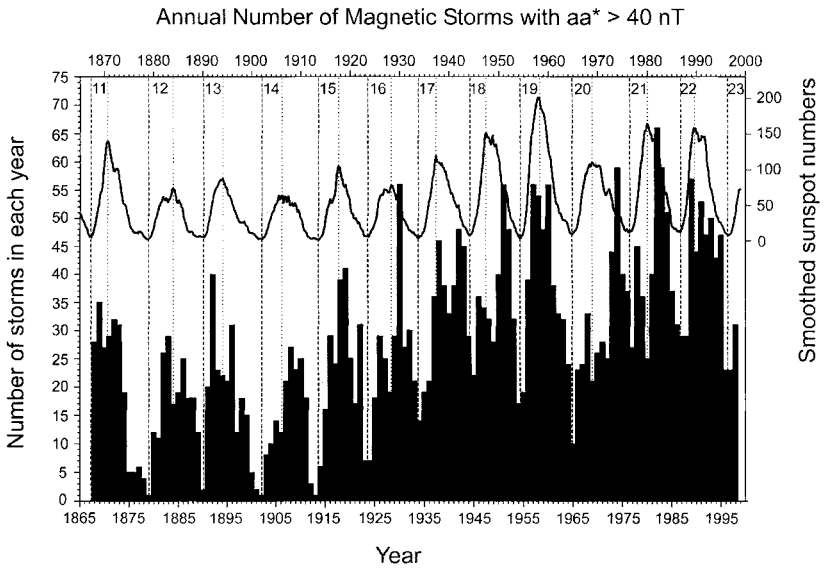

Figure 2. The sunspot number and the number of magnetic storms since 1865. A storm is defined as an occasion when the aa magnetic index exceeds 40 nT. The number of storms at all epochs of the solar cycle has increased markedly in the last 100 yr. (From Clilverd *et al* 1998.)

2 yr after sunspot maximum (see figure 2). However, the number of storms at each phase of the solar cycle has increased markedly over the last 100 yr. Figure 2 shows the number of storms per annum, storms being defined as when the geomagnetic aa index exceeded 40 nT. The aa index is a measure of the deviation of the Earth's magnetic field from its quiet level in each 3 h epoch of the day, as determined from two mid-latitude observatories. The broken vertical lines show the times of sunspot maximum and minimum and the second curve shows the sunspot number.

One of the effects of storms and substorms is to increase the temperature of the thermosphere by up to 400 K. This causes the atmosphere to expand and the density at a fixed altitude near 400 km altitude to increase by an order of magnitude. Also the atmosphere becomes less molecular, i.e. the O/N_2 ratio decreases. The recombination rate increases and the plasma concentration falls. This is most marked at F region altitudes where the concentration falls by up to an order of magnitude. Winds in the thermosphere also increase by a factor of 2–3, reaching up to 1 km s^{-1}. Although the initial energy from substorms is deposited in the thermosphere near the auroral oval, all latitudes are eventually affected through the transport of energy through winds and atmospheric gravity, or buoyancy waves. The latter propagate away from the auroral oval at close to the speed of sound in the thermosphere (750 m s^{-1}).

Solar proton events are when protons with energies of 1–500 MeV are ejected from the Sun. Such events, although infrequent, cause substantial changes to the minor species chemistry, especially O_3 and NO_x, in the atmosphere between 20 and 80 km altitude. They last from a few hours up to 10 days. Relativistic electron events (energies 1–20 MeV) are also observed inside the magnetosphere. The sources of these very energetic particles are still unclear. There are plausible arguments suggesting that the Sun, Jupiter, the dayside cusp or the geomagnetic tail may be the source of such particles. Like the solar proton events, their atmospheric consequence may be very significant in the aerosol chemistry. Both energetic ion and electron precipitation may also affect the global electric circuit. This is the cumulative effect of all the thunderstorms which charge the ionosphere to a potential of several 100 kV with respect to the Earth's surface. This potential difference drives vertical electric currents downward from the ionosphere to the ground in regions where thunderstorms do not occur. The fair weather electric current, as it is called, varies spatially and temporally according to the ionospheric potential and the total column resistance between the ionosphere and the ground. This column resistance may vary when very energetic proton or electron events are in progress.

The human impact of solar variability

All Earth-orbiting satellites fly in the ionosphere and magnetosphere, and satellites are used for a wide variety of purposes now. Modern communications use satellites to an ever-increasing extent. Geostationary satellites are used for television transmissions, and there is a massive increase of global mobile telephone systems that use satellites in a variety of orbits. Most navigation now uses the Global Positioning System (GPS), an extensive constellation of satellites in highly elliptical orbits. Earth observations, e.g. meteorological forecasting, hurricane track predictions and agricultural crop assessments,

extensively use space-based data. Marconi first used high-frequency (HF) (3–30 MHz) radio communications via the ionosphere a hundred years ago. Despite the advent of many new means of communication, HF communications are still of great importance in many areas of the world, being both cheap and usually reliable. All of these features underpin much of civilization today but they are adversely affected by solar variations that causes perturbations in the ionosphere and magnetosphere. Even the distribution of electricity by the power industry, and corrosion of long pipelines at high latitudes is affected by solar-induced changes, which are now known as space weather, the consequences for humanity being outlined below.

Spacecraft environment

Many satellites operate at geostationary orbit (∼40 000 km), a region where the effects of energetic particles on spacecraft operations are very important. During storms, the particle fluxes of energetic electrons and protons increase by many orders of magnitude. This is particularly prevalent in the outer radiation belts (see MAGNETOSPHERE OF EARTH: RADIATION BELTS). The high fluxes cause severe damage to spacecraft. The most energetic particles (energies ∼MeV) penetrate deep into the body of the spacecraft and into coaxial cables. This can lead to deep dielectric charging which results in damage to spacecraft components, and in turn leads to spurious signals and occasionally to complete failure of some or all of the spacecraft. The less energetic particles (∼keV) tend to cause surface charging and discharging which in turn can cause anomalous operation of the spacecraft.

Solar cells are also vulnerable. A modest solar flare can reduce their efficiency by ∼3% per event, ultimately affecting the lifetime of the satellite itself.

There are a variety of mitigating actions that can be taken to reduce the effects, many of which can be incorporated into the design of the satellite. Shielding of key elements and cables is the primary mechanism. Also during the operational phases avoidance of sensitive maneuvers during the storms is attempted.

The human perspective

The exposure of humans in space to the various radiations described above is a very significant hazard. US Shuttle flights have been curtailed to prevent astronauts receiving high dosages of radiation. Although the fluxes of particles at ∼15 km are tiny compared with the ionosphere, there is still a modest threat to the operation of high-flying aircraft, such as Concorde. Again electronics may be vulnerable and the total radiation dosage, especially to the crew, is an issue. The aeroplanes carry radiation monitors. If fluxes increase, the aircraft lowers its cruising altitude to reduce the damaging effects. The next generation of passenger aircraft will fly near 15 km and thus monitoring of the fluxes of energetic particles from geospace will be required.

Radio propagation

The presence of free electrons in the ionosphere and magnetosphere affect the propagation of radio waves from very low frequencies (3–30 kHz) up to the frequencies used to communicate with satellites (10^{12} Hz). Much of the knowledge of the ionosphere and magnetosphere has been determined by observing and then understanding the effects of radio waves that are refracted by the plasma. To a first order, the attenuation of radio signals is proportional to the inverse of the square of their frequency.

Propagation conditions change markedly as a result of the effects of the Sun on all time scales from seconds to a solar cycle. On a time scale of seconds, solar flares cause enhanced ionization in the D and E regions which results in additional attenuation of the radio signal. The normal diurnal variation of solar zenith angle causes the maximum electron concentration at F region altitudes to increase by up to 200% at sunspot maximum from midnight to noon. Thus the ionosphere can refract much higher frequencies at noon than midnight. As described above, the effect of storms is to reduce the electron concentration compared with quiet times owing to the composition changes, thus reducing the bandwidth for effective radio propagation.

At frequencies used in satellite communications, it is not the attenuation of the ionosphere that is important but the scattering of radio waves by small-scale (1 cm–10 km) plasma irregularities. These irregularities cause rapid fading of the signal. In practical terms, they can introduce errors into global positioning and cause distortion of images collected with synthetic aperture radars.

Spacecraft orbital decay

About 5000 spacecraft have been placed in Earth orbit, and about half of these remain there. The rest have re-entered the atmosphere. Of the remaining satellites, only 25% are still operational. In addition, many missions leave space junk, including booster rockets and explosive bolts. Satellites have blown apart and there are now approaching 10 000 pieces of spacecraft that can be tracked from the ground, i.e. items larger than ∼1 m, although the size that can be tracked depends on distance from the Earth. In addition, there are millions more pieces of space debris <1 m. There is a natural decay of spacecraft orbit due to atmospheric drag for all satellites below about 1500 km altitude. The atmospheric density increases by over an order of magnitude at F region altitudes at sunspot maximum compared with sunspot minimum. Thus much greater orbital mass falls to Earth during periods of high solar flux. This is illustrated in figure 3. In the years centered about the 1989–90 solar maximum, over 550 t of material re-entered the Earth's atmosphere, causing a noticeable fall in the satellite population.

Ground-based effects of solar variability

During substorms, very large currents (1 MA) flow horizontally in the E region of the ionosphere in the auroral oval. The magnetic variation from such

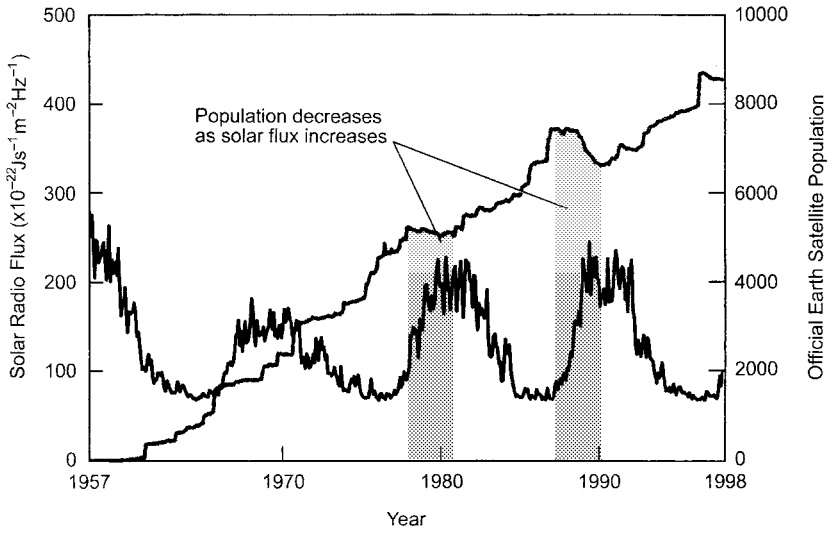

Figure 3. The 10.7 cm solar radio flux over the last 40 yr together with the satellite population. Here satellite is defined as any piece of spacecraft or debris >1 m in diameter. The shaded regions are about sunspot maximum. During these periods, the density of the atmosphere increased, resulting in enhanced satellite drag, faster decay to the orbit, and thus more debris burning up in the Earth's atmosphere.

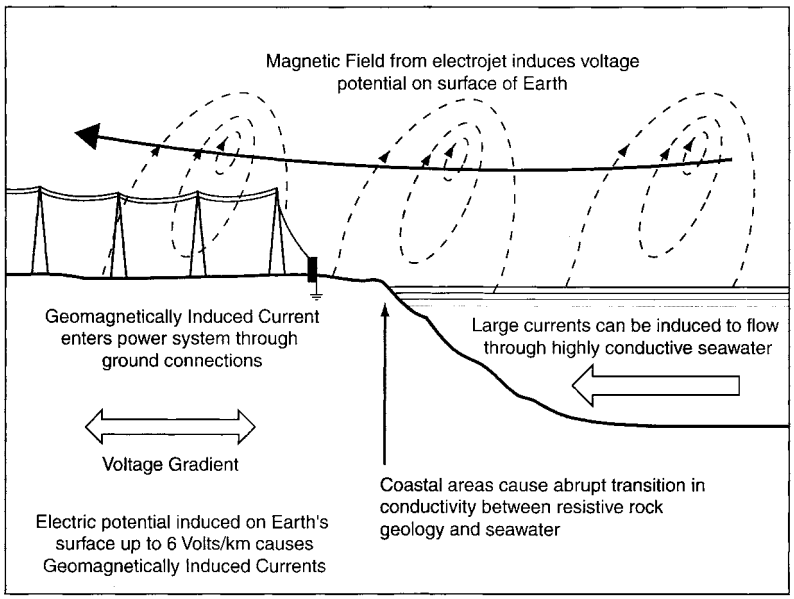

Figure 4. The electromagnetic coupling that occurs between the auroral electrojet in the ionosphere (110 km), the underlying geological features and the power systems. In regions of high resistivity (igneous rock) the Earth's potentials over large regions can cause large induced currents in powerlines. Also there may be induced currents in coastal areas when currents induced in sea water encounter the land.

currents, which are called the auroral electrojets, is $\leq$4000 nT. This represents about 10% of the Earth's field at the latitude where these currents occur. These ionospheric currents induce currents in the sea, on land and in power lines (figure 4). The main process for producing geomagnetically induced currents in electric power systems is induced Earth-surface potential due to geomagnetic field fluctuations during storms. The potential ($\sim$5 V km^{-1}) is imposed across grounded neutral points of three-phase transformers. This potential essentially acts as a voltage source and has a frequency range of a few mHz. The induced current biases the excitation characteristics of transformers causing half-cycle saturation, and hence distortion, and is thus

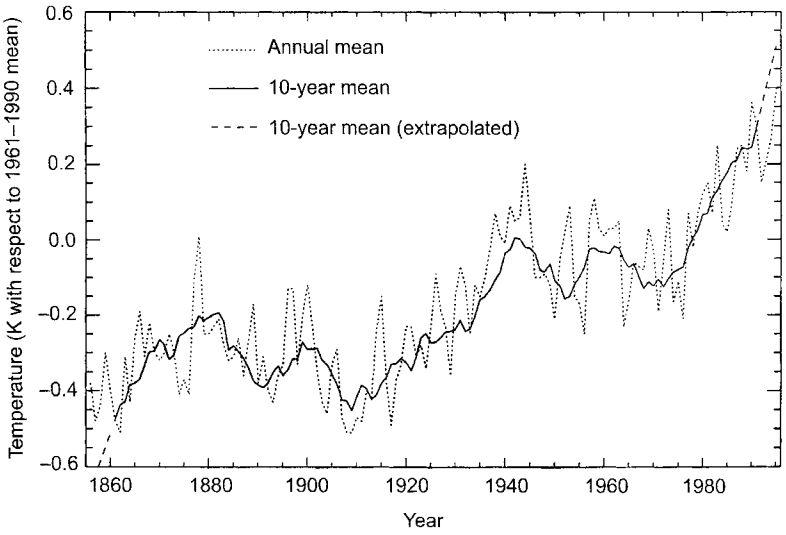

Figure 5. The mean annual global surface temperature (K) from 1856 to 1995 with respect to the mean for the period 1961–90 (dotted curve). The full curve is a 10 yr running mean. The broken curve is an extrapolation of the 10 yr mean.

rich in harmonics. The consequence is additional dissipation within the transformer itself which can lead to overheating and occasionally transformer failure. The best-documented event occurred in March 1989 when the entire province of Quebec in Canada was blacked out for more than 9 h. The economic effect of the failure was put at ∼$5 billion, i.e. similar to that of a hurricane.

Traditionally the Earth's magnetic field has been used for navigation, but with the development of GPS this is much less common nowadays. Variations in the apparent location of the magnetic pole can be several degrees during a storm, depending on the latitude of the observer. This is clearly an important effect for accurate navigation, but these large deviations last the duration of a substorm (<1 h). Ground, aircraft and, to a lesser extent, satellite measurements of the Earth's magnetic field are still important in geological survey work. This needs to be carried out during periods of quiet solar conditions, otherwise the required signals are corrupted by a combination of the ionospheric and induced currents, which are driven ultimately by solar variations.

The Sun and weather

There are >2000 papers published in the refereed scientific literature describing meteorological phenomena that have a statistically significant relationship with solar variability, and especially the 11 yr solar cycle. Over the last 30 yr during which accurate measurements have been possible, the output of the Sun has been remarkably constant (1460 W $m^{-2} \pm 0.5\%$ at the Earth's surface). The small uncertainties cannot account for the observed Sun–weather relationships directly. It is also interesting to note that the increase of global mean surface temperature (figure 5) and the occurrence of magnetic storms (figure 2) both increased markedly from about 1915. There are no generally accepted physical processes that can explain the data; however, in recent years several promising theories have been developed. On a longer time scale, the Earth's climate is known to be directly affected by variations in the Earth's orbit. These are known as the Milankovich cycles.

Predicting space weather

The requirement for accurate prediction of space weather is likely to become increasingly important with time. There is greater reliance on satellite-based communications and navigation systems, together with the prospect of much increased high-flying commercial passenger air transport and long-duration manned space flight to the International Space Station and other planets. The prediction of space weather is in its infancy, with the first comprehensive models of geospace under construction. There are two key elements where further scientific understanding of the coupled system is essential before accurate predictions can be a reality. The first is identification of the features on the Sun that lead to the severe storms. CME events that impact the Earth are certainly one important factor, but not the only one. Second, severe storms occur when the IMF is southward. There is at present no way of predicting the IMF remotely. The best input parameters for the present forecasting models are solar wind and IMF conditions from satellite measurements at the L1 libration point. (The L1 point is where the gravitational forces of the Sun and the Earth are equal, about 1.5 million km upstream in the solar wind.) These data give about a 1 h warning of the impacts on Earth, which is insufficient to take all the actions required to minimize the possible damaging consequences of magnetic storms which are caused by variations in solar processes.

Solar–Terrestrial Connection: Coupling Between Solar Wind, Magnetosphere, Ionosphere, and Neutral Atmosphere

The particle flux from the Sun and the magnetosphere represents a large source of energy and ionization for the lower thermosphere and ionosphere. The energy flux, which ranges from $<10^{-3}$ J m^{-2} s^{-1} to over 0.1 J m^{-2} s^{-1}, is deposited by particles with energies that range from hundreds of eV to several hundred MeV. The intensity, spectrum, and localization of the precipitation are functions of solar and geomagnetic activity (MAGNETOSPHERE OF EARTH: GEOMAGNETIC STORMS AND SOLAR WIND ORIGINS). The mean values also show longer-term dependence on the SOLAR CYCLE. The particle-induced ionization leads to dissociation of tightly bound N_2 molecules and to the formation of the reactive nitrogen compounds NO and NO_2. These compounds, when transported to lower altitudes, participate in a catalytic cycle leading to the destruction of ozone. Continuing research seeks to understand the impact of magnetospheric and solar energetic particles on the chemistry and electrodynamics of the middle atmosphere.

Atmospheric processes

During the last 25 years intensive efforts have been underway to develop an understanding of variations in middle-atmospheric ozone (O_3) due to natural processes and due to the effects of mankind (see OZONE HOLE). It is now reasonably well understood that the global balance of O_3 is governed in part by the balance between the production of O_3 and its destruction by reactions within the NO_y, Cl_y, HO_y, and O_y chemical families. One of the most important catalytic cycles in this global balance is that due to the following reactions:

$$\begin{aligned} NO + O_3 &\rightarrow NO_2 + O_2 \\ NO_2 + O &\rightarrow NO + O_2 \\ \hline O_3 + O &\rightarrow 2O_2 \end{aligned}$$

The bulk of the odd nitrogen (i.e. NO_y, oxides of nitrogen) in the stratosphere is formed from the oxidation of N_2O by $O(^1D)$ (excited atomic oxygen) forming NO. It is known, however, that middle-atmospheric NO_y is formed by ion chemistry initiated by the precipitation of energetic particles into the upper atmosphere (see SOLAR WIND: ENERGETIC PARTICLES).

The first step in determining the production of NO_y due to the precipitation of energetic particles is the calculation of the deposition of energy from particle penetration. The particle energy is absorbed by the atmosphere through collisions with, and scattering by, atmospheric constituents which result in either dissociation or ionization of the atmospheric constituents. Production of each electron pair within the atmosphere requires an energy deposition of approximately 35 eV. In addition to the energy imparted directly to the atmosphere during collisions, a certain amount of energy is converted to x-rays by the bremsstrahlung process. This is associated with the rapid deceleration of energetic electrons during their penetration into the atmosphere, providing additional ionization down to altitudes of 20 km.

The ion and neutral odd-nitrogen chemistry initiated by energetic particles produces secondary electrons, e^*, which in turn ionize and dissociate the major atmospheric species. This ionization is followed by a series of interchange and recombination reactions involving nitrogen and its ions which produce additional atomic nitrogen. The resulting atomic nitrogen may either be in the ground ^4S level or excited to the ^2D level. Nitric oxide is formed by the reaction of atomic nitrogen with O_2. Reactions involving excited nitrogen are faster than those with the ground-state N atom. The destruction of odd nitrogen proceeds through the reaction of N atoms with NO to produce molecular nitrogen and atomic oxygen. In the sunlit atmosphere the photodissociation of NO is important; however, in the fall, winter, and spring in the polar region, the photolytic reaction is negligible and the resulting NO lifetime is sufficient for transport to bring the NO into the mesosphere and stratosphere.

Current numerical models take into account the details of the photochemical complexities and are capable of calculating the odd-nitrogen production rates as functions of the energy-dependent ionization and deposition rates. Thus, if energetic particle precipitation can be measured, the auroral-induced emissions and the NO can be specified. As the NO produced in the thermosphere and mesosphere is transported to lower altitudes it reacts with ozone to form NO_2 and remains as this form of odd-nitrogen for the remaining time of transport.

There have been several studies of these effects suggesting that precipitating electrons could lead to the formation of oxides of nitrogen and hydrogen. These could affect O_3 near 60 km and the ion formation rates due to these electrons could dominate those of other processes down to approximately 40 km. Baker *et al* (1987) found ion formation rates using electron measurements from geostationary orbit that showed that the fluxes of energetic electrons and hence the ion formation rates were strongly modulated by solar activity. Callis *et al* (1991), using estimates of the precipitating electron fluxes derived from geostationary data and 2D simulations, concluded that the precipitating electrons could have a significant effect on the budgets of both NO_y and O_3 within the stratosphere. This coupling mechanism between solar activity, solar wind structures, the energetic particle populations within the magnetosphere, and the chemical state of the middle atmosphere represents an important linkage which must be understood to assess the natural variations in the global chemical state of the middle atmosphere.

Energetic particle sources

The energetic particle flux into the atmosphere has characteristic spectral features and temporal and spatial scales depending on latitude and local time. The most important sources include the solar energetic particles within the polar cap, the diffuse and discrete auroral precipitation within the auroral zone, the energetic magnetospheric electrons extending from midlatitudes throughout the auroral zone, and the ring current particles precipitating at midlatitudes. Table 1 summarizes the known particle input characteristics; in the following sections we discuss each type of particle input separately.

Solar energetic particle influx

Solar energetic particle (SEP) events extending in energy up to hundreds of MeV can produce dramatic enhancements in the ionization and NO_y production rates in the polar regions. Figure 1 shows instantaneous production rates of NO calculated for several solar particle events. These particles enter via the open magnetic field line regions. Also shown are the average production rates due to galactic COSMIC RAYS (GCRs) at solar maximum, and estimated production rates due to precipitating electrons (Brasseur and Solomon 1984). Note that solar protons can have a large effect between the altitudes of ~20 and 100 km.

Of the solar proton events shown in figure 1, that of 4 August 1972 was one of the largest on record, the kind that occurs roughly once a decade. However, SEP events of the size of the other two typically occur several times per year during solar maximum. Reid *et al* (1991) have calculated the ionization rates and resulting effects on NO_y and O_3 for the series of large solar proton events in late 1989 that were comparable in intensity to those of August 1972. They predicted NO increases as large as a factor of 20 near 60 km altitude, with corresponding peak O_3 depletion as large as 20% near 40 km in late October 1989. Furthermore, calculation of the latitudinal range over which the deposition occurs requires information of the geomagnetic cutoff. Because the cutoff can be lowered by several degrees at the time of these events due to associated GEOMAGNETIC STORM activity, the cutoff needs to be monitored at the same time. The scale on the right of figure 1 indicates the minimum energy proton that can penetrate to a given altitude, which shows that calculation of the ionization rate due to solar protons from 20 to 80 km requires information on the proton energy spectrum from about 3 to 500 MeV.

Relativistic electron precipitation

Baker *et al* (1986, 1987) reported observations of the fluxes of energetic (1–15 MeV) electrons at geostationary orbit (6.6 R_E) for the period 1979 to 1986, from solar maximum conditions to solar minimum. Their results indicated that large enhancements in the electron population were sporadic in the 1979–1981 solar maximum period. However, during the declining phase of the solar cycle, from late 1981 until mid-1986, frequent large increases in this population were observed. The average intensity and

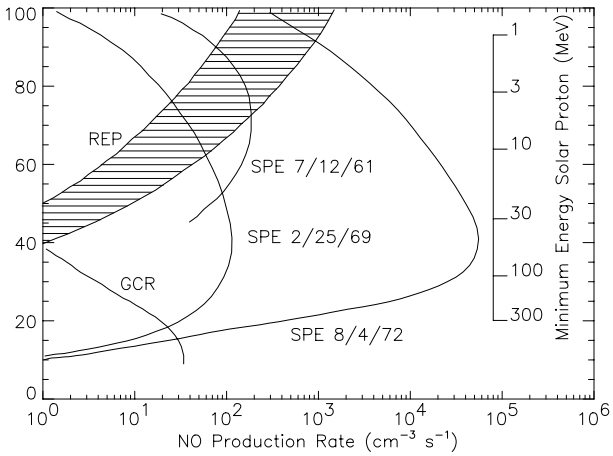

Figure 1. NO production from solar proton events (SPE), relativistic electron precipitation (REP), and galactic cosmic rays (GCR).

frequency of these events increased dramatically so that the 6-month average of the flux of these electrons was larger by a factor of 8 or 9 than a similar average observed during 1979–1980.

The population of relativistic electrons is known to be closely related to the occurrence of high-speed ($V_{SW} \geq 600$ km s^{-1}) solar wind streams and often shows a periodicity of 27 d. Since high-speed solar wind can be associated both with SOLAR CORONAL MASS EJECTIONS and with the cyclical development of solar CORONAL HOLES, their occurrence is temporally associated with the 11 y solar cycle. The maximum frequency of energetic electrons develops during the declining SUN-SPOT phase, but even near solar maximum conditions, very strong relativistic electron events appear in association with coronal mass ejections and the related magnetic clouds interacting with the Earth's magnetosphere. A dramatic example is the event of 24 March 1991, when a strong interplanetary shock struck the Earth's magnetosphere and generated several orders of magnitude increases in the fluxes of multi-MeV electrons and protons in the inner magnetosphere (see MAGNETOSPHERE OF EARTH). These results provide support for and strengthen the suggestion that relativistic electron precipitation may significantly influence the photochemical state of the middle atmosphere.

Auroral particle influx

The particle flux precipitating from the magnetospheric plasma sheet represents a large source of energy and ionization for the lower thermosphere and ionosphere (see MAGNETOSPHERE OF EARTH: PLASMA SHEET). The energy flux, which ranges from less than 10^{-3} J m^{-2} s^{-1} to over 0.1 J m^{-2} s^{-1}, is mainly deposited by particles with energies that vary from hundreds of eV to several hundred keV. The intensity, energy, and localization of the precipitation are functions of geomagnetic activity: higher localized fluxes

and higher mean energies are found during substorms, and the mean values also show longer-term dependence on the solar cycle.

The discrete AURORAS are highly structured and localized, and their occurrence frequency maximizes in the premidnight sector at auroral latitudes. Individual auroral arc widths vary from a few km to 100 km in latitude, but during substorms the discrete auroras can cover a region of about 1000 km in latitude and several thousand km in longitude. The discrete precipitation consists mainly of electrons in the energy range from a few hundred eV to a few tens of keV, often accelerated by field-aligned potential structures which produce a characteristic monoenergetic peak in their spectrum. Electrons in the 0.5–30 keV energy range make a significant contribution to the energy input to the lower ionosphere, and are important for maintaining ionization levels in the ∼100 km altitude region during the night when photoionization stops and particle impact ionization is dominant. Their energy and ionization inputs are thus important for the study of external influences on the mesosphere.

The diffuse auroras are less structured and persist in the auroral latitudes almost continuously. This more uniform precipitation consists mostly of electrons and ions with energies from a few hundred eV to many tens of keV. In particular, during the substorm recovery phase, energetic (tens of keV) electron precipitation is often found in the morning sector of the auroral oval affecting the chemistry at about 80 km altitude.

Ring current ion precipitation

At mid-latitudes the precipitation from the ring current just inside the plasmapause (see MAGNETOSPHERE OF EARTH: RING CURRENT) consists mainly of ions in the 10–200 keV energy range. The ions are anisotropic, with a peak near 90° pitch angle, and have been observed down to an altitude of about 120 km. The energy flux increases with magnetic activity from 10^{-7} to 10^{-5} J m^{-2} s^{-1}. For disturbed conditions, the precipitating ions and neutrals are the primary source of nighttime ionization at these altitudes and latitudes. Ring current ions interact with the outer edge of the plasmasphere, where they excite ion cyclotron waves (see MAGNETOSPHERE OF EARTH: PLASMASPHERE). These waves lead to scattering of the ring current ions, which most likely produces the observed precipitation. Outside the plasmapause there is another region of ion precipitation, where the observed precipitating flux is more isotropic. The filled loss cone suggests that a mechanism for strong pitch angle diffusion exists in the outer magnetosphere with energy deposition near 10^{-3} J m^{-2} s^{-1}.

Precipitation of energetic ions and neutrals ionizes and heats the thermosphere. Good agreement is found between the ionization rate based on the energetic ion and neutral precipitation with measurements of the electron density profile. The ionization profiles show a nearly constant rate of ionization from 120 to 200 km, and the ionization rates increase with magnetic activity from 10^{-1} to 10^2 cm^{-3} s^{-1}.

Present evidence of energetic particle coupling to atmospheric chemistry

The extensive thermospheric NO data set acquired by the Solar Mesosphere Explorer (SME) satellite has quite clearly shown that NO is produced above 100 km by impact of auroral particles with energies less than 10 keV. On the other hand, the observational evidence of the significance of NO_y production in the middle atmosphere and its subsequent downward transport has been limited: regular mesospheric NO measurements have become available only after the 1991 launch of the Halogen Occultation Experiment (HALOE) onboard the UARS satellite. These data have provided evidence that large amounts of NO are being produced in the mesosphere. Further evidence suggests transport to the stratosphere.

Callis *et al* (1996) looked at specific events and compared the observed NO changes with concurrent electron measurements by the SAMPEX satellite. They found significant NO increases (up to a factor of ten from 60 to 120 km) during longlasting electron events. A good correlation was found between the $E > 30$ keV electron measurement and the NO response measured by HALOE. Backed by 2D model calculations of ozone decreases due to enhanced NO_y, Callis *et al* (1996) made the provocative suggestion that NO_y enhancements such as discussed above were responsible for the ozone depletions

D N Baker

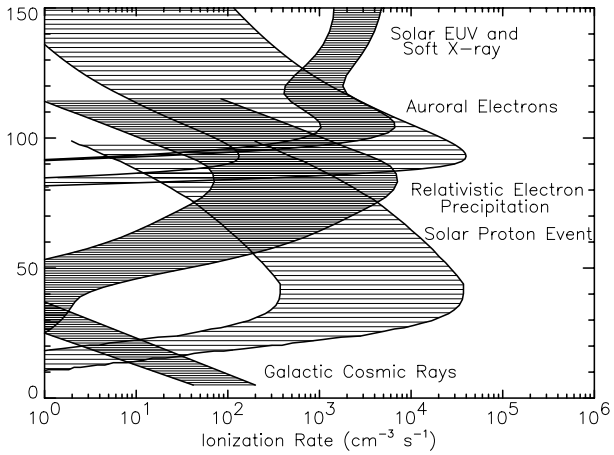

Figure 2. Comparison of energy inputs and subsequent ionization rates in the atmosphere due to energetic particle sources, solar EUV, x-rays, and galactic cosmic rays.

in the lower stratosphere. Thus, the current observational database suggests that the influence of energetic particle precipitation on atmospheric chemistry extends to as low as 25 km. Dedicated measurements of both NO_y and O_3 throughout the polar winter are clearly required to prove this contention.

In summary, as shown in figure 2, there are a wide variety of coupling processes between the Sun, solar wind, and magnetosphere on the one hand and the various layers of the atmosphere on the other. This coupling affects both the chemical and the electrodynamic properties of the middle and upper atmosphere. Thus, it is quite possible that solar wind and magnetospheric coupling to the lower layers of the atmosphere can have substantial effects on NO_y and O_3 concentrations.

Solar–Terrestrial Connection: Long-Term and Short-Term Climate Variability

The Earth's CLIMATE expresses the combined response of the atmosphere, the OCEANS and the continents to the energy that is received from the Sun. Any variation in the energy received from the Sun or radiated away from Earth and any change in the distribution of energy over the Earth's surface will therefore have an effect on climate (see also EARTH'S ATMOSPHERE).

By climate we usually understand the average state of the atmosphere over several years. Superposed on that is the large seasonal variation caused by the annual change of the solar zenith angle and the daily variation due to changes in the energy distribution over the Earth caused by the rotation of the Earth around its axis.

The observed climate is a mixture of many different atmospheric processes including a number of complex feedback mechanisms. Some of these processes are directly affected by human activity such as burning of fossil fuel. However, there is also a large natural variability, which it is necessary to understand in order to assess the possible contribution of humanity to climate.

Causes of climate changes

Causes of climate change can be divided into two main categories: those that are due to external forcing of the climate system and those that are due to an internal redistribution of energy and matter within the global climate system.

The internal redistribution has a significant effect on short time scales ranging from years to decades. The most prominent example of the interannual variability in the climate is the El-Niño-Southern oscillation (ENSO). It is due to a complicated interaction between various air masses in the tropics and anomalous warming of the eastern and central tropical Pacific Ocean. The heat capacity of the oceans and the nature of the ocean currents play a major role in controlling the state of the atmosphere and hence the climate. Ocean currents are in general not yet known with sufficient accuracy to enable us to predict their effect on climate. In addition, their effect is probably associated with chaotic behavior that may make it impossible to predict such changes. Indications of the probable range of such variations in a statistical sense may, however, be acquired from numerical climate models.

Changes in the energy budget of the Earth will result in persistent climate changes. The Sun's radiation is the source of the energy that drives the weather and climate. The Sun emits radiation at various frequencies. As a first approximation the Sun radiates energy corresponding to a black body with a temperature of 5770 K, the solar surface temperature. Integrated over all wavelengths the total irradiance from the Sun at the position of the Earth is approximately 1368 W m^{-2}, the solar constant. The cross section exposed to the solar energy corresponds to an area of πR^2 whereas the total surface area of the Earth including the night side is $4\pi R^2$. Distributed evenly over the Earth's surface we therefore need to divide the number by 4 to yield an average power of 342 W m^{-2} at the top of the atmosphere. In a steady state with no climate change the Earth would reradiate the same amount of energy as a black body at the global average temperature, approximately 288 K. This corresponds to a longer wavelength with a peak in the infrared part of the spectrum. The short-wave radiation from the Sun reaching the Earth's surface and the long-wave radiation from Earth to space have to pass through the Earth's atmosphere, which acts like a filter. The effect of the filter depends on the wavelength of the radiation and it has therefore a different effect on the incoming and outgoing radiation. The net effect of these processes, also called the Earth's radiation budget, is therefore highly dependent on the composition of the atmosphere. At present, the composition of the atmosphere is such that it keeps the global temperature about 31 K higher than the Earth would be without an atmosphere. The dominant gases contributing to this warming effect, the natural GREENHOUSE EFFECT, are water vapor and carbon dioxide (CO_2).

The composition of the atmosphere may change for a number of reasons. Volcanic activity is often accompanied by emission of considerable amounts of sulfur in the stratosphere. These emissions create aerosols that reflect sunlight and the effect is therefore a cooling of the Earth. Since the aerosols remain in the atmosphere for several years the effect on the Earth's average surface temperature may be quite significant. Energy balance calculations indicate that volcanic activity may have contributed to the observed global average temperature variations during the past 150 yr. In the stratosphere another gas, ozone (O_3), is varying because of the solar cycle variation in the ultraviolet radiation that produces O_3. However, the ozone layer is also depleted owing to the accumulating amount of anthropogenic chlorofluorocarbons (CFCs). Both CFCs and O_3 are very effective greenhouse gases but their combined effect on climate is significantly reduced because of the destructive effect of CFCs on O_3 (see OZONE HOLE).

Most concern is, however, associated with the effect of the atmospheric concentrations of greenhouse gases such as CO_2 and methane (CH_4). We know that these concentrations have increased considerably over the past 150 yr, after the start of industrialization and the rapid increase of the population of our planet. The gases absorb the long-wave radiation from the Earth's surface and are supposed to be responsible for at least part of the global warming that has characterized this century. The effect of human activity is rather complex, because the burning of fossil fuel that causes the increased concentrations of CO_2 has also caused an increase in the contents of sulfate aerosols in the troposphere. The effect of this may be a cooling similar to the effect of volcanic aerosols. Whereas the production of CO_2 is proportional to the amount of fossil fuel used, the emission of sulfate aerosols may

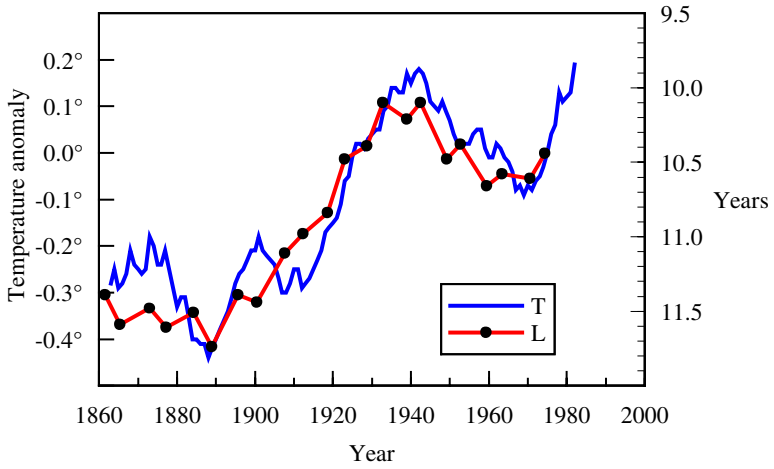

Figure 1. Smoothed length of the solar cycle (L) and the 11 yr running average of the northern hemisphere land temperature (T). (Figure taken from Friis-Christensen E and Lassen K 1991 Length of the solar cycle: an indicator of solar activity closely associated with climate *Science* **254** 698–700.)

be affected considerably by various measures to clean the exhaust, for instance the use of filters. The relative importance of these two atmospheric constituents that are products of fossil fuel burning has therefore changed in time and so has their expected impact on climate.

Long-term changes of climate

On very long time scales, billions of years, we know that the solar luminosity has been increasing monotonically with time. At the time of the formation of the Earth the Sun's output was only 70% of its present output. According to paleoclimatic records this huge change in luminosity has not, however, been associated with an expected corresponding increase in the average temperature of the Earth. This 'faint young Sun' paradox may be explained in several ways. Some of the most plausible ones are related to changes in the atmosphere and its composition. In particular, the large amounts of carbon trapped in carbonate sediments indicate that the abundance of CO_2 in the atmosphere must have been much larger during times in the past. An interesting theory by James Lovelock, called the Gaia hypothesis, even suggests that on very long time scales life itself is capable of modifying the Earth's environment, including the atmosphere, in order to optimize conditions for its own continued existence.

The history of Earth shows that climate has been varying on many time scales. Most prominent during the last two million years has been the repeated occurrence of glaciation with a period of approximately 100 000 yr. Reconstruction of past climate variations shows that, on top of this dominant quasi-cycle, shorter quasi-cycles of roughly 41 000 and 21 000 yr are superimposed. The apparent regularity of this phenomenon and the calculated periods has called for an astronomical explanation that was first quantitatively formulated by MILANKOVITCH in the 1920s. According to the Milankovitch theory the climatic cycles are related to the variations in the received solar energy and in particular its distribution over the Earth's surface. These variations can be predicted by changes in the rotational and orbital parameters of the Earth. The major period of about 100 000 yr is related to the variation of the eccentricity of the Earth's orbit around the Sun. The other parameters are related to the variation of the tilt of the Earth's axis between about 22° and 25° (~41 000 yr) and the precession of the equinoxes and solstices around the Earth's orbit (~21 000 yr). Although the changes may seem rather small, they have apparently been sufficient to initiate large oscillations in the Earth's climate in a manner still poorly understood. Model calculations show that the response to the orbital forcing is non-linear and that it involves internal processes and feedback mechanisms. These feedback mechanisms may involve changes in the atmospheric composition, in the amount of snow and ice, and in the biological cycle. It is still an open question, however, whether the external orbital forcing drives the internal processes or whether they act as a pacemaker for the free oscillations in the internally driven system. However, the apparent large climate sensitivity to small changes in the amount and latitudinal distribution of solar radiation has contributed further to the concern of possible effects of a humanly induced enhanced greenhouse effect.

Climate variations on shorter time scales

In addition to these crucial variations in the Earth's climate our records of past climate do show that climate has been varying also on time scales that are too short to be possible manifestations of orbital parameters. Some of these oscillations may be the result of internal oscillations but during the last century there has been an increasing number of scientific reports that indicate that some of them may be attributed to variations in the Sun.

Usually we regard the Sun as just an eternal source of energy that sustains life on Earth. Until recently the energy

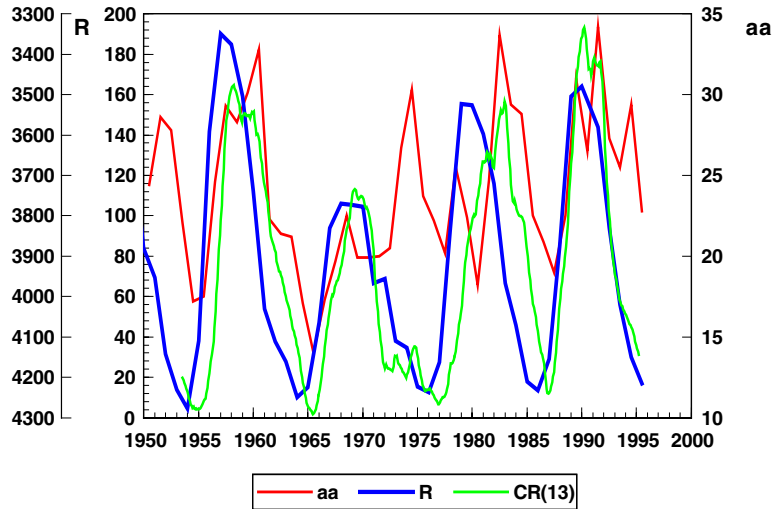

Figure 3. Variation of the cosmic ray flux (CR) observed at Climax station, USA, the yearly sunspot number (R) and the geomagnetic activity index *aa*. Note the reversed scale of the cosmic ray flux.

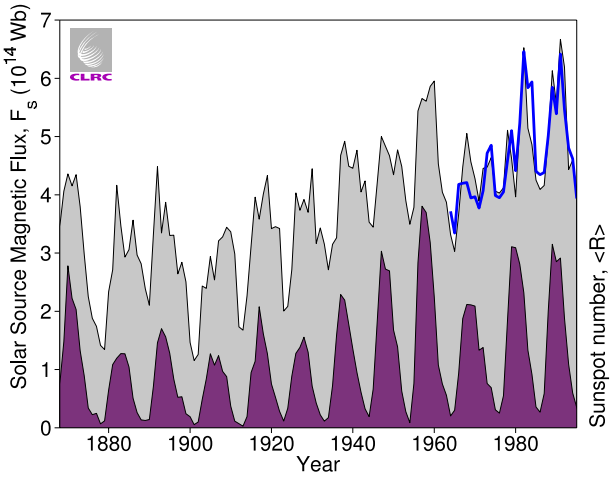

Figure 2. This figure shows estimates back to 1868 of the total solar magnetic flux emanating through the coronal source sphere. (Figure 3 in Lockwood M, Stamper R and Wild M N 1999 A doubling of the Sun's coronal magnetic field during the past 100 years *Nature* **399** 437.)

received from the Sun was believed to be constant, as the term 'SOLAR CONSTANT' for this value indicates. However, in astronomical terms the Sun is a variable star. This has been known for many centuries during which scientists have performed systematic observations of the Sun's surface. The observations demonstrate periodic variations on different time scales. Most pronounced among these is the nearly 11 yr cycle in the number of SUNSPOTS (see also SOLAR CYCLE). Direct indices for solar activity are not really available before the start of the use of telescopes around 1610. However, recently a promising tool has been developed which may enable us to derive indices of solar activity on much longer time scales. This method is based on indirect proxies, for example the cosmogenic radionuclides ^{14}C and ^{10}Be. These nuclides are caused by cosmic ray particles and, because they are electrically charged, both the geomagnetic field and the magnetic field in the heliosphere modulate their production rate. The magnetic field in the heliosphere has its origin in the solar surface magnetic activity. Therefore the inferred production rate of radionuclides in the atmosphere may be used to provide an index of solar magnetic activity back in time (see SOLAR ACTIVITY: LONG-TERM RECORDS).

Such estimates of solar activity variations in the past have made it possible to examine a possible relationship with past climate. A number of studies showing a striking correlation have been reported. During the last millennium the major historically recorded deviations from the present climate are the Medieval warm period during the 11th and 12th centuries, when the Vikings settled in Greenland, and the cool period in Greenland and Europe in the 17th century known as 'the Little Ice Age'. The warm period is associated with a period of high solar activity as deduced from the estimated very low production of radionuclides. On the contrary, the Little Ice Age is associated with a prominent minimum in solar activity, known as the Maunder minimum, during which the production of radionuclides was very high.

The occurrence of sunspots indicates only one manifestation of solar activity. However, it is by no way obvious that the sunspot number is the most relevant parameter for a possible direct effect on climate. Another index of solar activity is the duration of the solar cycle. On the average a solar cycle is about 11 yr but high-activity cycles are generally shorter whereas solar cycles with low peak activity are longer. During this century solar cycles were long at the beginning of the century whereas they were short at the end. In figure 1 the change in solar

cycle length during the last 130 yr is compared with the 11 yr running average of the northern hemisphere land temperature. The striking similarity between the two curves indicates that the Sun may have played a major role in global temperature change during this century.

Possible physical mechanisms for solar activity induced effects on climate

In order to claim a direct cause-and-effect relationship it is necessary to point at a plausible physical mechanism. An obvious candidate is the possibility that the total solar irradiance (the solar 'constant') varies in accord with solar activity. Accurate observations of the total irradiance are not possible from the ground because variations in the atmospheric composition by far dominate any changes that might be attributed to variations in the solar 'constant'. It was therefore not until direct measurements from satellites became available in the 1980s that the hypothesis of a solar cycle variation in total irradiance could be tested. These measurements did in fact demonstrate that changes exist, both on short time scales (days to weeks) and on longer time scales (decades). The competing effects of sunspot darkening and faculae brightening could account for the short-term variations. The variations on the decadal time scale did unambiguously show a variation in phase with the sunspot cycle but these variations only amounted to 0.1% between sunspot maximum and sunspot minimum.

The effect on the global temperature of such a change is, however, small compared with other radiative climate forcing parameters associated with changes in the composition of the atmosphere. Even if changes in total irradiance may amount to ∼0.25% over longer periods as has been suggested to be the case for the Maunder minimum, they may only be of minor importance for climate. Whereas the global warming during this century could be mainly due to the enhanced greenhouse effect this cannot be the case for the significant past climate variations. Since many of the past climate changes have been demonstrated to be correlated with changes in solar activity variations, people have looked for indirect mechanisms by which solar activity variations could modulate climate.

One possibility concerns the ultraviolet part of the solar irradiance. Solar cycle variations in this spectral band are much larger than for the visible light. Attempts have therefore been made to model the climatic effect of solar cycle variations taking into account also the modulating effect of the varying ultraviolet radiation on the lower stratospheric ozone. The models show an increased tropospheric Hadley circulation during high solar activity consistent with observations, although the observations also indicate a larger effect than the models predict. The effect may contribute to the observed very clear solar cycle signature in the height of constant pressure levels in the stratosphere, seen consistently during the last four solar cycles in particular between 20°N and 45°N in the Pacific–Atlantic area.

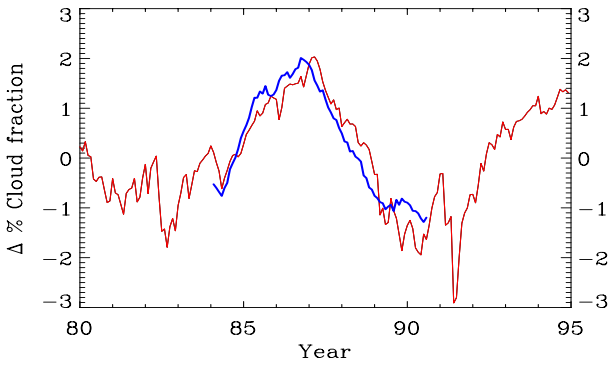

Figure 4. Variation of total cloud cover and cosmic ray flux observed at Climax. (Figure taken from Svensmark H and Friis-Christensen E 1997 Variation of cosmic ray flux and global cloud coverage—a missing link in solar–climate relationships *J. Atmos. Sol.-Terr. Phys.* **59** 1225–32.)

Even more pronounced manifestations of solar cycle effects in the solar energy output are associated with the solar wind, the emission of particles and fields from the solar surface. Although the energy in the solar wind is negligible compared with the energy in the ultraviolet and visible spectral bands, the relative variations are much larger. A direct effect of the varying solar wind is seen in the fluctuations in the geomagnetic field due to electric currents in the magnetosphere and the ionosphere. The *aa* index has been derived from such fluctuations recorded at two geomagnetic observatories in England and Australia since 1868. From the time series of this index it has been inferred the total magnetic field leaving the Sun may have increased by a factor of more than 2 during this century (see figure 2). Such an increase is most likely the cause of the decreasing cosmic ray flux during this century, which has been observed from the ground since the 1930s and which has also been inferred from the ^{10}Be data from ice cores in Greenland. Figure 3 shows the cosmic ray flux observed at the Climax Neutron Monitor station in Colorado. Note the reversed scale indicating a clear solar cycle modulation nearly in antiphase with the variation of the sunspot number, R. The figure also shows the geomagnetic activity index, *aa*, which has a solar cycle variation quite different from the sunspot cycle.

One of the major uncertainties in climate models is the role of clouds (see also CLOUDS IN PLANETARY ATMOSPHERES). In particular there are large difficulties associated with the parameterization of these effects in general circulation models used in climate studies. Recent studies indicate that cloud formation may be influenced by Galactic cosmic rays through ionization changes that cause microphysical changes in the atmosphere. Hereby nucleation and growth of ice particles may be affected.

A change in cloud cover would indeed be a very effective amplifying mechanism for climate forcing because the energy necessary to condense water vapor is small compared with the resulting changes in energy of

solar radiation received at the Earth's surface. Figure 4 shows the result of an examination of the compiled International Satellite Cloud Climatology Project (ISCCP) data. The 12 months running mean of the total cloud cover (thick curve) is shown together with the 12 months running mean values of cosmic ray intensity measured at the Climax Neutron Monitor station, Colorado. The correlation between the cosmic ray flux and the global cloud cover is very high and indicates a direct relationship although a detailed mechanism is still lacking.

Summary

The Earth's climate is a very complex system with a number of elements and with many feedback mechanisms. Various processes including variations in solar activity can cause climate changes. The detailed mechanisms and the relative importance of the different processes are still not very well known but increased understanding of our environment including the processes on the solar surface and in the heliosphere will considerably improve our ability to estimate the effect on climate of human activity.

Solar–Terrestrial Connection: Space Weather Predictions

'Space weather' refers to the dynamic state of the magnetosphere and ionosphere, which is determined by the SOLAR WIND. Interest in the ability to predict space weather, and its effects on Earth, really began during World War II. For the first time, electronic technologies, such as radars and radio communications, were heavily relied on, and it soon became clear that these technologies could be seriously disrupted by solar activity. After the war, more uses were developed for electronic technologies, including the start of the space program. Since then, our need to be able to forecast solar activity has continued to increase as technology becomes more widespread. Under disturbed conditions, satellite- and ground-based technological systems, e.g. communications networks, electric power grids and satellites, can suffer harmful effects. Such systems are particularly vulnerable during severe GEOMAGNETIC STORMS. Large storms are relatively infrequent but, when they occur, they can stress the susceptible systems for prolonged periods of time over large geographic areas. Secure operation of systems can still be maintained and hazards can be minimized if the occurrence, duration and severity of impending storms can be accurately predicted in a timely manner. Thus, space weather forecasting is important for protecting national assets in both the commercial and military sectors.

In the early days of solar forecasting, it was assumed that when a large FLARE occurred on the Sun there would be a very predictable geomagnetic disturbance on Earth within a few hours or days. Later it was realized that it was the SOLAR CORONAL MASS EJECTIONS (CMEs) that had a greater effect on Earth. It was therefore believed that improved forecasting was just a matter of making better observations of the Sun so that flares and CMEs could be detected immediately after they occurred. Experience, however, soon showed that the effects on Earth did not correlate so simply with events on the Sun and, moreover, not all mass ejections had a noticeable effect on Earth. Sometimes geomagnetic storms occurred when there was no apparent eruptive activity on the Sun. We now know that how the Sun's magnetic field connects with the geomagnetic field makes a big difference in how solar activity affects Earth. When a mass of PLASMA is ejected from the Sun, the plasma travels outward in the solar wind. These plasma bursts have their own magnetic fields, which are carried along with the plasma. How these fields are oriented when they arrive at Earth determines whether or not the event will be effective. When the direction of the solar wind field is opposite the direction of Earth's field, MAGNETIC RECONNECTION occurs, and the magnetosphere essentially becomes joined to the solar magnetic field. In this condition, Earth is much more prone to the effects of the solar wind. Solar wind particles can enter the magnetosphere more easily, and those already within the magnetosphere are energized. If the magnetic field of the solar wind is in the same direction as the Earth's field, then magnetic reconnection does not occur and the magnetosphere is much more separated and protected from the solar wind. Under these conditions, the effects of CMEs are much less significant. In order to know what is going to happen on Earth it is important to know not only what happened on the Sun but also the characteristics of the magnetic fields that are carried along with the solar wind. Accurate forecasts of large storms are difficult to achieve because the propagation of solar disturbances to the Earth and magnetic field characteristics are difficult to predict with high accuracy. Using the solar wind and interplanetary magnetic field quantities measured upstream from the Earth as input, however, can warn of the impending arrival of solar wind structures and, therefore, predict their geoeffectiveness, that is to say, their effect on the Earth. Forecasters have reviewed large amounts of historical solar wind data and have found that they can identify and predict the occurrence of large storms, with accuracy in the range 70–80%.

Recently, a number of spacecraft have been launched

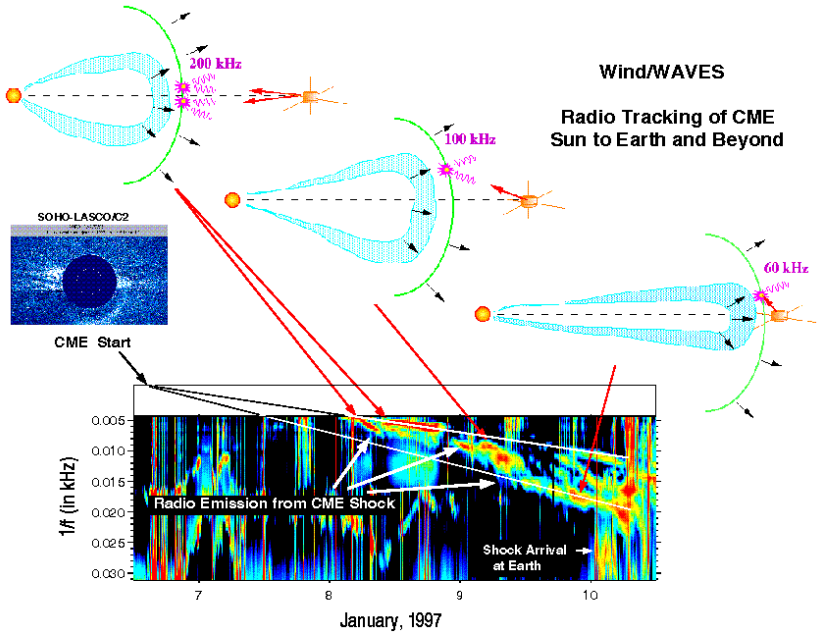

Figure 2. Dynamic spectra of radio data taken by the WIND spacecraft during 6–11 January 1997 in the frequency range 23–245 Hz. Radio emissions from the CME shock are marked on the figure and decrease in frequency as the CME moves further from the Sun. The cartoon above the spectrogram represents the progress of the CME as it expands away from the Sun towards the WIND spacecraft located about half a million miles in front of the Earth.

which have improved our ability to forecast space weather disruptions. SOHO (Solar and Heliospheric Observatory), a joint NASA (National Aeronautical and Space Administration) and ESA (European Space Agency) mission, provides near-real-time images of the Sun and its CORONA, clearly showing ACTIVE REGIONS, flares and CMEs. Events occurring on the side of the Sun—the limb—are regularly seen which will not affect the Earth. Sometimes, however, CMEs occur on the side of the Sun facing Earth. These events appear to be very different when viewed from Earth. Instead of looking like a 'bubble' of plasma, they form a circle of light around the Sun. This light is much dimmer than the Sun itself, so it is necessary to put an occulting disk in front of the Sun in order to see what goes on around it—like an artificial solar eclipse. The instrument used to do this is called a CORONAGRAPH. An example of such a 'halo' event is shown in figure 1, together with one occurring on the limb for comparison.

The faster CMEs have outward speeds of up to 2000 km s^{-1}, considerably greater than the normal solar wind speeds of about 400 km s^{-1}. These produce large shock waves in the solar wind as they plow through it, much like a jet breaking the sound barrier drives a sonic boom into the atmosphere. In the case of the CME shock, however, the sonic boom takes the form of very intense, low-frequency radio emissions known as solar type II bursts. (Instruments on Earth cannot detect the type II bursts because the ionosphere blocks the waves. Only a radio receiver in space can detect them.) As the shock approaches Earth, these type II bursts drift down in frequency (see figure 2) because the electron density of the interplanetary medium to which the solar bursts are 'tied' is also constantly decreasing. Space-borne instruments are capable of detecting these radio bursts from a great distance, long before the CME arrives at Earth. These radio receivers can also determine the direction from which the waves are arriving. Combined with the known propagation speed of the shock, this information allows forecasters to track the CME shock front nearly from the time that it is no longer visible to the solar telescopes, all the way to Earth. Finally, as mentioned above, it is critical to have a satellite between the Sun and Earth so that the nature of the solar wind can be observed before it arrives. In August of 1997, NASA launched ACE, the Advanced Composition Explorer satellite, which is located a million miles upstream of the Earth. This location allows ACE to detect the Earth-directed solar wind about 1 h before it impacts us.

The NOAA Space Environment Services Center (SESC) in Boulder is one of the world centers making forecasts of solar and geomagnetic activity (see figure 3). Daily predictions are issued for the likelihood of solar flares, proton flares, x-ray events and magnetic storms. Longer-range forecasts are also made so that the launches of manned space flights can be planned with more safety. The SESC receives about 1400 data streams daily, including x-ray and particle flux data from the GOES satellites, Hα images and magnetograms from observatories around the world, measurements of the geomagnetic field at many locations, and 10.7 cm radio levels from several

Figure 3. The new NOAA Space Environment Forecast Center. In a similar manner to meteorologists checking temperatures, winds and pressure to predict the weather on Earth, scientists monitor the Sun and the space environment to help forecast space weather.

radio telescopes. Each day the features of the solar disk are mapped by hand so that the evolution of active regions, coronal holes, filaments, and neutral lines may be carefully studied. Forecasters attempt to consider all of this information when making their daily forecasts of solar effects on Earth. At the present time, these forecasts are not very reliable; major flares are sometimes not forecast and predictions that are made often do not come true. Even though forecasters have a large amount of data to work with, the physics of the Sun, the magnetosphere and the interplanetary medium is not well understood. At the present time, many partial mathematical models have been developed, but there is no comprehensive model of the solar–terrestrial environment.

In most cases, the ability to predict the behavior of nature comes from a mathematical model. Earth weather forecasters have been trying for the last 30 yr to construct a mathematical model of the global weather using the very complex equations of fluid dynamics to describe the circulation of the oceans and atmosphere. Even with the best supercomputers to run these models, it has proven impossible to precisely model Earth weather. Modeling the solar–terrestrial environment is vastly more complex. The physics necessary to do this includes not only fluid dynamics but also Maxwell's equations. This combination is known as MAGNETOHYDRODYNAMICS (MHD), and at the present time the equations of MHD cannot be completely solved analytically.

Research to improve solar forecasting is occurring in three major areas. The *first* is improving the basic understanding of the way in which eruptions from the Sun occur, namely of prominence eruptions and CMEs. In particular, a workable two-dimensional model of the way a coronal arcade loses equilibrium and erupts as an MHD catastrophe is being developed into a three-dimensional model. Also, models are being developed for the three-dimensional evolution of coronal structures before they erupt. The *second* area is the correlation of observable phenomena with effects on Earth. For example, a strong correlation has been observed between sunspot cycles and disturbances on Earth. However, this correlation is very coarse; it is known that during a certain period of years there will be high levels of solar activity and accompanying disturbances on Earth. It is not yet possible to accurately predict these disturbances as happening over specific days or hours. Many researchers are trying to refine the correlations between observable symptoms, such as increased radio emission, and subsequent eruptions of mass. Some of the best correlations yet are those that have been found between the evolution of sunspot groups and eruptions.

The *third* area of work is that of constructing a model for the solar–terrestrial environment. In addition to the complexities of MHD, the problem is difficult because there are three different domains involved, which all couple together. The first domain is that of the Sun; to simply construct a mathematical model of the Sun is far beyond researchers at the present time. There are still many mysteries about what processes occur inside the Sun, what triggers flares and even why sunspots form. The second domain is the interplanetary medium, once thought of as empty space. This space is filled with the solar wind plasma, which is not fully understood. The third domain is the Earth's magnetosphere, with its many regions and currents. The magnetotail, extending for millions of kilometers out from Earth, has been difficult to

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

study directly and remains poorly understood. Models for any one of these domains by themselves are not even close to completion, but the final complication arises because these three domains are not at all separate. A change in one of these domains can have major consequences on the Earth. Scientists and forecasters alike continue to analyze misses and false alarms in detail to better understand the performance characteristics of the prediction methods, and a number of improvements have been developed to deal with the known failure modes. It is hoped that one day there will be a comprehensive model for the entire solar–terrestrial environment but this is certainly a problem for physicists of the future. Forecasters will continue to make forecasts based on present knowledge and available data, and hopefully the forecasting ability will continue to improve. The physics of the solar–terrestrial environment is still one of the great frontiers, awaiting new generations of scientific explorers.

SolarSoft

The SolarSoft system (SSW) is a set of integrated software libraries, databases, and system utilities which provide a common programming and data analysis environment for solar physics. The SolarSoft environment provides a consistent look and feel at widely distributed co-investigator institutions to facilitate data exchange and to stimulate coordinated analysis. Commonalities and overlap in solar data and analysis goals are exploited to permit application of fundamental utilities to the data from many different solar instruments. The use of common libraries, utilities, techniques and interfaces minimizes the learning curve for investigators who are analyzing new solar data sets, correlating results from multiple experiments or performing research away from their home institution.

SolarSoft is primarily written in the Interactive Data Language (IDL) which is ideal for manipulating and visualizing image, spectral, time series and other data types common in solar physics. The extensibility of IDL and large number of SSW contributors, coupled with SolarSoft automated upgrade and software exchange utilities, stimulates rapid evolution of analysis capabilities. The SolarSoft system was originally built from the Yohkoh, SOHO, Solar Data Analysis Center (SDAC), and the Astronomy IDL software libraries and it draws upon contributions from many members of those projects. More recent participants in SolarSoft include TRACE, HESSI, SXI, and many ground-based optical and radio observatories.

Principal goals of SolarSoft

The primary goals of SolarSoft include:

- *Provide a large reusable software library.* The shared, general purpose SSW library provides a large and growing collection of observatory and instrument independent software. This permits instrument Principal Investigator (PI) teams to concentrate software efforts on detailed analysis and calibration issues rather than reinventing general use development and analysis software.
- *Promote an evolutionary environment.* Feedback and contributions from the many SSW institutes and users are strongly encouraged. Utilities to simplify remote SSW upgrades and accept user contribution are designed to make the system evolutionary instead of stagnant and divergent.
- *Promote the use of standards that will facilitate coordinated data analysis.* Through use of a *minimal* set of suggested standards, many powerful applications are immediately available for the analysis of new data sets.
- *Provide easy access to supporting ancillary databases.* Access to supporting data sets from ground-based and satellite-based solar observatories are provided with consistent interfaces to facilitate coordinated analysis.
- *Provide a file-format-independent analysis environment.* To accommodate the largest number of solar data sets, file I/O is isolated and analysis applications are designed to operate on objects which are independent of file type.
- *Provide a hardware- and site-independent analysis system.* Fundamental shared software is written in a hardware-independent and site-configuration-independent form. The SSW setup utilities support local configuration files to tailor the site and user's environment.
- *Permit simplified and customized installation and environment definition.* Due to the large number of contributing instruments and libraries, integrated function should be preserved when any desired subset of libraries is included in a local installation or individual analysis session.
- *Maximize Principal Investigator team control of instrument level software.* Within the integrated system and analysis environment, allow PI teams full control of the instrument specific analysis software and provide system utilities and suggested guidelines to faciliate integration.
- *Provide integrated access to other IDL packages.* When IDL libraries that provide a useful extension to SSW capabilities are identified, they are integrated into the SSW system.

The reusable software library

The reusable software library is the heart of the SolarSoft system. Routines in this library are instrument and mission independent, and available to all users for analysis and application development. This library represents an evolutionary system, dating back to SMM analysis at the Solar Data Analysis Center at Goddard Spaceflight Center (GSFC). It has since evolved through the Yohkoh and SoHO missions, and now includes contributions from TRACE, HESSI, and from many other solar instrument PI team members.

A very small sample of existing library capabilities include:

- time series analysis, time conversions, time series plotting
- spectral fitting
- image and image cube (movie) processing and display
- solar image data routines (limb fitting, image and grid overlay, coordinate transformations, feature tracking, co-alignment, etc)
- file I/O (generic binary, ASCII, FITS, etc)
- IDL data manipulation (structure, string, array, mathematics, etc)
- WWW interface (HTML conversion, file conversions, FORM handling, WWW server mode)

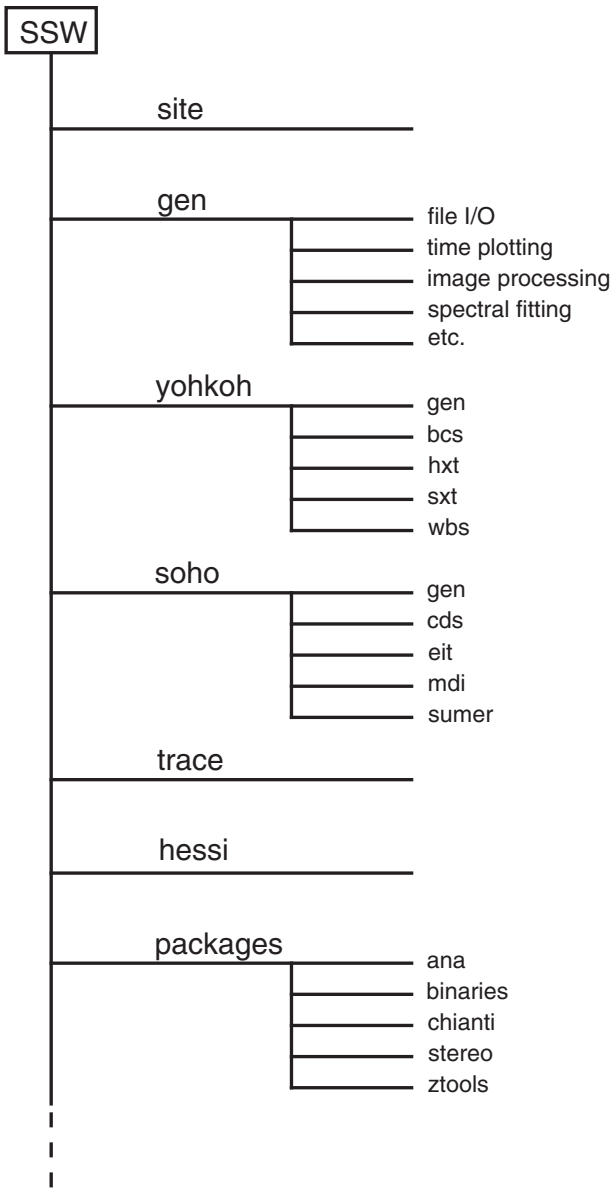

Figure 1. SolarSoft directory tree structure. The software libraries for each instrument are organized into a number of functional subdirectories which are not shown.

SolarSoft system overview

Library and path organization

A schematic of the upper level SolarSoft library and directory hierarchy is illustrated in figure 1.

The topmost level includes a SITE branch for local configuration files, the GEN branch which contains the SSW general purpose library and an extensible number of mission level branches. For clarity, only a representative subset of missions are included in the figure. In this context, a mission is a set of one or more related instruments or observatories. Mission branches include single instrument observatories, such as TRACE and HESSI, multi-instrument observatories, such as Yohkoh and SoHO, and groupings of related ground based observatories, such as optical and radio.

This intermediate level of organization by mission facilitates access to shared libraries among the related instruments or observatories. The contents of those libraries are mission dependent but instrument independent. For example, all of the instruments on a multi-instrument orbital observatory desire access to spacecraft ephemeris software and data bases. The gen branches under the mission level provide common, single source software to all of the related instruments (Yohkoh-gen and SoHO-gen for example).

The instrument level branches contain the calibration files and software which are required for detailed or specific instrument data analysis. With the exception of very minimal library and setup file naming conventions, the contents and organization of the branches under the instrument levels is (and *must be*) defined by and controlled by the the instrument PI teams.

Mastering, integration, and verification

The master copy of SolarSoft and support utilities is maintained at the Solar Data Analysis Center at GSFC. This is also the master site for the general purpose SSW library. Only a few core SSW members are authorized to update the general library. Since this is automatically distributed to all remote SSW sites, routines must remain backwardly compatible and continued support for older IDL versions must be considered. All additions and modifications are logged, and backup copies of modified modules are maintained by the *SSW online* utility. Additional protection is provide by the SDAC system facilities, which include multiple levels of automated backup and disk recovery.

Principal Investigator (PI) teams from each participating instrument define and control the master libraries and databases for the individual instruments. These instrument and mission level master sites are widely distributed, and currently include institutes in Japan, England, France, Switzerland, and many institutes within the United States.

SolarSoft utilities running on the SSW master site at GSFC update from the various instrument master sites into the SSW master for centralized integration and distribution. Due to the very large number of contributing sites and routines, background utilities (written in SSW) monitor incoming additions and flag potential conflicts within the integrated system. Additional SSW utilities monitor modifications and sizes of software libraries and data bases to generate system files required by the installation and upgrade utilities.

Now that the SolarSoft organization, monitoring, and distribution system is in place, adding new instrument libraries into the infrastructure approaches 'plug and play' simplicity, assuming that the PI teams are willing to address any conflicts which are flagged by the system. There is an intermediate level of integration available which allows new libraries to take advantage of the

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

conflicts checking and distribution portions of SSW without requiring more rigorous, conflict-free standards suggested for fully integrated libraries.

Remote installation and upgrades

SolarSoft is easily installed through a web-based interface. Although the number of instrument libraries and databases under SSW is extensive, a primary design goal was to permit remote sites to install any desired subset of SSW while still preserving the integrated function. The SSW installation FORM allows the WWW client to select the desired instrument libraries and generates a customized installation script. When executed on the local machine, the script creates the necessary directories, automatically transfers the required installation files from the designated SSW host, and installs them to produce the local customized SolarSoft tree. Due to the evolutionary philosophy of SolarSoft, frequent periodic upgrades are strongly suggested (daily is typical) and utilities are included in the SSW distribution to automate upgrades of the local SSW system. The installation and upgrade utilities use a programmable SSW host internet address for file transfers to permit use of the SSW 'master' with the best internet connection to the local site. Following the initial installation and configuration, it is sufficient to add instrument or mission names to a SSW site configuration file to automatically include new branches in the local SSW system. The upgrade process is incremental so that only new or modified software is transferred.

The history of SolarSoft

The overall organization and philosophy of the SSW system structure draws heavily from the Yohkoh data analysis system. Even though Yohkoh observatory included four very different science instruments, it was obvious that there were a large subset of common analysis goals and that the use of some common definitions would permit use of fundamental cross instrument software. For example, all four instrument teams required access to Yohkoh ephemeris and supporting ancillary databases—those commonly desired software functions should be written once, not rewritten four times. The analysis of data from each Yohkoh instrument is greatly enhanced by crucial context provided by the other instruments. A minimal set of parameters, such as observation time, were defined in common formats to simplify cross-instrument access and facilitate coordinated analysis.

A key requirement and innovative feature of the Yohkoh system was a simple, internet-based installation, upgrade and feedback infrastructure. Since the Yohkoh co-investigator institutes included widely distributed sites in Japan, the UK, and several states in the US, it was important to propagate changes and incorporate contributions quickly enough to avoid divergent libraries at the remote institutes. Installation and upgrade utilities developed prior to Yohkoh launch (and predating the WWW) greatly simplified this task.

Another design goal was platform independence. At the time of Yohkoh design, many different computer platforms were in use at the Institute for Space and Astronautical Science (ISAS) in Japan and at many co-investigator institutes in the UK and USA. Systems designated for Yohkoh analysis included DEC VMS, DEC Ultrix, and Sun and RISC workstations running Unix.

Selection of IDL

The Interactive Data Language (IDL) software package written by Research Systems Inc. (RSI), Boulder, Colorado was ideal for analysis of the disparate science data sets on Yohkoh, which include images, spectra and time series. The use of IDL also moved the majority of the system dependency burden from Yohkoh programmers to the RSI/IDL programmers. Some of the Yohkoh team members had previously worked at the SDAC on the Solar Maximum Mission (SMM)—several of the SMM instrument teams and SDAC members were using IDL for data analysis and this provided an experience base and the starting seed for a general purpose IDL library.

Initially, some Yohkoh teams tried to maintain portions of the software using heritage Fortran programs. They rapidly discovered that, in order to support the different platforms used for Yohkoh analysis, five or more executables needed to be built for each task. Updating and propagating an application to the distributed investigator sites in a timely fashion was nearly impossible, since the multiple executables required verification on each of the architectures. It was therefore decided to translate the bulk of the remaining Fortran software into IDL. There are still a very few tasks written in Fortran or C, but these are primarily applications which have specialized use and only need to be run at a restricted number of sites.

By following a few simple programming rules and extending the language as required with a few key interface routines, the Yohkoh IDL-based system was easily transportable. For example, filenames are never specified with an explicit directory or path—environmental variables, or their equivalent are used to indicate file locations located within the computer file system. The mapping of several key environmentals to the local, hardware specific pathnames is accomplished by simple modification to setup files in the site branch. Relative pathnames are then constructed dynamically by interface routines which use the context of the current operating system. Yohkoh contributors were encouraged to prefix instrument-specific routine filenames with their instrument acronym in order to minimize potential collisions in routine names.

From Yohkoh to SolarSoft

Prior to the launch of the Solar and Heliospheric Observatory (SoHO) it was decided to review the Yohkoh utilities, identify all of the truly mission independent routines and place them into a shared library. A prime motivator for this was that quite a few of the Yohkoh science and programming team were now members of

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills, Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

various SoHO instrument or analysis teams and they desired to continue using and extending familiar analysis and programming utilities. A common library was then available for Yohkoh, SoHO and future missions for applications development and analysis and offered future potential for coordinated analysis. A mission level layer was added to the existing Yohkoh instrument level library and path infrastructure and SolarSoft was created.

Recent trends—SolarSoft and the World Wide Web

An extensive set of SolarSoft routines and techniques have evolved which leverage WWW technologies and offer great potential for distributed solar physics analysis. In addition to extensive file converters, movie making tools and HTML generators written in IDL, SolarSoft also includes an innovative set of utilities for executing SolarSoft applications through any WWW client (browser). This system uses a very simple (about five line) CGI script to pass information from an WWW FORM to an IDL server which is running the SolarSoft environment. An SSW IDL interface function converts the FORM stream directly into an IDL data structure. This infrastructure implies that all data base searching, access, analysis, and display functions which are available within an interactive SolarSoft session are also available through a WWW client. Examples of this server mode SSW application include the remote SolarSoft software and data base installation FORMS, customized Yohkoh/SXT movie maker, the TRACE WWW catalog search and data request system and many others. The HESSI team and Max Millennium Program is using this SSW server technology to provide WWW client access to the ancillary data bases available at the SDAC.

Instruments supported by SolarSoft

By 1999, analysis capabilities for a large number of instruments from many different solar missions were fully integrated into SSW, including:

Yohkoh: BCS, HXT, SXT, WBS
SoHO: MDI, EIT, CDS, SUMER, LASCO
TRACE: TRACE
CGRO: BATSE
GOES: Soft X-ray Monitor
Spartan: Spartan
SMM: XRP, HXIS, HXRBS, CP UVSP, GRS
Radio: ETHZ, Nancay, Nobeyama
Optical: SOON, La Palma

Descriptions of the space-based instruments may be found in SOLAR TELESCOPES and INSTRUMENTS: SPACE. The ground-based radio and optical observatories are described in SOLAR TELESCOPES and INSTRUMENTS: GROUND.

Other missions which are expected to participate, with the planned launch dates indicated, include:

HESSI: Hessi (2000)
GOES: Soft X-ray Imagers M,N,O (2000-2005)
Solar-B: SOT, XRT, EIS (2004)

Software packages by other individuals or groups which provide useful extensions are integrated and distributed with SSW. These SSW *packages* include:

Chianti: UV and EUV diagnostics; K Dere
ANA: public domain data analysis; R Shine
Stereo: dynamic stereoscopy; M Aschwand
Ztools: vector and solar tools; C DeForrest
SPEX: spectral analysis; R Schwartz

Acknowledgments

The success and evolution of solarsoft depends upon contributions from its many users and SSW instrument team members. Special thanks are due to members of the Yohkoh and SoHO co-investigator institutes, the Solar Data Analysis Center at GSFC, and the Yohkoh Data Archive Centre (YDAC), at the Mullard Space Science Laboratory. A portion of the work for design and administration of SolarSoft is supported under NASA contracts NAS8-40108, NAS5-32966, and NAS5-38099.

Solstices

The point on the ecliptic at which the Sun reaches its maximum declination north or south of the celestial equator. The greatest northerly declination corresponds to the summer solstice, the greatest southerly declination to the winter solstice. In the Northern Hemisphere the summer solstice occurs on 21 or 22 June and the winter solstice on 21 or 22 December. In the Southern Hemisphere, where the seasons are reversed, the situation is exactly the opposite.

In the Northern Hemisphere at the time of the summer solstice, the North Pole is tilted 23.45° towards the Sun. Because the Sun's rays are shifted northward by the same amount, the vertical noon rays are directly overhead at the Tropic of Cancer. Six months later, the south polar end of the Earth is inclined 23.45° towards the Sun. On this day of the summer solstice in the Southern Hemisphere, the Sun's vertical overhead rays progress to their southernmost position, the Tropic of Capricorn.

Sombrero Galaxy

Popular name for M104, a spiral galaxy in the constellation of Virgo which is almost edge-on as seen from the Earth. The disk that surrounds its unusually large central bulge contains a very prominent lane of obscuring dust which, because the disk is tilted to the line of sight by a small angle (about 6°), cuts across the face of the bulge. These features cause the galaxy to look rather like a wide-brimmed sombrero hat.

Located at a distance of about 60 million light-years, the Sombrero Galaxy is a massive spiral with a bright compact nucleus that is star-like in appearance. Spectroscopic observations reveal high rotational velocities inside this nucleus, and imply that about a billion solar masses of material is concentrated very closely together, possibly within a supermassive black hole, at the center of M104

Somerville, Mary [née Fairfax] (1780–1872)

Physicist and mathematician, born in Jedburgh, Roxburghshire, Scotland, self-educated, and educated with the aid of her brother's tutor. With the early death of her husband, she found herself a widow of independent means and took up mathematics, studying astronomy and dynamics. She carried out experiments on magnetism and the solar spectrum. She wrote a popularized rendition of Laplace's *Mecanique Celeste* and Newton's *Principia* called *The Mechanism of the Heavens*, and an account of *The Connection of the Physical Sciences*. Her discussion of a hypothetical planet causing the orbital perturbations of Uranus inspired JOHN ADAMS to make calculations of the position of Neptune. Mary Somerville and Caroline Herschel (see HERSCHEL FAMILY) were the first two women to write papers read to the Royal Society. *Somerville College* in the University of Oxford was named after her.

Sosigenes of Alexandria (*c.* 50 or 90 BC–?)

Peripatetic Greek philosopher, born in Alexandria, astronomer and mathematician who advised Julius Caesar on calendar reform. He recommended a year of 365.25 days, and inserted extra days into the year 46 BC to bring the calendar back in register with the seasons. His account of Eudoxus's planetary system is the most complete surviving account.

South African Astronomical Observatory

The South African Astronomical Observatory (SAAO) is the national facility for optical and infrared astronomy in South Africa. Its prime function is to further fundamental research in astronomy and astrophysics at a national and international level through the provision and use of a world-class astronomical facility. There are strong international links to other countries worldwide through scientific collaboration and technological exchange. The SAAO contributes to the future development of South Africa by providing training in a scientific and high-tech environment; by stimulating young people to follow careers in science and technology through a school and teacher science education program; and by helping to create a culture of science and technology amongst all communities by a vigorous science awareness program.

The SAAO is one of a number of research facilities in South Africa run by the National Research Foundation and it is financed by a government grant. SAAO's headquarters are in Cape Town (at the Royal Observatory, Cape of Good Hope, founded in 1820) and the telescope facilities are located at Sutherland in the Northern Cape. The four main telescopes range in aperture from 1.9 m to 0.5 m. The major new facility will be the SOUTHERN AFRICAN LARGE TELESCOPE (SALT) to be constructed by South Africa and international partners. This 10 m class telescope will be based on the Hobby–Eberly Telescope at MCDONALD OBSERVATORY, Texas and is of tilted-Arecibo design.

For further information see
http://www.saao.ac.za.

South African Astronomy

Prior to the middle of the eighteenth century almost all of the astronomical observations made in South Africa were those necessary for the determination of position—particularly that of the Cape of Good Hope. Some exceptions were the independent discovery of bright comets, of which van Riebeeck's comet of 1652, named after the first Governor of the Cape, is an example.

Because of the need for a comprehensive survey and catalog of the southern sky, in 1751 the French Academy of Sciences sent Nicolas Louis de la Caille (1713–62; usually known as LACAILLE) to the Cape for two years. Establishing a small observatory in Strand Street, Cape Town, during the 12 month interval starting in August 1751 Lacaille measured the positions of over 9800 stars. With this came knowledge of about 40 nebulae and clusters. In order to give classification numbers to the brightest stars, Lacaille invented many of the southern constellations that are in use to this day: Horologium, Octans, Microscopium etc.

During his second year Lacaille measured an arc of meridian in order to determine the radius of the Earth at the southern latitude of 34°.

The Royal Observatory, Cape of Good Hope

No further significant astronomical observations were made in South Africa until the founding of the Royal Observatory, Cape of Good Hope (RO CGH, figure 1) in the third decade of the nineteenth century. The foundation of this observatory, located about three miles east of Cape Town, was motivated by the fact that British astronomy was falling behind that on the European continent. The two responses were the founding of the Astronomical Society (later the Royal Astronomical Society) and the observatory at the Cape.

The RO CGH was built during 1825–8 and was directed by Fearon FALLOWS (1788–1831) who had been a Cambridge mathematician and exact contemporary of John HERSCHEL. The observatory was equipped for meridian astronomy—with a transit instrument and meridian circle identical to those employed at the ROYAL OBSERVATORY, GREENWICH.

Fallows died in 1831 from the effects of scarlet fever before he could prove the worth of the instruments. He was succeeded in 1831 by Thomas HENDERSON (1798–1845) who only remained a year, but his extensive use of the meridian instruments resulted in his detection and measurements of the parallax of ALPHA CENTAURI—one of the first of measured distances to stars. In 1833 Henderson left to become the first Astronomer Royal for Scotland, at the ROYAL OBSERVATORY, EDINBURGH.

Henderson was succeeded in 1834 by Thomas MACLEAR (1794–1879), who labored successfully to make the RO CGH into a world-class institution. Maclear and his principal assistant Charles Piazzi SMYTH (1819–1900), who succeeded Henderson in Scotland in 1845, were deeply engaged from 1837 to 1850 in re-measuring and extending Lacaille's arc of meridian with the result

Figure 1. The Royal Observatory, Cape of Good Hope.

that fewer stellar positional catalogs were produced than expected. When Maclear's principal work, the results of the arc of meridian, was published in 1866 it was considered the finest of its kind, and Maclear is known more as the founder of trigonometric survey in South Africa than for his contributions to positional astronomy.

During his first four years at the RO CGH Maclear worked closely with Sir John Herschel, who resided at the Cape from 1834 to 1838, providing him with accurate positions of the bright stars needed by the latter for reducing his 'sweeps' of the sky for nebulae, clusters and double stars.

Edward James Stone (1831–1897), who had been Chief Assistant to the Astronomer Royal, George Biddell AIRY, at Greenwich, became director of the RO CGH in 1870 and until he left in 1879 concentrated on preparing for publication all of the positional observations made by Maclear and his assistants. His 'Cape Catalogue' of 12 441 stars, published in 1880, included the extensive work of himself and his predecessor.

The RO CGH continued into the twentieth century as the only professional observatory in South Africa. Stone was replaced in 1879 by David GILL (1843–1914) who was later described (by Sir Robert BALL) as 'the most distinguished practical British astronomer since BRADLEY who has presided over one of our national observatories'. Gill's exceptional talents in design and application of astronomical instrumentation raised the RO CGH to the equal of any observatory in the world. His measurement of stellar parallaxes and (among many other examples) of the positions of Jupiter's satellites, using a heliometer of his own design, gave fundamental data of the highest available precision. His invention of wide-field photography for use in construction of catalogs of positions of stars led directly to the 'Cape Photographic Durchmusterung' and to the 'Astrographic Catalogue'.

David Gill's organization of an international campaign of observation of the minor planets Iris, Victoria and

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

Sappho, led to his deducing a solar PARALLAX and (indirectly) a mass determination for the Moon that were both accurate and not improved upon for many decades. As with Maclear, Gill participated in and supervised a major trigonometric survey, extending into what is now Zimbabwe. After retirement in 1906, Gill (knighted in 1900) returned to Britain; his principal occupation was the production of his book *History and Description of the Royal Observatory, Cape of Good Hope*, which was modeled on F G W Struve's similarly monumental description of the Pulkova Observatory, which had strongly influenced Gill in his development of the RO CGH.

Among the new instruments that Gill had designed and had built at the Cape Observatory were a unique Reversible Transit Circle, a twin 18/24 in refractor and the astrographic telescope. These continued to be employed in the first half of the twentieth century by Gill's successors: Sydney Samuel Hough (1870–1923; director 1907–23), Harold SPENCER-JONES (1890–1960; 1923–33), John Jackson (1887–1958; 1933–50) and Richard Hugh Stoy (1910–1994; 1950–68). During this time the work of the RO CGH was largely to produce another multivolume star catalogue—the *Cape Photographic Catalogue*, but new areas of astrophysical measurement were introduced in support of the catalog: in particular photometry and spectral types for most of the brighter stars.

A large effort was made in production of stellar parallaxes, using the photographic 24 in refractor, and Spencer-Jones organized an international campaign of observing the minor planet EROS from which he deduced another value for the solar parallax.

As, in effect, the national observatory, although it continued to be run by the British Admiralty until 1965, the RO CGH provided the time service for South Africa—initially through time balls, then electric telegraph and from 1925 by radio transmission. To this day the noonday cannon on Signal Hill in Cape Town is fired by electric impulse from the observatory.

At the end of 1971, through an agreement between the British and South African governments, the RO CGH ceased to exist and was reorganized at the beginning of 1972 as the SOUTH AFRICAN ASTRONOMICAL OBSERVATORY (SAAO).

The Union (later Republic) Observatory

The first truly South African observatory was opened in Johannesburg on 17 January 1905 as the Government Meteorological Observatory. Its director was Robert Thorburn Innes (1861–1933), who had worked at the RO CGH under Gill. When Gill was asked to recommend a director for the meteorological observatory he undoubtedly knew that Innes would soon expand that institution's work to include astronomical observations—Innes was a dedicated observer of visual DOUBLE STARS. By 1907 he had installed a 9 in refractor and in 1909 the South African government agreed to the purchase of a $26\frac{1}{2}$ in refractor from the Dublin optical firm of Sir Howard GRUBB. This was only installed in 1925. However, as a gift from the English amateur astronomer John FRANKLIN-ADAMS, in 1909 a 10 in photographic refractor was acquired and the resulting Franklin-Adams photographic atlas of the southern sky was the standard reference for the subsequent 50 years.

In 1912 what had been known as the Transvaal Observatory was officially designated the Union Observatory, with its director entitled the Union Astronomer. Altogether there were four Union Astronomers in the working life of the observatory: Innes (1912–27), H E Wood (1927–41), W H van den Bos (1941–56) and W S Finsen (1957–65). The work of the observatory (renamed the Republic Observatory in 1961) was largely the measurement and computation of double-star orbits—in later years the measurements of very close double stars were made with an ingenious 'eyepiece' interferometer invented by Finsen. Some 3000 southern double stars were found with the large refractor. However, much photographic survey work was also carried out, leading to the discovery of PROXIMA CENTAURI by Innes, the discovery of asteroids by Wood—up to the end of Wood's directorship about 600 asteroids had been found—and tens of thousands of photographs of Mars by Finsen.

The Republic Observatory was effectively closed in 1972 when the recently (1968) acquired 20 in reflector was moved to the site of the new national observatory in Sutherland. The $26\frac{1}{2}$ in refractor remains at its original location and is used occasionally for public demonstrations.

The Boyden Observatory

In 1927 Harvard College moved its Boyden Observatory from Arequipa in Peru to the resort of Mazelspoort, near Bloemfontein. Equipped with the Bruce astrograph, the 60 in Rockefeller reflector and a 13 in Alvan Clark refractor, a variety of observational programs were possible. The first director, John Stefanos Paraskevopoulos (1889–1951) carried out all-sky photographic patrols of variable stars and made detailed studies of variable stars, particularly in the LARGE and SMALL MAGELLANIC CLOUDS.

Later collaboration with other northern observations resulted in the acquisition of the ADH (Armagh–Dunsink–Harvard) Schmidt telescope of 36 in aperture.

The observatory was given to the University of the Orange Free State in 1972, after which it operated at only a very low level. The 60 in reflector is currently being modernized and should soon be brought into full-time operation.

The Leiden Southern Station

In 1923 Innes at the Union Observatory negotiated an agreement that enabled astronomers from the LEIDEN OBSERVATORY in Holland to make use of the Union Observatory's facilities. In 1938 the South African government provided funds for a building in the Union Observatory's grounds to house the Leiden Observatory's twin 16 in astrograph, known as the Rockefeller Telescope. In 1954 a dark site, remote from the Johannesburg

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

city lights, was chosen at Hartebeespoort and first the Franklin-Adams telescope and then the twin astrograph moved there. This site was operated by Leiden observers, although officially an outstation of the Union Observatory. A 36 in reflector devoted to multichannel stellar photometry was established there in 1957 by Theodore Walraven. This telescope was later moved to the EUROPEAN SOUTHERN OBSERVATORY in Chile; the Franklin-Adams telescope remains, used for educational purposes.

The Yale Observatory, Johannesburg

A 26 in visual refractor was established in 1925 by Yale Observatory, on the campus of the University of the Witwatersrand in Johannesburg. This was a southern station used for photographic parallax measurements. The directors were H D Alden (from 1925 until 1945) and C Jackson from 1945 until the telescope was transferred to Canberra, Australia, in 1952.

The Lamont–Hussey Observatory

In 1927 the University of Michigan established a 27 in visual refractor on Naval Hill at Bloemfontein. The director was R A Rossiter (1886–1977) who, by the time of his retirement in 1951, had discovered 7120 new southern double stars. F Holden was director from 1952 until the observatory was closed in 1974. The optics of the refractor returned to Michigan; the observatory dome remains, the property of Bloemfontein City Council.

The Natal Observatory

Edmund Nevill (alias Edmund Neison, 1849–1940), Government Chemist for the Province of Natal, was the first and only director of the provincial observatory erected at Durban in 1882. Neison is best known for his book *The Moon*, published in 1876, before he went to South Africa. Lack of funds prevented the Natal Observatory from publishing the work (mostly meridian observations) carried out. The observatory closed in 1911.

The Radcliffe Observatory, Pretoria

The Radcliffe Observatory in Pretoria (figure 2) was established in 1939 from the proceeds of the sale of the observatory in Oxford, owned by the Radcliffe trustees. The observatory was equipped with a 74 in reflector by Grubb Parsons (this was the largest in the southern hemisphere at the time), but the mirror's arrival was delayed by the Second World War, so the telescope only started work in 1948. The first director was Harold Knox-Shaw (1885–1970), transferred from Oxford. He retired in 1951 and was replaced by Andrew David Thackeray (1910–78) who directed the observatory until it was sold to the South African government in 1974 and the telescope moved to Sutherland, where it came into operation in 1976.

During its 26 years of active life, and operating on a very small annual budget, the staff and visitors at the Radcliffe Observatory put astrophysics in South Africa into the world class. Initially the observational program concentrated on radial velocities of OB stars with a view to determining the dynamics and structure of the Galaxy, but later usage expanded into studies of the spectra of peculiar stars, production of color–magnitude diagrams for southern clusters, and particularly spectroscopy and photometry of stars in the Magellanic Clouds.

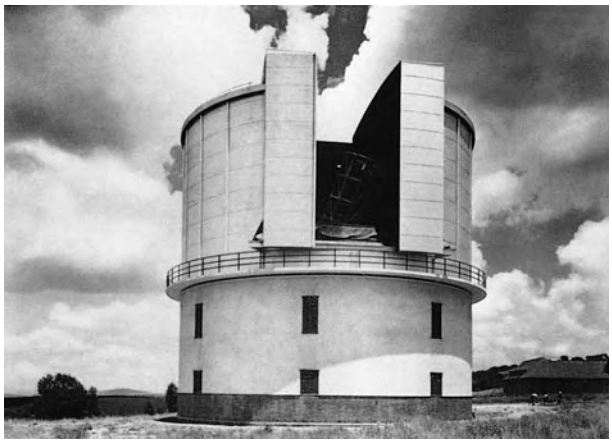

Figure 2. The Radcliffe Observatory, Pretoria.

The Astronomical Society of Southern Africa

This society was founded in 1922, from an amalgamation of societies in Cape Town and Johannesburg—the former having been formed in 1910 through the interest stimulated by Halley's Comet that year. The society comprises mostly amateur astronomers, with the addition of most of the professionals. There is a policy of electing presidents alternately between amateur and professional status. The society's postal address is at the South African Astronomical Observatory in Cape Town. It publishes a regular journal (the *Monthly Notes*) and an annual almanack known as the *Handbook*. There are active local centers in many parts of the country.

Astronomy at South African universities

The only South African university that possesses an autonomous Department of Astronomy is at the University of Cape Town. A sub-department exists at the University of South Africa (a distance-learning university) in Pretoria. The Physics and Electrical Engineering Department at Rhodes University, Grahamstown, specializes in radio astronomy and uses the national HARTEBEESTHOEK RADIO ASTRONOMY OBSERVATORY (HARTRAO). Active astronomical research is carried out by individuals in science departments at the University of the Orange Free State (Bloemfontein), the University of the Witwatersrand (Johannesburg) and the University of Natal (Durban).

South African Astronomical Observatory: from 1972 to the Present

In the late 1960s the Science Research Council (SRC) in the UK seriously considered closing the Royal Observatory at the Cape of Good Hope (see SOUTH AFRICAN ASTRONOMY), but the observatory (located in Cape Town) was saved by the establishment in January 1972 of a joint agreement between the SRC and the Council for Scientific and Industrial Research (CSIR) of South Africa, whereby the two Councils would fund and run the observatory. To make it possible to compete in astrophysical research it was necessary to move the principal telescopes in South Africa to a better site, away from the lights and bad winter weather of Cape Town, and away from the lights and cloudy summer weather of Johannesburg. As a result, a site was chosen at Sutherland, in the Northern Cape Province, roughly 380 km by road from Cape Town, which lies between the two heavy rainfall areas and is consequently non-seasonal and has low rainfall (annual average about 20 cm) (figure 1). This semidesert area has about 50% photometric nights and a further 25% usable for spectroscopy and differential photometry. The Sutherland site is in essence a field station, with a modest size technical support staff. The headquarters of the South African Astronomical Observatory (SAAO) is housed in buildings of the old Royal Observatory in Cape Town and that is where the astronomers and the majority of the support staff are located. The staff complement of the SAAO, including astronomers, technical and administrative support team, is about 70.

The 1 m reflector from Cape Town and the 50 cm reflector from the Republic Observatory in Johannesburg were moved to the new site in 1972, and, following the decision of the Radcliffe Trustees to withdraw from support of astronomy, the 1.9 m reflector which had been in Pretoria since 1939 was sold to the South African Government, moved to Sutherland in 1975, and was back in operation at its new location by 1976. There are still small telescopes, including an 18 in reflector as well as the 24 and 18 in Maclean refractor, at the old site in Cape Town, but these are now rarely used for research purposes.

Figure 1. The Sutherland Observatory of the South African Astronomical Observatory (SAAO).

The agreement between the British and South African scientific Councils lapsed in 1986, since when the SAAO has been funded entirely from within South Africa and has fallen under the administrative control of the CSIR and its successors the Foundation for Research Development and the National Research Foundation. Telescope instrumentation that had been contributed by UK institutions was made the legal property of the SAAO. The SAAO is a National Facility, with its own research staff, which makes time available both to university astronomers within South Africa and to visiting researchers. Approximately 50% of the observing time is used by SAAO staff, 12% by South African universities and the remainder by overseas visitors.

Under successive directors (Sir Richard van der Riet Woolley 1972–76, Dr Michael Feast 1977–92, Dr Robert S. Stobie 1992–present) the SAAO has maintained an international standing in several areas of astrophysical research, specializing largely in optical spectroscopy and in optical and infrared photometry of stars and galaxies. Although possessing only telescopes of relatively modest apertures, the availability of adequate amounts of observing time over extended periods has enabled long-term programmes to be carried out by staff researchers and university users (principally from the University of Cape Town: for further information see http://artemisia.ast.uct.ac.za) that are often not practicable at other observatories. Some general examples are long-term light curves in the optical and infrared of MIRA VARIABLES and other long-period variables, monitoring of QUASARS, extensive photometry of Cepheid variables in the Galaxy and the MAGELLANIC CLOUDS, discovery of variable stars in clusters and towards the Galactic centre, asteroseismology, and studies of cataclysmic variables. In recent years major campaigns were undertaken on the SUPERNOVA (1987a) in the Large Magellanic Cloud and as part of PLANET, which is searching for extrasolar planets through the effects of GRAVITATIONAL LENSING. An important support programme at the SAAO and its predecessor has been the provision of accurate photometric standard stars in the southern hemisphere—both the 18 in reflector in Cape Town and the 20 in reflector at Sutherland have for three decades been equipped only for standard star photometry, which has resulted in great stability of the photometric system.

The Sutherland site hosts a number of international instruments. Since 1990 one of the telescopes in the global system of the Birmingham Solar Oscillation Network, used for HELIOSEISMOLOGY, has been in operation. A 0.75 m robotic telescope (the Automatic Photometric Telescope) for stellar photometry, a joint project of the SAAO, the University of Cape Town and the University of South Africa, came into operation in 2001. Other

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS21 6BE, UK

robotic telescopes are under construction. A 1.4 m reflector, the Infrared Survey Facility, constructed in Japan for the Nagoya University, started work at Sutherland in November 2000. Details of the telescopes and observing facilities at the SAAO can be found at http://www.saao.ac.za/.

There are also seismographs, operating as parts of national and international networks, housed at the Sutherland site. In 2000 a Geodynamic Observatory, installed by the GeoForschungsZentrum, Potsdam, and employing a superconducting gravimeter, came into operation.

A major project for the period 2001–04 is the construction at Sutherland of the Southern African Large Telescope (SALT), which is a near copy of the Hobby–Eberly Telescope (HET) run by the University of Texas at MCDONALD OBSERVATORY. This is an international project, involving the Governments of South Africa and Poland, and institutions in Germany, New Zealand, the UK and the USA. SALT and HET, each with 91 hexagonal mirrors of 1 m diameter mounted to simulate a telescope of about 11 m aperture, are designed largely to specialize in spectroscopy—both of very faint objects for work, for example, in extragalactic research, and of bright objects at very high dispersion, which can be used, for example, for discovery of extrasolar planets. There are agreements in place that will enable researchers to use both large telescopes, thereby gaining access to most of the sky with similarly powerful telescopes. SALT is expected to be commissioned towards the end of 2004. Information about the SALT Project can be obtained from http://www.saao.ac.za/salt/. In parallel with the SALT Project, an Information Centre is to be developed in the Sutherland village and a large Education Centre at the Observatory site itself.

South American Astronomy

South America is a region where astronomy has reached a fairly good level of development and has produced a substantial number of outstanding astronomers. However, the development of astronomy in that part of the world has been always heavily dependent on governmental financial support which has not always been as generous as necessary.

The South American countries where astronomy has grown stronger are, in alphabetical order, Argentina, Brazil, Chile, Uruguay and Venezuela. To a smaller extent, some astronomy is also carried in Bolivia and in Colombia, and is developing in Paraguay and Peru. Table 1 illustrates the situation by quoting the present status of the South American membership of the INTERNATIONAL ASTRONOMICAL UNION (IAU).

Peru in 1984, and Paraguay, in 1986, adhered to the Visiting Lecturers Program established by the IAU in 1983, and a few of the young people that attended the courses later graduated, particularly in Brazil but also in Argentina, and are returning to their home countries to help start a tradition in astronomical research.

Argentina

In Argentina, astronomical activities started with the very progressive-minded President Domingo Faustino Sarmiento, who, in 1869, invited Benjamin Apthrop Gould, the founder of *The Astronomical Journal*—whom Sarmiento had met in the US while he was Argentine Ambassador—to become the first Director of the Argentine National Observatory. This was erected in the outskirts of the city of Córdoba and had its dedication on 24 October 1871, being transferred to the local university in 1955. Córdoba produced excellent astrometric work and was well known for the *Uranometría Argentina*, an atlas of all stars visible with the naked eye from Córdoba, produced before any instrumentation became available at the site, and a series of stellar catalogs and the stellar atlas known as the *Córdoba Durchmusterung*. In the early days the observing conditions were so good that stars as of magnitude 7 were visible with the naked eye.

Table 1. The South American Countries and the International Astronomical Union.

Country	Year of adherence	Number of individual members	Country status
Argentina	1927	89	
Brazil	1961	108	
Chile	1957	44	
Uruguay	1970	3	
Venezuela	1953	11	
Bolivia	1997	0	Associate
Peru	1988	1	Associate
Colombia		3	Non-member
Ecuador		0	Non-member
Paraguay		1	Non-member

An important step was taken in 1909 when Director Charles Dillon Perrine, from the LICK OBSERVATORY, in California, decided that Córdoba ought to engage also in astrophysical work, and asked for funds for a 1.50 m telescope, that, because of the attempt to figure the mirror in-house, was not dedicated until 6 July 1942, as the main instrument of the observatory's Bosque Alegre Astrophysical Station, some 40 km southwest of the city at an elevation of 1250 m. For many years the world's first stellar spectrograph with all-reflecting optics, giving a dispersion of about 40 Å mm^{-1}, designed and built in-house by physicist Enrique Gaviola with the cooperation of physicist Ricardo Platzeck, was used at the Cassegrain focus of the telescope. At present a Russian-built multifunction instrument (a spectrograph and a 1024 CCD direct imager) is in use.

Over the course of time, several additional astronomical institutions were established in Argentina. Chronologically, the second one is the LA PLATA OBSERVATORY that started in 1882 in the charge of the Province of Buenos Aires and which was transferred to the local university in 1905. The main instrumentation, acquired in France, consisted of an 80 cm reflecting telescope, a 43 cm refractor, used extensively for the measurement of visual double stars, particularly by Michigan graduate Bernhard H Dawson, a comet-seeker and a *Carte du Ciel* astrograph. In 1935 La Plata established, during geodesist Félix Aguilar's directorship, the first University curriculum in astronomy in the country. In 1938 there were only three registered students attending, but at present this figure is of the order of 100 for the introductory courses. In 1957 Córdoba also started offering astronomical courses towards a PhD degree in astronomy. In both places one may become a *Licenciado* (a somewhat higher degree than that of Master) and, then, a Doctor in Astronomy. Altogether, La Plata and Córdoba produce about 13 *Licenciados* and four to five PhDs a year.

In 1958 the La Plata Observatory, with the strong support of the university's rector Danilo Vucetich, decided to engage in the acquisition of a modern instrument and in extended site surveying. A 2.15 m (84 in) telescope, similar to the telescope then recently acquired by the US KITT PEAK NATIONAL OBSERVATORY, was aimed at. Early in 1971 the instrument and the figured Pyrex discs were already in La Plata but different problems delayed the continuation of the project and the dedication of the new observatory only occurred in 1986. Erected on top of one of the peaks in the El Leoncito astronomical reservation in the province of San Juan, at an elevation of 2500 m, in the Andes, this place is now a national observing facility, the CASLEO (El Leoncito Astronomical Complex), run by the National Research Council (CONICET) and the universities of La Plata,

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

Córdoba and San Juan. A recent addition to the instrumentation is a submillimeter solar radiotelescope (SST), a joint collaborative effort between the University of Berne, Switzerland, the Brazilian CRAAM (Center of Radioastronomy and Space Applications), IAFE and CASLEO. Soon a solar spectrograph for the ranges of 3700–4400 Å and of 5500–8000 Å will also become operational. In addition, the 60 cm Canadian reflector that had been at Cerro Las Campanas in Chile will be installed on top of another peak in the area. The auxiliary equipment for the 2.5 m telescope, named the Jorge Sahade Telescope at CASLEO's tenth anniversary celebration, consists, at present, of two stellar spectrographs, a CCD camera and a photopolarimeter belonging to the Torino Observatory.

The El Leoncito area had previously been chosen as a good astronomical site by astronomers of the University of San Juan for the installation of a Yale–Columbia double astrograph for proper-motion work, at what is now known as the Carlos U Cesco High Station. This installation is part of the University of San Juan's Félix Aguilar Observatory that was built on the outskirts of the city of San Juan and dedicated in 1953. It has carried out fundamental work with the modernized meridian circle of the Córdoba Observatory and in cooperation with the US Naval Observatory and with Russian and Chinese astronomers. At the end of 1998, Cesco's Station obtained an automated mirror coronograph from the Max-Planck-Institut-für-Aeronomie, Lindau, and a 10 cm telescope with Lyot filter for 6563 Å from the Max-Planck-Institut-für-Extraterrestriche Physik, Garching. The University of San Juan has recently established its own school of astronomy.

Other astronomical institutions in Argentina are the Argentine Radioastronomy Institute (IAR) and the Institute of Astronomy and Space Physics (IAFE), both, at present, mostly on CONICET's payroll. The IAR was established about 20 km north of La Plata because of the interest of the Province of Buenos Aires Research Council (CIC) in the matter, and dedicated on 26 March 1966, the instrumentation being two 30 m parabolic antennas provided by the Carnegie Institution of Washington, with receivers for around 21 cm wavelength. The IAFE has been formally in existence since 1971, as an outgrowth of the former National Center for Cosmic Radiation. The idea for setting up the IAFE was to have a center that would cover modern topics outside the realm of interest of the other Argentine astronomical institutions, and, in fact, early on research with balloons, space projects and high-energy astrophysics were the main subjects. At present, the IAFE's principal endeavours are centered on solar physics and cosmology, participating in the analysis of data collected with the German solar instruments at El Leoncito's Cesco Station.

Astronomy is also being done by small groups at the University of Rosario, at the University of Tucumain and at the CRICYT Institute in Mendoza, and there is a Naval Observatory entrusted with the country's official time service.

Argentina has an astronomical association (AAA) founded in 1958, at present with over 300 members, about half of them holding PhD degrees. Argentina spends about 5 million US dollars a year on astronomy, including a 2.5% participation in the Gemini Project.

In Argentina there are quite a number of amateur groups, the most important and largest being the Argentine Association Friends of Astronomy (AAAA) in Buenos Aires, founded over 70 years ago, that has had and continues to have close connections with well known professional astronomers like the late Bernhard H Dawson and José Luis Sérsic.

Brazil

Brazil is one of the South American countries where astronomy received official attention at an early date. Its Imperial Observatory was created in Rio de Janeiro on 25 October 1827, and the first director was appointed in 1845. When Brazil became a Republic, the Imperial Observatory became the National Observatory, and in the 1920s it experienced one of the most brilliant periods of its history, being equipped with a 46 cm Cooke refractor of short focal length and a Heyde zenith tube for the study of latitude variations. The difficult economic times Brazil experienced for a number of years afterwards were instrumental in damping down any possible interest in supporting astronomy. Neither the success abroad of the Brazilian scientist Mario Schönberg, who worked with S Chandrasekhar and George Gamow, nor the fact that very important foreign groups had come to the country for the 1947 total eclipse of the Sun, helped to reverse the situation. A great change took place only when Professor Abrahão de Moraes, a celestial mechanician, took over the directorship of the Institute of Astronomy and Geophysics (IAG) of the University of São Paulo in 1955. He strongly believed that the growth of astronomy in Brazil required that interested young people be sent abroad for training. Fortunately for the plan, the Fund for the Support of Research in São Paulo (FAPESP) was set up and, in 1962, Sylvio Ferraz Mello and Giorgio Giacaglia started the program that has continued steadily ever since. In carrying out such a program the traditional ties Brazilian astronomy had with French astronomy were not forgotten.

The country's financial support for astronomy has grown steadily and, at present, Brazil not only participates in the Gemini Project, also with 2.5% of the total cost, but is also the main partner (31%) in the SOAR (Southern Observatory for Astrophysical Research) Project , and pays a considerable amount of money to have the right to use ESO's (European

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

Southern Observatory's) 1.5 m telescope at La Silla, in Chile. The SOAR Project instrument is a 4 m telescope to operate on the same peak as the Gemini South telescope, on top of Cerro Pachón, in Chile.

The largest telescope now in operation in Brazil is a Perkin–Elmer 1.6 m reflector located in Brasopolis, Minas Gerais, at the National Astrophysical Laboratory, together with a Zeiss telescope and a Boller and Chivens 60 cm telescope. The location was chosen after a long site survey effort led by the National Observatory, then under the active directorship of Luiz Muniz Barreto, the facility having been dedicated in 1981.

In Brazil there are several institutions engaged in astronomy teaching and/or research, namely:

- The National Observatory, in Rio de Janeiro, equipped with a 46 cm Cooke & Sons telescope and a Danjon astrolabe.
- The Institute of Astronomy and Geophysics of the São Paulo University.
- The Astrophysics Group of the Physics Institute, University of Rio Grande do Sul, Porto Alegre, MG.
- The Physics Department of the Federal University of Rio Grande do Norte, Natal, RN.
- The Astronomy Department of the Federal University of Rio de Janeiro, RJ.
- The National Institute of Space Research (INPE), São Jose dos Campos, SP.

For observing, besides the National Observatory and the National Astrophysical Observatory already mentioned, Brazil has several small observatories at different places:

- The Abrahão de Moraes Observatory at Valinhos, SP, equipped with a meridian circle with CCD.
- The Antares Observatory at Feira de Santana, BA, equipped with a Danjon astrolabe.
- Piedade at Belo Horizonte, MG, with a 60 cm Zeiss telescope equipped with a Zeiss spectrograph and a single-channel photometer with CCD.
- The VALONGO OBSERVATORY at Rio de Janeiro, RJ, equipped with a 30 cm Cooke & Sons telescope.

The observing conditions are, however, not too good and this explains why the Brazilians are participating in projects in other countries.

In addition, we have to refer to the important Itapetinga Radioastronomical Observatory in Atibaia, SP. The attempt to do radioastronomy in Brazil started in 1959 and provides a long and interesting story. The most important installation at present is located in Itapetinga and it was achieved through the help of a number of people and organizations. The main instrument is an Essco 13.7 m diameter precision telescope in a 19.4 m radome, maximized for the frequency of 22 GHz and used for frequencies between 7 MHz and 94 MHz. Pierre Kaufmann is the soul of this enterprise, which cooperates with several organizations in the US and Russia. Research is done on the Sun, on interstellar molecules, on active nuclei of galaxies, etc. As mentioned earlier, a solar telescope for submillimeter waves has been installed at CASLEO, in Argentina, as a cooperative effort between Itapetinga, the University of Berne, Switzerland, IAFE and CASLEO.

Brazilian astronomers are all members of the Brazilian Astronomical Society (SAB) that was established in 1974, and the present membership numbers about 400, nearly half of them with PhD degrees. The yearly government spending in astronomy of about 15 million US dollars covers Rio, São Paulo, the National Astrophysical Laboratory, the participation on the SOAR and Gemini Projects and the fellowship program, of some 100 fellowships a year. This is the largest support for astronomy among the South American countries, and it does account for the very large growth that Brazilian astronomy has experienced in the past few decades.

Chile

Chile is characterized, in its northern half, by extremely good astronomical skies, similar to those of the southern coast of California in the early days of the MOUNT WILSON OBSERVATORY.

Astronomical activities in Chile began in 1849 when Lieutenant James M Gilliss, of the US Navy, started carrying out observations of Mars near opposition and of Venus near its stationary phases, to determine the solar parallax. The instrument, a 16.5 cm equatorial telescope, was installed at the Cerro Santa Lucía (Santa Lucía Hill) , in Santiago. Stellar positions in the declination range of −65°—90° were also measured with a Pistor and Martins meridian circle. In 1852, at the end of Gilliss's mission, both instruments were bought by the Chilean Government and the observations were continued under Karl Wilhelm Moesta without interruption. During Moesta's directorship the observatory was moved down from the hill in 1856 and there was a cooperative undertaking with Pulkovo and Washington for the observation of the declination of Mars at its 1862 opposition.

Another American expedition came to Chile in 1903, namely the D O Mills expedition from the Lick Observatory, under William H Wright, with the plan of measuring radial velocities of southern stars with a 92 cm reflecting telescope that was installed at Cerro San Cristóbal, close to Santiago. At the end of the mission in 1909, the instrument was bought by the Catholic University at Santiago, with the idea of developing an astronomy department.

Within the long history of astronomy in Chile, we should point out that, early in the century, astronomy

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

found a strong supporter in President Pedro Montt, who was in power from 1903 to 1910. During his term of office the observatory was under the active leadership of Friedrich Wilhelm Ristenpart, who also encouraged cooperation between South American observatories and the production, down to magnitude 10, of stellar charts south of declination −42°, that were missing in the *Córdoba Durchmusterung*.

In 1927, the National Observatory was transferred to the University of Chile and not much actually happened until 1950 when Federico Rutllant Alcina took over as director. He moved the observatory to its present location on Cerro Calán, 860 m above sea level and at some 14 km northeast of the center of Santiago, and things changed in such a way that the University of Chile was able to establish in due course an astronomy department. It is possible now to work for a Magister in Astronomy degree, and it is envisaged in the near future to make it possible to work for a PhD degree.

Rutllant not only undertook the moving of the observatory but also encouraged Gerard Kuiper, then director of the YERKES OBSERVATORY, to consider a joint project between the universities of Chicago, Texas and Chile to take advantage of the excellent climatic conditions of the latter country for astronomy. This initial proposal and the site survey carried by Jürgen Stock finally gave rise to the CERRO TOLOLO INTER-AMERICAN OBSERVATORY (CTIO) with the involvement of AURA (the Associated Universities for Research in Astronomy) and the financing of the National Science Foundation (NSF). CTIO was dedicated in November 1962, and was followed by the installations of the EUROPEAN SOUTHERN OBSERVATORY (ESO) at Cerro La Silla, dedicated seven years later, by those of the Carnegie Institution of Washington at Cerro Las Campanas, in 1976, and the huge ESO set-up of four 8 m telescopes at Cerro Paranal, the Very Large Telescope (VLT) Project, in the north of Chile, VLT1 having been officially dedicated in December 1998. Chilean astronomers do have access to 10% of the observing time on all the foreign telescopes on Chilean soil. Moreover, the country is also a partner in the Gemini Project (5% of the total cost), a fact that implies an additional percentage of observing time for the Chilean astronomers.

Under Rutllant and his successor, Claudio Anguita, who took over in 1964, Cerro Calán turned into an important research center from both the astrometric and the astrophysical point of view. Moreover, the access to the telescopes and to the fellowships granted by the foreign organizations involved in the different astronomical projects in Chile have opened unique possibilities for interested young people.

In 1959 the then Soviet Academy of Sciences sent to Cerro Calán a group of astrometrists headed by Pulkovo astronomer M S Zverev, that observed stellar positions to serve as astrometric standards for the southern hemisphere. Later, the Russians built an astrometric observatory at Cerro El Roble, 80 km north of Santiago, equipped with a double-meniscus Maksutov astrograph that was erected in 1962, and planned for an astrophysical extension. When President Salvador Allende was overthrown, the Russians abandoned the country and the El Roble station, together with the instruments, were transferred to the university.

At Maipú, some 30 km southwest of Santiago, there has been important radioastronomical activity, first in cooperation with the Carnegie Institution of Washington and then with the University of Florida. Radioastronomical research is still continuing but Maipú is no longer active.

As we have already mentioned, the Catholic University in Santiago, has its own astronomy department which is growing at a fast pace. At present the department offers courses that lead to the degree of *Licenciado* in astronomy and plans to soon extend the course to PhD level. At present it is possible to work on an astronomical subject for a degree in physics.

A large radioastronomical project, known as the ATACAMA LARGE MILLIMETER ARRAY (ALMA), is under consideration at the present time as a Europe–US collaborative project, but it may turn out to become a truly global astronomical undertaking. Its location will be at Chajnantor, in the Atacama Desert in the northern part of the country, at some 5000 m altitude.

In view of the extraordinary observing possibilities that exist for astronomers working in Chile, some universities, like those at Antofagasta, at Concepción and at Tarapaca, have astronomers on their teaching staffs and may offer degrees in astronomy in the future. In Santiago itself there is a very small group of astronomers at the Isaac Newton Institute.

At the moment there is no astronomical society established in Chile. The country's expenditure in astronomy was estimated to be some 3.5 million US dollars in 1999.

The impact of the erection of so many foreign observing facilities on Chilean soil with so much observing time at the disposal of Chilean astronomers is beginning to show its beneficial effects upon the development of Chilean astronomy and promises a very bright future for the field. Now, in regard to the effect upon astronomy in the rest of the South American countries, CTIO could be singled out for accepting observing proposals from their own astronomers, something that has been also true in the case of Las Campanas and, in a very few special cases, of La Silla. On the contrary, the present very large telescope projects reserve observing time for the members of their partnership and for Chile.

Uruguay

Astronomy has been present in Uruguay since the end of the eighteenth century when observations of the transit of Mercury were made in Montevideo by an expedition led by Alejandro Malaspina. Moreover, astronomy has been taught, as a subject in secondary schools, since 1889.

A small observatory equipped witth a Zeiss 20 cm *f*/15 refractor was dedicated in 1938 and Comet 1947IV was discovered with it. In 1955 a Spitz Planetarium was opened in Montevideo, thanks to the fact that the City Mayor was then an amateur astronomer.

A Chair of Astronomy was established in 1946 at the new Faculty of Humanities and Sciences of the University of Montevideo by Félix Cernuschi, a Cambridge PhD in Physics who had post-doctoral training in Zurich and at Harvard. Cernuschi, successful in setting up a Department of Astronomy in 1955, was very active in developing theoretical astronomy in Uruguay (and also in Argentina), but his efforts were impaired by political problems in both countries, and suffered an interruption during the military regime (1973–85). In the interval 1966–70, thanks to Cernuschi's endeavors, a radiointerferometer operated in the outskirts of Montevideo for the study of solar radiobursts.

In 1985 the situation experienced an improvement. A faculty of sciences was established at the University of Montevideo, and within it a physics institute with an astronomy department. A Master's degree in astronomy is offered, and the main areas of research relate to the solar system, in particular to comets, asteroids and planet formation. Since 1994 there has been a small observatory at Los Molinos, near Montevideo, equipped with a 35 cm Cassegrain telescope with a CCD camera, that is used to train students and to carry out small programs of photometry and astrometry of asteroids and comets.

Uruguay has an Astronomy Society with about 25 members, but not all of them are professional astronomers. Urugauy has a yearly astronomy budget of the order of 150 000 US dollars.

Venezuela

The history of modern Venezuelan astronomy actually starts in 1953, when the Director of the Cagigal Naval Observatory, Eduardo Röhl, with Presidential approval, ordered from Askania and Zeiss, in Germany, seven astronomical instruments—a meridian circle, a photozenith tube, a refracting telescope, a Schmidt camera, a reflecting telescope, a double astrograph, and a planetarium—that arrived in Venezuela in 1957. In order to decide what to do with the instruments, Röhl's succesor, José Abdala, asked the US National Academy

of Sciences for advice. Then a committee of seven astronomers from the US, one from Mexico, one from Argentina and the Executive Secretary of the US Academy, who was a physicist, met in Caracas, in 1962, to consider the situation. As a result, Jürgen Stock, who had carried out the site surveying for Cerro Tololo in Chile, was entrusted to find the best possible site for an observatory in Venezuela, and the compromise was found in the region of Mérida, where there was already a university. CONICIT, the recently established Venezuelan Research Council, decided, then, in 1971, to set up a National Institute of Astrophysical Research and, in 1973, a governmental decree created the Francisco J Duarte Foundation Center for Research in Astronomy (CIDA) in Mérida. The observatory is 50 km from the city, at an elevation of 3600 m.

The Naval Observatory remains in Caracas with the meridian circle, the photozenithal telescope and the transit instrument.

Astronomy is taught at the University of Los Andes, Mérida, at the University of Zulia in Maracaibo, and at the Universities in Caracas. At the Central Venezuelan University there is an important group engaged in cosmology and relativity.

The University of Los Andes has about 10 students that take astronomy as their subject, and perhaps one student graduates every year at either of the levels of graduation. In Caracas, maybe one student graduates in astronomy every three years.

Bolivia

Perhaps because of the altitude of the mountainous regions and the high temperature on the lowlands, professional astronomy in Bolivia has only started recently. The scientific or technical activities that have characterized Bolivia are those for which very large altitudes or the geographic coordinates are ideal factors, like those related to cosmic radiation research, for which Chacaltaya, at an altitude of over 5000 m, is a good example, or the installations at Patacamaya to track Russian artificial satellites. As for professional astronomy, the story starts in 1982 when the Bolivian National Academy of Sciences and the then USSR Academy of Sciences signed a cooperative agreement. As a result, the Pulkovo Observatory installed a Bolivian–Russian Astronomical Observatory, 15 km southeast of the city of Tarija, at an altitude of 2000 m, close to the boundary with Argentina. The instrumentation consisted of several telescopes, the largest one being a 60 cm Zeiss reflector. The work performed includes stellar catalogs, proper motion determinations, studies of supernova 1987A, polarimetry, etc. At present the activity continues in the same fields.

In Bolivia there are also a few small observatories that belong to educational institutions.

Colombia

The National Observatory, which was transferred to the National University of Colombia when this educational institution was created, in 1867, and indeed to its Faculty of Sciences in 1965, was built between May 1802 and August 1803. The instrumentation available is old and present-day research is mostly based on observations carried out elsewhere or on celestial mechanics problems. There have been plans by Jorge Arias de Greiff and Eduardo Brieva to build a modern observatory at a suitable site, at a certain distance from Bogotá, but the required financial support has not materialized and, in addition, the site became seriously affected by an earthquake.

Small groups interested in astronomy have existed and exist elsewhere in Colombia, but they have tended to be short-lived.

Peru

Peru is well known in astronomical circles because towards the end of the nineteenth century, in Arequipa, a city in the southern part of the country, Harvard Observatory carried out the observations for the southern extension of the *Henry Draper Catalog*. The instrumentation was moved to South Africa in 1926 because apparently the observing conditions had become poorer.

In Lima there are a few universities interested in astronomy, in particular, the Universidad Nacional Mayor de San Marcos, which is the one that participated in the IAU's Visiting Lecturers Program. There is an association of amateur astronomers in Lima that is active and has existed for nearly 40 years.

Acknowledgments

I am very much indebted to Claudio Anguita, Felipe Barrientos, Eduardo Brieva, Gloria Cassab, Alejandro Clocchiatti, Julio Fernández, Sylvio Ferraz Mello, Emilio Lapasset, Dante Minniti, Marta Rovira, Jürgen Stock, Jeanette Stock, Rodolfo Zalles Barrera and the IAU Secretariat for information that has permitted me to write the present article.

South Pole–Aitken Basin (SPA Basin)

The largest and deepest multiringed impact structure on the Moon. It lies almost entirely on the Moon's farside, and extends for over 2500 km from the south polar region to the 135 km diameter crater Aitken, at 16.8 °S, 173.4 °E. The impact that produced the basin is estimated to have occurred around 4.1 billion years ago, near the beginning of the solar system's great cratering episode known as late heavy bombardment. At its deepest point the SPA Basin is nearly 13 km below the Moon's mean surface level. It was first revealed by the Lunar Orbiter photographic reconnaissance of the mid-1960s, but its full extent was not appreciated until the Moon was revisited by spacecraft in the 1990s. Galileo photographed it in 1992 and showed it to have a darker coloration than its surroundings. Its size was established by the Clementine orbiter in 1994, which also found that the basin's floor is rich in titanium and iron oxides. It has been suggested that this compositional anomaly indicates that the impact reached a depth of 120 km, penetrating the crustal rocks completely and excavating metal-rich material from the mantle.

Space and Time References: Concepts

Space and time are generally considered as separate unrelated concepts. This is deeply rooted in our common sense and is basically postulated in Newtonian mechanics in which they play completely separated roles. The Theory of Relativity introduced a deep linkage between these concepts and one has to modify one's way of thinking whenever it is not possible to ignore this theory, particularly in its general form. But for many cases in astrometry, it is legitimate to keep them separated.

In order to specify quantitatively the position of a celestial body in astronomy, one uses a system of spherical coordinates. The direction is defined by two angles: for instance right ascension along the celestial equator and declination along the celestial meridian. A third parameter, the distance, is added whenever appropriate, whether it is measured directly by the duration of transit of an electromagnetic wave or measuring the parallaxes of stars (the parallactic effect is the apparent angular displacement of the direction of a star when the Earth circles the Sun; see PARALLAXES). Within the solar system, rectangular (Cartesian) coordinates are used for dynamical studies, but astrometric work is done always in spherical coordinates. Similarly, on the Earth, one uses longitudes, latitudes and heights, or three rectangular geocentric coordinates.

The triad that defines the coordinate system cannot be materialized. It is a virtual ensemble called a *reference system*, whether celestial or terrestrial. Among all possible systems, one chooses a *conventional reference system*. Then its realization consists in providing an operational method to obtain the coordinates of a point on the sky or on the Earth. In practice, the system is realized by providing the coordinates in the reference system of a certain number of objects, together with the variations of their positions with time. Such an ensemble, which can either be a catalog or ephemerides of objects, is called a *reference frame*. It may be supplemented by secondary catalogs with many more objects linked to the reference frame.

Celestial reference systems

In a celestial reference system, the coordinates of objects without detectable proper motions (because they are very far) must remain fixed. This is the condition that is used to define a *kinematic* celestial reference frame. This is the case of the present system chosen in 1995 and called the *International Celestial Reference System* (ICRS) defined at the barycenter of the solar system. Its definition states that, in the mean, an ensemble of remote extragalactic radio sources does not present any residual rotation. It became in 1998 the official celestial reference system for all uses in astronomy and celestial mechanics.

In this latter case, applications to the motions in the solar system require the addition of the third component so as to have access to the three-dimensional space. With the present level of our knowledge of the motions in the solar system, this has to be done in the framework of the theory of General Relativity. The level at which this has to be applied was specified in 1991 by the International Astronomical Union. The status is that the four space-time coordinates $(x^0 = ct, x^1, x^2, x^3)$ must be selected in such a way that in a coordinate system centered at the barycenter of the solar system, the squared interval ds^2 is expressed in the form:

$$ds^2 = -c^2 d\tau^2 = -(1 - 2U/c^2)(dx^0)^2 + (1 + 2U/c^2) \times [(dx^1)^2 + (dx^2)^2 + (dx^3)^2]$$

where c is the velocity of light, τ the proper time, and U is the sum of the gravitational potentials of the ensemble of masses, and of a tidal potential generated by bodies external to this ensemble, the latter potential vanishing at the barycenter. In the coordinate x^0, t is the coordinate time. The system of coordinates so defined is such that the proper local triad (x, y, z) at the barycenter of the solar system coincides with the triad of the ICRS. Similarly, one can define a geocentric reference coordinate system used to describe the motion of artificial satellites.

Another way to force a celestial system to be fixed is based on the fact that if the motion of planets is referred to a rotating or accelerating system of coordinates, the bodies are accelerated. This is detectable and hence can be suppressed by choosing an adequate reference. This *dynamical* definition of celestial reference systems requires a Newtonian space. It was used until recently in the absence of observations allowing a kinematic definition, but its definition in the framework of General Relativity is not well understood, and in any case cannot be extended to the Galaxy and even less so to the universe.

Celestial reference frames

The realization of the ICRS was made using observations of positions of extragalactic radio-sources by VLBI (see EXTRAGALACTIC REFERENCE FRAMES). About one-third (the best observed) of the 608 sources in the catalog constitutes the *International Celestial Reference Frame* (ICRF). These objects are not observable optically with a sufficient accuracy to serve as fiducial points in optical astrometry. So a secondary star catalog, the Hipparcos Catalogue, was linked to the ICRF (see HIPPARCOS AND TYCHO CATALOGUES) and is the realization of the ICRS in optical wavelengths. In the case of a dynamical definition of the celestial reference frame, the observed positions of planets are the moving fiducial points to which a fundamental catalog of star positions and proper motions is referred (see DYNAMICAL REFERENCE FRAMES).

Terrestrial reference system and frame

The concept of a terrestrial reference system is analogous to its celestial counterpart. It is represented by a set of fiducial points on the surface of the Earth. The system is so defined that, despite the motions of the tectonic plates on which the points are located, their ensemble has no global residual rotation. This is how the *International*

Dirac House, Temple Back, Bristol, BS1 6BE, UK

Terrestrial Reference System (ITRS) is defined. It is realized by a set of positions and motions of geodesic stations (see TERRESTRIAL COORDINATE SYSTEMS AND FRAMES), called the *International Terrestrial Reference Frame* (ITRF).

Time scales

To be complete, a reference system of coordinates must include the time dimension. The equivalent of a coordinate for time is a time scale. Historically, a time scale was conceived as the independent variable of the dynamics in the solar system. At present, the basis of time is derived from the fact that the frequency of an atomic transition in given conditions is a constant. A time scale is obtained by integrating basic periods produced by an atomic frequency standard (see TIME SCALES: ATOMIC). It is a (local) proper time in the theory of General Relativity.

To extend the scale outside the laboratory, one has to apply the relativistic ds^2 and to define precisely the coordinate system by the metric form to which it belongs. The time scale that results is called a coordinate time. This is the case of the *Terrestrial Time* (TT), obtained by the addition of seconds of the International System of Units on the geoid (see TIME SCALES: TERRESTRIAL). The Geocentric Coordinate Time (TCG) is attached to the geocentric coordinate reference system and differs from TT by a constant rate. It is used for the dynamical studies and monitoring of artificial Earth satellites. The Barycentric Coordinate Time (TCB), which is to be used in studying the motions in the solar system, differs from TT not only by a constant rate, but also by some periodic terms.

Space Geodesy

Geodesy is the science studying the size and the figure of the Earth including the determination of the Earth's gravitational field. Geodetic astronomy is that part of astronomy dealing with the definition and realization of a terrestrial and a celestial reference frame (see TERRESTRIAL COORDINATE SYSTEMS AND FRAMES). By space geodesy we mean, then, those aspects of geodesy and geodetic astronomy studied by using natural or artificial celestial bodies as observed objects or as observing platforms. In the older literature the term cosmic geodesy is sometimes used as a synonym. Space geodesy is thus defined through the observation techniques, below referred to as space geodetic techniques or methods.

Space geodesy evolved rapidly in the second half of the twentieth century. The space age was initiated by the launch of the first artificial satellite, Sputnik I, on 4 October of the International Geophysical Year 1957. In the space age it became possible to deploy and use artificial satellites either to study the size and figure of the Earth from space or to observe them as targets from the surface of the Earth. The use of artificial Earth satellites for geodetic purposes is also referred to as satellite geodesy. The second essential development consists of the technique of very long baseline interferometry (VLBI) as a new tool to realize an extraordinarily accurate and stable inertial reference system and to monitor Earth rotation using quasars (see EXTRAGALACTIC REFERENCE FRAMES).

Today, space geodetic techniques are the primary tools to study size, figure and deformation of the Earth, and its motion as a finite body in the inertial reference system (see SPACE AND TIME REFERENCES: CONCEPTS). Space geodetic techniques are thus the fundamental tools for geodesy, geodetic astronomy and geodynamics.

Space geodetic observations contain information about the relative positions and/or motions of the observed object and the observer. Let $\boldsymbol{GO}(t_i)$ be the position of the observer at some time t_i in the terrestrial reference frame and $\boldsymbol{GS}(t_i)$, the position of the satellite in an inertial reference frame. An observation $O(t_i)$ made at that time and corrected for various perturbing effects described below, can be expressed mathematically as

$$O(t_i) = F(\boldsymbol{GO}(t_i), \mathrm{d}\boldsymbol{GO}(t_i)/\mathrm{d}t, \boldsymbol{GS}(t_i), \mathrm{d}\boldsymbol{GS}(t_i)/\mathrm{d}t)$$

or usually only of some of the components of these vectors. For instance:

- several observations of a satellite in a known position at the same time from several observatories provide equations linking the positions of these observatories;
- several observations of the same satellite performed at the same observatory provide equations containing information on the trajectory of the satellite, and consequently also on the forces acting on it;
- observations of several satellites of known positions by a single station provide the geocentric position of the observer.

In scientific space geodesy, several 'geodetic' satellites are observed many times from many stations. The set of equations so obtained is solved for the satellite orbits (Tapley 1989), the gravitational field of the Earth (Reigber 1989), the relative positions of the observing stations or any of these quantities if others are known. Because the positions of the stations and of the satellites are in different reference frames, space geodetic observations also contain information concerning the transformation between the terrestrial and the inertial systems. The Earth orientation parameters, i.e. polar motion, UT1, precession and nutation (see EARTH'S ROTATION: THEORY, POLAR MOTION AND LENGTH OF DAY) define this transformation.

The role of the Earth's atmosphere

In space geodesy the signals of the observed or observing celestial bodies have to cross the Earth's atmosphere. This changes the paths and the travel times of the signals. These are referred to as *refraction effects*. Refraction is usually considered a nuisance in astronomy, geodesy and geodynamics—as a matter of fact it is the motivation for many spaceborne experiments related to this field of science. In recent years refraction effects have been considered and understood as a primary source of information for atmospheric science and are monitored through space geodesy methods. Let us point out that the same signals and space geodetic analysis methods are used to study the Earth's atmosphere as for geodetic and geodynamic purposes. Interdisciplinary studies and projects have become important aspects of modern space geodesy.

Whether the atmosphere-related signal is useful depends on the wavelengths of the analysed signals. If we measure, for example, distances or distance differences to satellites using optical signals, refraction effects may be computed with subcentimeter accuracy using pressure, temperature and humidity registrations at the observing sites. We may therefore conclude that laser ranging is not capable of contributing to atmosphere monitoring. This fact may also be formulated in a positive way: laser observations are well suited for calibrating other techniques, which are more prone to atmospheric effects.

For microwave techniques (Doppler, GPS, VLBI) we have to distinguish between ionospheric refraction stemming from the ionized upper part of the atmosphere (extending up to about 1500 km) and tropospheric refraction, stemming from the lower, neutral layers of the atmosphere. Ionospheric refraction is wavelength-dependent and may be (almost completely) eliminated if coherent signals are sent through the atmosphere on different carrier wavelengths. In the VLBI technique this is achieved by observing the quasars in different wavelengths, in the Doppler or GPS technique the same is achieved by using two different wavelengths for signal transmission.

For microwave techniques tropospheric refraction is the ultimate accuracy-limiting component in the error budget. As opposed to range observations in the optical

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills, Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

band, we have to take into account the so-called 'wet component' of tropospheric refraction, which is highly variable in time and space. This fact forces analysts using microwave observations to introduce station- and time-specific parameters (or to model the effect as a random process). It allows, on the other hand, analysts to determine the water vapor content above an observatory with high accuracy and high temporal resolution (Bevis *et al* 1992).

Optical period

For centuries, optical (astrometric) observations were the only type of observation available in astronomy. In the pre-space era a series of astrometric instruments was used for the purpose of defining a terrestrial reference frame and for monitoring the rotation of the Earth. The photographic zenith tube and the Danjon astrolabe were probably the most advanced of these instruments. They were widely used by observatories contributing to the International Polar Motion Service (IPMS) and the Bureau International de l'Heure (BIH) to determine the geographic latitude of a station with a precision of about 10–40 mas (milliarcseconds) in one night. We refer to Moritz and Mueller (1988) for more information.

Optical observations were made by the first generation of artificial Earth satellites, like Sputnik 2 and Explorer 1. The balloon satellites Echo 1 and 2 and PAGEOS (passive geodetic satellite), which could be seen by the naked eye, were observed by a worldwide optical tracking network. These satellites were (supposedly) spherical, and consisted of layers of aluminized mylar foil, and, thanks to their brightness, their tracks could easily be photographed against the star background. It was not trivial to assign time-tags to specific points of the track. Much more suitable from this point of view, although more difficult to track, were smaller satellites like Geos 1 (Explorer 29) and Geos 2 (Explorer 36) equipped with flash lamps allowing for tens of thousands of high-precision optical observations. Obviously, quasi-simultaneity of observations from different sites was possible.

Fascinating results came out of this first phase of satellite geodesy. The geodetic datums on different continents could be related to the geocenter and thus to each other with an accuracy of about 5 m. The first reliable coefficients of the gravity field (spherical expansion up to degree and order 12–15) could be also derived.

The astrometric technique, when applied to artificial satellites in the 1960s and 1970s, had serious disadvantages. The star catalogs were not of sufficiently good quality and the processing time (time between observation and availability of results) was of the order of a few weeks in the best case. This, and the advent of new observation techniques promising higher accuracy, actually ruled out astrometric techniques for a number of important applications. The optical technique no longer played a significant role in space geodesy after about 1975.

In view of newly developed observation techniques (CCD (CHARGE COUPLED DEVICE) techniques) and much better star catalogs based on astrometry missions (e.g. the HIPPARCOS mission) it may well be that optical observations will again play a role in space geodesy in the future.

Doppler period

The US Navy Navigation Satellite System (NNSS), also called the Transit system after the survey transit instrument, had a significant impact on the development of space geodesy. It proved that a system based on the measurement of the Doppler shift of a signal generated by a stable oscillator on board a satellite could be used for relative positioning with remarkably high accuracies (0.1–0.5 m relative, about 1 m geocentric). The satellites sent information on two carrier frequencies (400 MHz and 150 MHz) near the microwave band.

The two frequencies allowed for a compensation of ionospheric refraction. Rather small receivers connected to omnidirectional antennas made the technique well suited to establish regional or even global geodetic networks. Observation periods of a few days were required to obtain the above mentioned accuracy.

The NNSS satellites were in polar, almost circular, orbits about 1100 km above the Earth's surface. Only one satellite at a time could be observed by one receiver. As opposed to astrometry the Doppler technique is weather independent. Until a significant part of the Global Positioning System (GPS) was deployed (around 1990) the NNSS played a significant role in space geodesy. Many Doppler campaigns were organized to establish local, regional or global networks. With the full deployment of the GPS in the 1990s the geodetic community eventually lost interest in the Doppler system. The Transit system was shut down as a positioning system in December 1996 but continued operating as an ionospheric monitoring tool. For more information concerning the Doppler system we refer to Kouba (1983).

Satellite and lunar laser ranging (SLR and LLR)

'Laser' stands for light amplification through stimulated emission of radiation. The laser technique, developed in the 1950s, is able to generate highly energetic short light pulses (of a few tens of picoseconds (ps) (1 ps $= 10^{-12}$ s)). These pulses are sent out by a conventional astronomical telescope, travel to the satellite (or the Moon), are reflected by special corner cubes (comparable to the rear reflectors of bicycles) on the satellite (Moon) back to the telescope, where they are detected. The measurement is the travel time Δt of the laser pulse from the telescope to the satellite and back to the telescope. Apart from refraction this light travel time, after multiplication by the speed of light c in a vacuum, equals twice the distance ρ_r^s between satellite and telescope at the time the light pulse is reflected from the satellite $\rho_r^s \approx \Delta t \times c/2$. Today's satellite laser ranging (SLR) technique is used to determine the 'true' distances between observatories and satellites with an accuracy of a few millimeters and, if required, with a high repetition rate (several times per second).

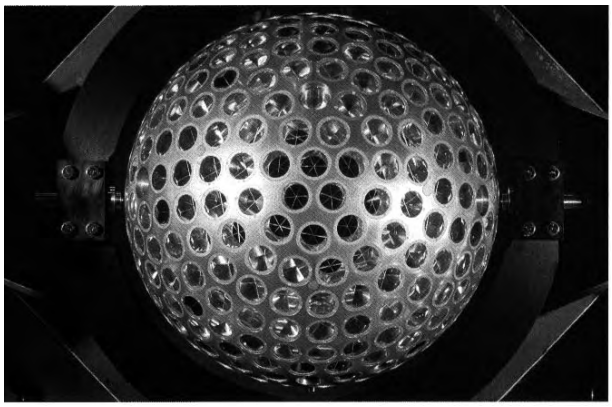

Figure 1. The Lageos II spacecraft.

SLR techniques may be used for every satellite equipped with corner cubes. Figure 1 shows Lageos II, a typical SLR-dedicated satellite which was launched in 1992. Lageos II is a spherical satellite with a diameter of 0.6 m and a weight of 405 kg. 426 corner cubes are inlaid in its surface. Lageos II is a close relative of Lageos I, which was launched in 1976. The two Lageos satellites are in stable, almost circular orbits about 6000 km above the surface of the Earth.

The two Lageos satellites are the primary scientific tracking targets for the International Laser Ranging Service (ILRS). The two satellites have contributed in a significant way to the determination of the Earth's gravity field. Many more targets are regularly observed by the ILRS. Some, like the French low-orbiting satellite Starlette, with a diameter of 24 cm, are similar in design to the Lageos satellites and serve a similar purpose. For others SLR is just the primary or backup technique for precise orbit determination.

With the exception of UT1, the SLR technique is capable of determining all parameters of geodetic interest (station coordinates and motion, Earth rotation parameters, gravity field). The unique and most valuable contributions lie in the determination of the Earth's (variable) gravity field, in the determination of the geocenter (i.e. the location of the polyhedron formed by connecting the SLR stations with respect to the geocenter), and in calibrating geodetic microwave techniques.

From the technical point of view there is no major difference between SLR and LLR (lunar laser ranging): light travel times are measured from the observatory to one of the laser reflectors deployed on the Moon by the Apollo space missions or the Russian unmanned Lunokhod missions. The scientific impact of LLR is significant. LLR was capable of measuring directly the secular increase of the Earth–Moon distance (3.8 cm per year), an effect which is in turn coupled with the deceleration of the angular velocity of Earth's rotation. Also, LLR is well suited to the evaluation of gravitational theories (see REFERENCE FRAMES AND TIMESCALES IN GENERAL RELATIVITY).

Very long baseline interferometry

Very long baseline interferometry (VLBI) is the only non-satellite geodetic technique contributing data to the International Earth Rotation Service (IERS). Its main features are discussed in the article on EXTRAGALACTIC REFERENCE FRAMES.

Its unique and fundamental contribution to geodesy and astronomy consists of the realization of the inertial reference system and in the maintenance of the long-term stability of the transformation between the celestial and terrestrial reference frame.

The ICRS (International Celestial Reference System) was defined by the International Earth Rotation Service (Arias *et al* 1995). It was adopted by the International Astronomical Union (IAU) as the primary celestial reference system replacing the optical predecessors.

An accurate and stable celestial reference frame is a prerequisite for a terrestrial reference system. In this sense VLBI plays a decisive role in the definition of the terrestrial reference system, and in establishing the transformation between the two systems. In particular, VLBI is the only technique providing the difference UT1 − UTC, i.e. the difference between Earth rotation time and atomic time with state-of-the-art accuracy and excellent long-term stability. Also, VLBI is the only technique capable of determining precession and nutation with an angular resolution below the milliarcsecond level.

The observation and analysis aspects are today coordinated by the IVS, the International VLBI Service (see table 1).

The global positioning system (GPS)

GPS is probably the best known space geodesy technique today. The system has an impact on science and society reaching far beyond space geodesy. GPS has revolutionized surveying, timing, car and aircraft navigation. Millions of hand-held receivers are in use today. Spaceborne applications of the GPS have a deep impact on geodesy and atmospheric sciences.

GPS is a navigation system allowing for instantaneous, real-time, 'absolute' positioning on or near the surface of the Earth with an accuracy of a few meters. An unlimited number of users may use the system simultaneously. 'Absolute' means that the estimated coordinates may be established using only one receiver and that they refer to a geocentric Earth-fixed coordinate system. This coordinate system, the WGS-84 (World Geodetic System), is today aligned with sub-meter accuracy to the ITRF, the International Terrestrial Reference Frame maintained by the IERS.

The space segment of GPS nominally consists of 24 satellites (21 operational satellites plus three active spares). The satellites are in almost circular orbits distributed in six planes approximately 20 000 km above the Earth's surface. These planes are separated by 60° on the equator and inclined by 55° with respect to the equator. The revolution period is half a sidereal day (11h 58m), which means that for a given location on the Earth's surface the satellite

Figure 2. Block II satellite.

constellation above horizon repeats itself after one sidereal day (solar day minus four minutes). Figure 2 shows the Block II satellite. This is the satellite with which the first full GPS generation was built. We distinguish the main body of the satellite with the antenna array pointing to the center of the Earth and the solar panels. The attitude is maintained by momentum wheels, which have to guarantee that the antenna array is always pointing to the center of the Earth and that the solar panel axes are perpendicular to the Sun–satellite direction. The satellite is capable of rotating the solar panels into a position perpendicular to this direction.

Each satellite broadcasts on two carrier frequencies L1 and L2 of 1.575 42 GHz and 1.227 60 GHz respectively, corresponding to wavelengths of $\lambda_1 \approx 19$ cm and $\lambda_2 \approx 24$ cm. Two types of codes are sent out, allowing users to reconstruct the so-called pseudorange p_r^s (definition in equation (1)).

The pseudorange p_r^s and the geometric distance ρ_r^s between the satellite at signal emission time and the receiver at signal reception time are related through

$$p_r^s = \rho_r^s + c(\Delta t_r - \Delta t^s) + \Delta\rho_{\text{atm}} \qquad (1)$$

where Δt^s is the error of the satellite clock with respect to the 'true' (or system) time, Δt_r is the receiver clock error. $\Delta\rho_{\text{atm}}$ is the correction of the light travel time due to the atmosphere (sum of ionospheric and tropospheric refractions).

In addition, and among other important information, broadcast orbits allowing computation of the satellite position at emission time and satellite clock corrections mitigating the satellite synchronization error Δt^s w.r.t. the 'true' or system time are sent out continuously using the phase modulation technique on L1 and L2.

Two kinds of code have to be distinguished, the so-called C/A code (coarse acquisition code) allowing an accuracy of about 3 m, and the P code (precision code) allowing an accuracy of about 0.3 m. Modern digital receivers show a much better performance. The P code is currently only available to privileged (i.e. US Department of Defense authorized) users. The C/A code is transmitted on L1, an encrypted version of the P code on both carriers. The broadcast orbits usually have an accuracy of about 3 m. Prior to 1 May 2000 the satellite clock information was made available to non-authorized users only with moderate accuracy, limiting the real-time 'absolute' positioning accuracy to about 100 m. On 1 May 2000 the Press Secretary of the White House issued the 'Statement by the President regarding the United States' decision to stop degrading Global Positioning Accuracy'. In consequence, since 2 May, 4:00 h UT (Universal Time), the satellite clock information has been made available to all GPS users without restrictions. This implies in particular that real-time 'absolute' positioning using dual-band receivers is now accurate to usually better than about 5 m (rms error) in all three coordinates. 'Absolute'

Dirac House, Temple Back, Bristol, BS1 6BE, UK

positioning with L1 receivers (based on the C/A code) is limited by ionospheric refraction but still is usually better than 10 m in all coordinates.

Let us briefly address the principles of absolute GPS positioning and navigation: a GPS receiver is simultaneously observing several satellites (ideally all that are above the horizon). Using broadcast orbits to compute the satellite positions in the Earth-fixed system, standard atmospheric models to account for refraction, and the broadcast clock information to adjust the satellite clocks to system time, we are left with only four unknowns in equation (1), namely the three coordinates of the receiver position and the receiver clock error Δt_r—provided we consider only simultaneous observations. It is thus necessary and sufficient that a receiver tracks four satellites simultaneously in order to compute an instantaneous position (and a receiver clock error) with an accuracy of a few meters or about 100 m for users having no access to P code respectively. The GPS constellation was designed, as a matter of fact, to ensure that (to the extent possible) four or more satellites are available all the time at each location on the surface of the Earth.

For scientific purposes phase observation plays a decisive role. It is in essence identical to the so-called accumulated Doppler observation of the NNSS and it is closely related to the GPS code observation as well. From the mathematical point of view, there are 'only' two essential differences between phase and code, namely the much higher measurement accuracy of phase (millimeters rather than meters), and an additional unknown, the initial phase ambiguity parameter N_r^s, per satellite pass. All GPS receivers used for high-accuracy geodetic applications record the phase observations on both carriers L1 and L2, in addition to the code.

The phase observations yield local GPS networks with millimeter accuracy, regional and global networks with about centimeter accuracy. This is only possible if precise satellite orbit and clock information, such as that generated by the International GPS Service (IGS), is available. Figure 3 shows the IGS network as of October 1998.

Over 200 IGS sites, distributed all over the globe, permanently observe all satellites in view, transmit their observations (at least) on a daily basis to IGS data centers.

The data are then analysed by IGS analysis centers, which deliver rapid and final products. Rapid IGS products are available with a delay of about one day, final products with a delay of about eleven days. Daily products include satellite orbits with an accuracy of about 0.05–0.1 m, satellite clocks with an accuracy of about 0.3 ns, daily values of polar motion components accurate to about 0.1 mas (milliarcseconds), corresponding to 3 mm on the Earth's surface, and length of day (lod) estimates with an accuracy of about 30 μs d^{-1}. These products are essential contributions to the monitoring of the EARTH'S ROTATION.

In addition the IGS analysis centers perform weekly global coordinate solutions of their portion of the IGS network. These results are used, together with the results of the other space techniques, for the establishment of the International Terrestrial Reference Frame.

The IGS products (orbits, Earth rotation parameters, coordinates and velocities of IGS stations) are used as known *a priori* information to establish regional networks for crustal deformation studies (e.g. the Californian SCIGN (http://www.scign.org), the Japanese 1000-receiver network for Earthquake monitoring) or for regional reference frame establishment and maintenance (e.g. the EUREF network http://www.oma.be:/KSB-ORB/EUREF/eurefhome.html, or the South American SIRGAS network http://www.dgfi-badw-muenchen.de/gps/sirgas.html).

More and more, the IGS network is used for purposes other than space geodesy. Let us mention that the IGS network has been enhanced to include time and frequency transfer and that it is able to monitor the ionosphere. For more information concerning the IGS and its interdisciplinary impact we refer to Beutler *et al* (1999).

From the point of view of space geodesy, GPS is a 'work horse' with important contributions to the establishment and maintenance of a dense terrestrial reference frame, and which provides Earth rotation parameters with a high time resolution. It should not be forgotten, that the GPS—like every satellite geodetic method—is not able to maintain a long-term stability of UT1 or of precession and nutation. Moreover, despite the fact that GPS is a satellite geodetic technique, it is not well suited to determine the Earth's gravity field or the motion of its station polyhedron w.r.t. the geocenter. The height of the GPS satellites is one of the limiting factors.

For more information concerning GPS as a tool for geodesy and geodynamics we refer to Teunissen and Kleusberg (1998).

Other satellite microwave techniques

The Russian GLONASS (Global Navigation Satellite System) is so closely related to the GPS that there are a number of combined GPS and GLONASS receivers available. These receivers were used in the first global GLONASS tracking and analysis campaign, the IGEX-98 (International GLONASS Experiment 1998). The experiment revealed that a combined analysis of GPS and GLONASS is very promising for science and navigation.

The French DORIS system (Doppler Orbitography by Radiopositioning Integrated on Satellite) has proved to be a very powerful tool for orbit determination. It is one of the orbit determination system used in the TOPEX/Poseidon mission (see below). Also, DORIS possesses a very well designed ground tracking network. This is one reason why DORIS was accepted as an official space technique by the IERS (see table 1).

The German PRARE (Precise Range and Range-rate Equipment) system may be viewed as the German counterpart of the DORIS system. It is used as an orbit determination tool on the European Space Agency's ERS-2 (Earth Remote Sensing) spacecraft.

Satellite missions

There have been many satellite missions in the past and there will be more in the future in which the satellite is used as an observing platform to study aspects of the Earth relevant to geodesy and geodynamics. Let us mention in particular that altimetry missions have significantly improved our knowledge of the sea surface topography, ocean currents, tidal motions of the oceans, etc.

Figure 4 shows the TOPEX/Poseidon spacecraft. The mission is a combined US and French altimetry mission. It is actually the first mission which was specially designed to investigate ocean currents. One entire volume of the *Journal of Geophysical Research* was devoted to this mission (JGR, 1994). For space geodesy the TOPEX/Poseidon mission was a kind of 'Rosetta stone mission' because its orbit was determined using three independent systems, the French DORIS system, SLR tracking and the GPS. All three systems proved their capability. The radial component of the orbit (which is of crucial importance for altimetry missions) could be established with an accuracy of a few centimeters. Let us mention that TOPEX/Poseidon was neither the first nor will it be the last altimetry mission.

For geodesy, geodynamics and atmospheric physics the upcoming missions CHAMP (Challenging Mini-Satellite Payload for Geophysical Research and Application, German mission), GRACE (Gravity Recovery and Climate Experiment, US/German mission) and GOCE (Gravity field and Ocean Current Explorer, ESA mission) are fascinating. It is expected that our knowledge of the gravity field (using spaceborne GPS receivers, accelerometers or gradiometers) to measure the non-gravitational forces with respect to gravity gradients will significantly increase through such missions.

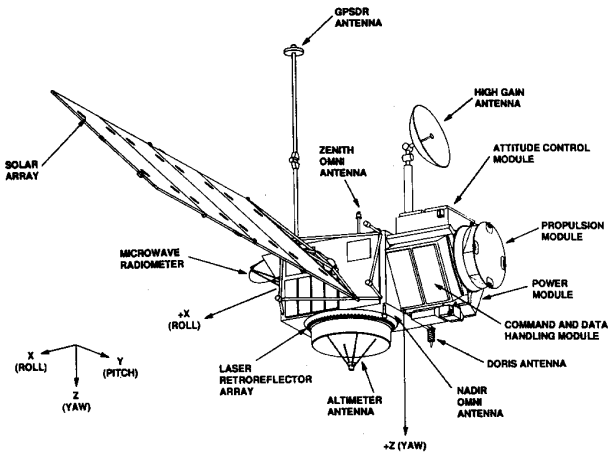

Figure 4. The TOPEX/Poseidon spacecraft.

Also, CHAMP, GRACE and GOCE are able to produce atmosphere profiles using the occultation method: the signal (phase and code) of a GPS satellite is monitored by a spaceborne GPS receiver on a low-Earth orbiter (LEO) during the time period in which the line of sight LEO–GPS satellite scans through the Earth's atmosphere. These developments support our initial statement that interdisciplinary aspects are becoming more and more important in space geodesy.

Organizations

Table 1 gives an overview of the institutions relevant for space geodesy.

They are all IAG (International Association of Geodesy) services. The IERS and the IVS are in addition

Dirac House, Temple Back, Bristol, BS1 6BE, UK

IAU services (International Astronomical Union). The IERS and the IGS are members of FAGS (Federation of Astronomical and Geodesical Data Analysis Services).

IGS, ILRS and IVS are technique-specific services. The IERS is a multitechnique service. It was established in 1988 as successor to the International Polar Motion Service (IPMS) and the Earth rotation branch of the Bureau International de l'Heure (BIH). The IERS products are based on the products of the technique-specific services.

CSTG is a commission of IAG and a subcommission of COSPAR (Commission on Space Research). It has a coordinating function within space geodesy. During 1995–9 it was, for example, responsible for creating the ILRS and the IVS, and it organized the first global GLONASS experiment IGEX-98.

More information about these services may be found at the internet addresses in table 1.

Space Infrared Telescope Facility (SIRTF)

Fourth of NASA's 'Great Observatories', due for launch in 2001–2. Planned as a 1 metre, cryogenically cooled space telescope for infrared astronomy. Can be serviced by the Shuttle or at a manned space station. Instruments will provide high sensitivity and spatial resolution. Designed to study circumstellar dust clouds, brown dwarfs, infrared galaxies and quasars. Instruments include a wide field and high resolution camera covering the 2–30 micron region; an imaging photometer covering 3–700 microns, and a spectrometer.

Space Instrumentation: Astrometry

ASTROMETRY is the measurement of accurate positions of stars or other celestial objects, and is the basis of many of the most fundamental measurements in astronomy. Precision astrometry makes possible the determination of distance to stars via annual PARALLAX. The HIPPARCOS astrometry satellite, launched in 1989 by the European Space Agency, was the first mission designed for precision astrometry.

Precision astrometry opens up many areas of astronomy and astrophysics, by providing unambiguous distances to stars out to large distances in the Galaxy. Accurate distances enable accurate measurement of the absolute luminosity of stars, which has applications for fundamental stellar astrophysics and also in firmly calibrating the stars which form the basis of the UNIVERSAL DISTANCE SCALE. An important goal from space-based astrometry is the detection of planets orbiting nearby stars, using the 'wobble' in the position of the parent star due to the gravitational pull of the planet. Detection of planets as small as a few Earth masses should be possible.

Astrometry with ground-based instruments is fundamentally limited by instabilities in the Earth's atmosphere. Space-based instruments overcome this limitation, and allow a much wider range of astronomical uses for precision astrometry, by attaining microarcsecond levels of accuracy. Several new missions have been proposed for astrometry from space. The Full-sky Astrometric Mapping Explorer (FAME) mission, which builds on experience with Hipparcos, was recently approved for development by NASA. The NASA SPACE INTERFEROMETRY MISSION (SIM) is currently in the design phase, with the goal of reaching a precision of a few microseconds on targets as faint as V magnitude 20. The European Space Agency is currently studying GAIA as a future Cornerstone Mission of the science program. Also building on the very successful experience of Hipparcos, GAIA would conduct a very large sky survey with an astrometric accuracy comparable to that of SIM, down to V magnitude 15.

Science with precision astrometry

Hipparcos represents the current state of the art in astrometry, with around 1 milliarcsecond accuracy in the positions and parallaxes of 118 000 stars and complete at around ninth magnitude. Applying the definition of annual parallax, this corresponds to 10% accuracy in the distance of stars out to 100 parsecs. Among the important science results from Hipparcos are: distances and ages of globular clusters, using parallaxes of local subdwarf stars; the internal dynamics, distance and age of the Hyades open cluster; a measurement of the distance to the Pleiades cluster; and limits to the masses of planets around stars for which radial velocity detections of planets have been made.

Ground-based instruments can achieve an accuracy of around 1 milliarcsecond in global astrometry—the measurement of large arcs across the sky. These measurements must be referenced to a global reference frame in which parallax and PROPER MOTION of stars are defined. Accurate distances require parallax in an absolute reference frame, or a close approximation to one. Similarly, problems in Galactic structure require measurements in a frame which does not share in the Galactic rotation.

Global astrometry on the ground is done by long-baseline optical interferometers (see INTERFEROMETRY: GROUND), such as the Navy Prototype Optical Interferometer (NPOI) located near Flagstaff, Arizona. This instrument features a Michelson interferometer design, and is carefully optimized for astrometry by minimizing the effects of atmospheric turbulence, and is expected to achieve a limiting magnitude of around $V = 8$.

Extending the reach of parallax distances to include most of the Galaxy (say 10 kpc) would require a further factor of 100 improvement in global astrometry, or an accuracy of around 10 microarcseconds. In addition, such measurements have to be more sensitive, because the targets are much fainter. For instance, a solar-type star at 10 kpc is almost twentieth magnitude. The Space Interferometry Mission is being designed with the precision and sensitivity to perform such measurements.

With much of the Galaxy accessible to direct distance measurements, many indirect methods of calculation of distance become unnecessary. Distances to globular clusters can be measured simply from the parallax of a few member stars. SIM will allow a calibration of the long-period Cepheids which are one of the fundamental distance indicators in the universe. The spiral structure of the Galaxy, and the dynamics of the Galactic halo can be studied using the proper motions of stars selected as 'test particles' in the gravitational potential. Distances to spiral galaxies may be measurable, by detection of the proper motions of stars due to rotation around the Galactic center.

Space astrometry with survey instruments

There are currently two approaches to space astrometry: survey instruments and pointed instruments. Hipparcos, FAME and GAIA are examples of survey instruments. SIM is a pointed instrument. Fundamentally, survey instruments achieve a lower astrometric accuracy, and that accuracy depends on star brightness. The number of observations and the integration time are typically fixed by the mission design. A pointed instrument can achieve higher accuracy, and go fainter, by increased integration time and more frequent observation. However, survey instruments are more efficient by a very large factor: FAME will observe approximately 40 million stars, whereas SIM will observe around 40 000 stars. So in practice, these instruments are complementary. Studies of Galactic structure in which a large star sample is essential to average out random motions, may be more suited to a survey instrument, whereas a pointed instrument is better suited to very demanding studies of carefully selected samples, as in the search of few-Earth mass planets around nearby stars.

Dirac House, Temple Back, Bristol, BS1 6BE, UK

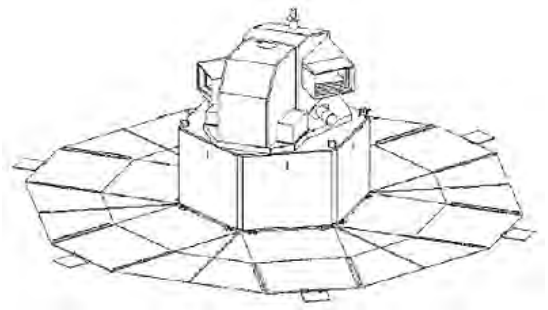

Figure 1. Sketch of the FAME spacecraft. During operation the spacecraft rotates about the (vertical) symmetry axis. Solar pressure on the combined sunshade and solar array (bottom) results in slow precession of the spin axis. The two fields of view are perpendicular to the spin, and separated by 81.5°. (Figure courtesy of Astronomical Applications Department, US Naval Observatory.)

The Full-sky Astrometric Mapping Explorer (FAME) is a space telescope designed to obtain highly precise position and brightness measurements of stars. Due to launch in 2004, it will operate, like Hipparcos, by simultaneously imaging two small fields separated by a fixed, large angle. The spacecraft rotates steadily about an axis which passes star fields from one camera to the other (figure 1). Precession of the spin axis allows all-sky coverage over a period of few weeks. Over an observing lifetime of 2.5 years, each target brighter than ninth magnitude will be observed almost 1000 times. For targets brighter than $V < 9$ the expected precision is 50 microarcseconds. In addition to astrometry, FAME will perform photometric observations through four filters with millimagnitude accuracy.

The European Space Agency is studying a follow-on mission to Hipparcos, called GAIA, operating on the same basic principles as Hipparcos. This mission, which could launch as soon as 2010, is much more ambitious than the NASA FAME mission. Reaching much further out into the Galaxy, it would yield a catalog of more than a billion stars—a factor of 25 more than FAME. GAIA would have a limiting magnitude of about $V = 20$, comparable to SIM, and would deliver an astrometric accuracy of about 10 microarcseconds for stars as faint as $V = 15$.

GAIA will create an extraordinarily precise three-dimensional map of stars throughout our Galaxy. In the process, it will map their motions, which encode the origin and subsequent evolution of the stars. Through comprehensive photometric classification, it will provide the detailed physical properties of each star observed, characterizing their luminosity, temperature, gravity and elemental composition. This massive stellar census will provide the basic observational data to tackle an enormous range of important problems related to the origin, structure and evolutionary history of our Galaxy. By reaching out to large distances, and having the ability to process large numbers of stars, GAIA is better suited than SIM to certain problems in Galactic structure. For instance, a study of the triaxial nature of the Galactic bulge requires a large number of stars as well as high precision, and is ideally suited to GAIA.

Figure 2. Artist's impression of the Space Interferometry Mission in orbit. The main structure houses the optical telescopes and Michelson interferometric beam combiner. The boom supports a system of laser metrology gauges which monitor the exact positions of the first optical elements in each telescope, a 40 cm siderostat. (Figure courtesy of Jet Propulsion Laboratory, California Institute of Technology.)

A key capability for GAIA will be the collection of simultaneous multi-band photometric data and stellar radial velocities. Three-dimensional datasets for velocity and position in the Galaxy are very important for many studies, for instance the abundance and distribution of dark matter in the Galactic disk, through its influence on stellar motions. A ground-based program to provide these supporting data is possible but very difficult and expensive. GAIA will yield a truly immense dataset of positions, kinematics, photometry and radial velocity which will be major a resource to astronomers over the coming decades.

Space astrometry with interferometers

The Space Interferometry Mission (SIM) is a space-based 10 m baseline optical Michelson interferometer, due for launch in 2006. Currently it is the only space-based interferometer specifically designed for precision astrometry. SIM will measure positions and parallaxes to about 4 microarcseconds of stars as faint as $V = 20$ by the end of its 5-year mission. One of its principal scientific goals is an extremely sensitive search for low-mass planets orbiting nearby stars. SIM will also demonstrate the interferometry technologies needed by future missions such as the Terrestrial Planet Finder.

This mission will open up many areas of astrophysics, via astrometry with unprecedented accuracy—more than 200 times more accurate than Hipparcos, and with fainter targets to much fainter magnitudes than FAME, albeit for a much smaller target list. SIM will have two basic operating

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

modes: narrow-angle and wide-angle (global) astrometry. In narrow-angle mode, the instrument measures the target position relative to a 'local' set of reference stars within about 0.5°. This mode provides the highest astrometric accuracy, allows relative (but not absolute) positions to about 1 microarcsecond in a 1 h measurement. Relative parallaxes and relative proper motions are determined by observations repeated during the mission. This mode will be used primarily for the search for low-mass planets orbiting nearby stars. The sensitivity limit is expected to be about a few Earth masses for stars within 10 pc. Other narrow-angle problems include: internal dynamics of globular and open clusters, binary orbit determinations and distances to nearby spiral galaxies using rotational parallaxes.

The intrinsic 'field of regard' of the instrument (without repointing the spacecraft) is 15°. To measure angles larger than this, SIM sets up and monitors a grid of approximately 3000 reference stars. Science observations are referenced to this grid, and the ultimate accuracy of measurements such as parallax is linked to the grid accuracy. Included in the grid will be around 50 quasars to define an inertial frame, and to tie the SIM catalog into the International Astronomical Union's ICRF system. The proper motion accuracy is expected to be around 2 microarcsec per year, corresponding to a transverse velocity of 10 m s^{-1} for a star at a distance of 1 kpc.

SIM will actually operate three interferometers simultaneously. Two are dedicated to observing bright guide stars, sensing drifts in the spacecraft attitude and providing corrections to the third, science, instrument. This design makes possible long integrations on very faint science targets.

With precision global astrometry, SIM will be able to address a broad range of topics in Galactic astronomy. In Galactic dynamics, it will reach stars far out in the halo, probing the mass distribution on large scales, as well as in the disk. This should also lead to a better understanding of the dynamics of stellar populations of different ages. By observing the brightest stars in the closest neighboring galaxies, SIM will study the dynamics and evolution of the local universe outside the Galaxy. SIM can exploit astrometric signatures created in a microlensing encounter to reconstruct the mass and kinematic properties of the lens—not currently possible with the vast majority of photometric-only detections. It does this by measuring the signature of parallax and proper motion of the unseen lens on the gravitational bending. Fundamental astrophysics will benefit from extremely accurate luminosities (via accurate parallaxes)—for instance of OB stars and planetary nebulae, which are relatively rare in the solar neighborhood.

Looking beyond SIM, the next generation of survey instrument, the European Space Agency's GAIA, described above, will usher in an even more exciting era in the methodical and detailed systematic exploration of our Galaxy and beyond.

Space Instrumentation: Cosmic Backgrounds

The COSMIC MICROWAVE BACKGROUND (CMB) radiation contains approximately 99% of the electromagnetic radiation energy in the universe, and its photons outnumber the known massive particles by a factor of $\sim 10^8$. It is the primary observable indicator of conditions in the early universe and, according to COBE, the Cosmic Background Explorer satellite, it is remarkably featureless. Its spectrum is indistinguishable from a perfect blackbody spectrum with a temperature of 2.725 K. Other than the dipole variation, likely due to the motion of the solar system with respect to the CMB rest frame, its brightness is nearly isotropic with rms variations of only 30 μK on angular scales of 10°. The cosmic infrared background (CIB) radiation recently detected by COBE is presumably due to the accumulated infrared emission from the first dusty galaxies to form in the universe. The observed properties of the infrared background will place strong constraints on the star formation history of the universe.

The COBE mission carried three instruments designed to probe these cosmic background radiations. DIRBE was designed to make an absolute measurement of the spectrum and angular distribution of the diffuse infrared background. The FIRAS instrument was designed to study the spectrum of the CMB, and the DMR was a set of differential radiometers designed to measure the anisotropy of the CMB. A follow-up mission to COBE, called MAP, will carry a set of differential microwave radiometers that will remeasure the anisotropy of the CMB with much higher sensitivity and spatial resolution than did DMR. In the years leading up to the launch of MAP there have been a number of ground and balloon-based measurements of the CMB that have provided the first look at degree-scale anisotropy. These measurements are covered in the general article on COSMIC MICROWAVE BACKGROUND. A follow-up mission to MAP, planned by ESA and called PLANCK, is to follow the MAP satellite and is supposed to provide the definitive measurement of the CMB anisotropy.

DIRBE

The DIRBE instrument was designed to make an absolute measurement of the spectrum and angular distribution of the diffuse infrared radiation. One of the most challenging aspects of this experiment is the need to understand and remove foreground emission from our own Galaxy and solar system, which is known to substantially outshine the CIB. This drives the design of the instrument to include many well-spaced frequency channels each of which requires very accurate absolute photometry.

The instrument is a cryogenically cooled ten-band absolute photometer that covers the wavelength range from 1.25 μm to 240 μm in ten bands with a design sensitivity per field of view on the sky of $\lambda I_\lambda = 10^{-9}$ W m^{-2} sr^{-1}. The instrument also measures two perpendicular components of linear polarization in its short-wavelength bands at 1.25, 2.2 and 3.5 μm. The polarization measurements were included to help distinguish the CIB from sunlight scattered by INTERPLANETARY DUST. To further aid in separating interplanetary emission from more distant sources, the DIRBE optical axis is oriented 30° from the spin axis of the COBE spacecraft, so it views half the sky every day at solar elongation angles ranging from $\varepsilon = 64^\circ$ to 124° with many redundant scans. Over the course of six months, every celestial direction is redundantly sampled at all possible solar elongation angles in this range.

The DIRBE optics were carefully designed for strong stray light rejection (figure 1). The configuration includes extensive internal baffling as well as a reflective forebaffle, and a complete light-tight enclosure within the COBE dewar to eliminate any optical cross-talk from the dewar or the FIRAS instrument. Additional protection from the Earth and Sun is provided by the shield surrounding the COBE dewar, which prevents any direct illumination of the dewar from these strong local sources. The front end of DIRBE utilizes an off-axis folded GREGORIAN TELESCOPE with a 19 cm diameter off-axis segment of a parabolic mirror as the primary. An off-axis segment of an elliptical secondary forms an image of the primary at a pupil stop (Lyot stop) which is smaller than the image of the primary, blocking radiation diffracted from the primary mirror. The secondary mirror also images the first field stop at a second field stop which is smaller than the first, blocking stray radiation scattered or diffracted at the first stop and setting the $0.7^\circ \times 0.7^\circ$ instantaneous field of view. An ellipsoidal tertiary mirror images the pupil (Lyot stop) at a tuning fork chopper with mirrored blades. When the chopper is open, sky light reaches the elliptical quaternary mirror which images the pupil via a folding flat onto detector assembly 2. With the chopper closed, the aspheric mirror (M5) reimages the pupil onto detector assemblies 1 and 3.

In this arrangement, all detector assemblies are located at a pupil image and all of the spectral bands view the same instantaneous field of view. Each detector assembly receives radiation chopped alternately between the sky and the cold beam stop. The cold beam stop is a black enclosure maintained below 3 K, producing no detectable signal at any DIRBE wavelength. DIRBE sky measurements are thus continuously referenced to zero flux—a crucial feature for reliable absolute photometry. Instrumental offsets are determined by blocking the sky with a cold shutter located at the prime focus. The shutter has been demonstrated to attenuate saturation level sky signals to well below instrument noise levels at all DIRBE wavelengths. The back of the shutter has a mirror which allows light from an internal reference source (IRS), located out of the path of the sky beam, to reach the detectors via the secondary and subsequent mirrors when the shutter is closed. Measuring the instrument signal with the shutter closed and the IRS off permits determination of instrumental noise levels and electrical and radiative offsets. Turning on the IRS at fixed levels permits monitoring of system gain stability.

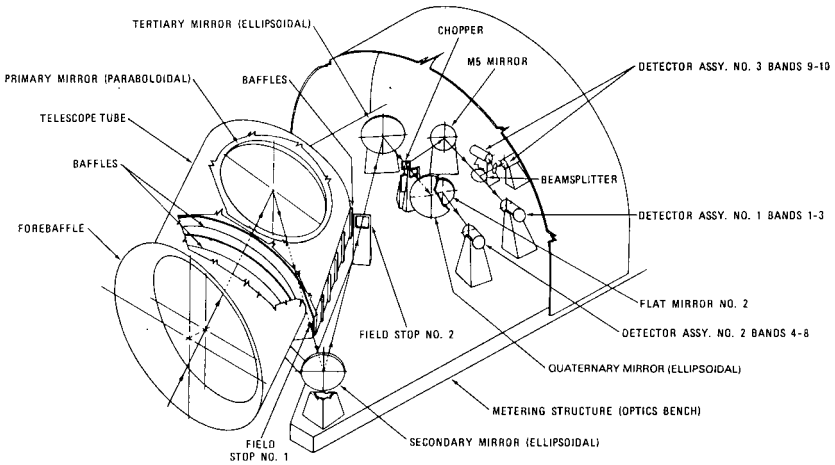

Figure 1. A schematic overview of the COBE DIRBE ten-channel absolute photometer.

The instrument readout with the shutter closed and the IRS turned off defined zero sky brightness for the DIRBE measurements.

FIRAS

The FIRAS instrument was designed to study the spectrum of the CMB. As with the DIRBE instrument, this experiment requires very accurate absolute photometry and high gain stability. One of the key features of FIRAS is that it is differential: the instrument directly measures the difference between the sky signal (in a 7° beam) and that from a temperature controlled internal reference body (ICAL) whose emission is within 5% of a blackbody. The absolute calibration of FIRAS was accomplished in orbit by inserting an external blackbody calibrator (XCAL) periodically into the mouth of the sky horn. The XCAL is a precision temperature-controlled blackbody, with an emissivity greater than 0.999. Both the ICAL and XCAL are temperature controlled by command over the range from 2 to 25 K. This allows the sky signal to be approximately balanced and aids in distinguishing sky signals from instrument self-emission. The differential nature of the instrument and the commandable temperature controlled inputs are the keys to the accuracy of FIRAS.

The heart of instrument is a four-port Michelson INTERFEROMETER with two inputs (used differentially) and two outputs (figure 2). The two input ports are fed by optically matched quasi-optical horn antennas. The interferometer uses polarizing grids as beam splitters and creates an interferogram (Fourier transform of the source spectrum) by scanning a movable mirror platform. A dichroic filter at each output port further splits each beam into low- and high-frequency bands. The low-frequency band, extending from 0.5 mm to 1 cm, was designed to measure the CMB spectrum. The high-frequency band, from 0.12 to 0.5 mm, was designed to measure the emission from dust and gas in our galaxy and to allow the removal of this foreground from the low-frequency

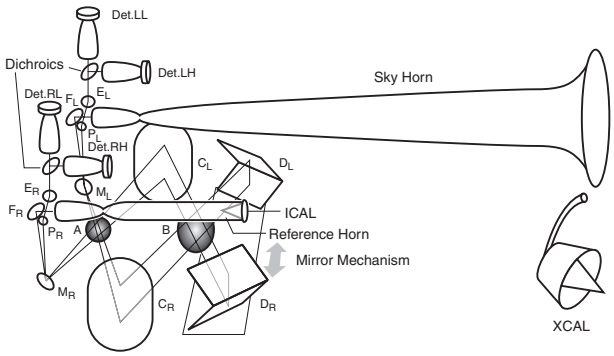

Figure 2. A schematic diagram of the Far Infrared Absolute Spectrophotometer (FIRAS).

CMB data. The objective was to attain a sensitivity of $\nu I_\nu \simeq 10^{-9}$ W m^{-2} sr^{-1} (0.1% of the peak brightness of a 2.7 K blackbody) in each 5% wide spectral element, in each 7° sky pixel. The FIRAS uses bolometric detectors in both frequency channels.

A movable mirror mechanism modulates the path difference, x, between the two optical paths resulting in a varying signal at the output ports proportional to the cosine transform of the input spectra $I(x) = \int \mathrm{d}\nu S(\nu) \cos 2\pi\nu x$. The design symmetry and phase delays imposed by the beam splitter and analyser polarizers make FIRAS a differential instrument. The nearly blackbody ICAL signal is controlled by attached heaters to nearly balance the sky input from the CMB. This reduces the net input signal by 99% and is responsible for the ability of FIRAS to detect deviations of the CMB from a perfect blackbody to less than 0.005% (rms) of the peak.

Absolute measurements of the sky flux require knowing the emission of the ICAL and other components of the instrument. This is done by examining the changes in the observed spectrum with variations in the component temperatures. For the ICAL and two

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

horns, variation is produced by commands to attached heaters. The overall throughput of the instrument is measured by placing an external calibrator, or XCAL, in the sky horn aperture—replacing the sky signal with a known input. The XCAL signal is known because it is a blackbody to within 0.005% both by construction and as verified in ground measurements. Its temperature is controlled by an attached heater and measured by a set of thermometers. Errors in the thermometry of the XCAL are the limiting factor when comparing the absolute sky flux measurements of FIRAS with other instruments.

Other design features that contribute to the success of FIRAS include a large etendue (throughput) for high sensitivity; two path length differences for the mirror mechanism (1.2 and 5.9 cm) allowing for higher frequency resolution for the longer stroke length; and two scan speeds for the mirror mechanism to help distinguish instrument errors. The entire instrument is operated in a vacuum and cooled to 1.5 K by conduction to a superfluid liquid helium tank. A large external conical shield protects the cryostat and instruments from direct radiation from the Sun and the Earth.

DMR

The purpose of the differential microwave radiometers (DMR) experiment is to measure large-angular-scale anisotropy of the CMB. Measuring the temperature of the microwave sky to an accuracy of one part in 10^5 requires careful attention to possible sources of systematic errors. Due to the extraordinary isotropy of the CMB, one of the primary concerns is instrument stability since any small perturbation to the instrument in the form stray radiation, electronic pick-up or thermal effects can easily produce a false signal that exceeds the anisotropy signal. One of the most important safeguards is to make the instrument differential. The DMR instrument consists of six differential microwave radiometers, two nearly independent channels (labeled A and B) at each of three frequencies: 31.5, 53 and 90 GHz. Each radiometer measures the difference in power, expressed as a differential antenna temperature, between two regions of the sky separated by 60°. The combined motions of spacecraft spin (73 s period), orbit (103 m period) and orbital precession (~1° per day) allow each sky position to be compared with all others through a highly redundant set of all possible difference measurements spaced 60° apart. The DMR has three separate receiver boxes, one for each frequency, that are mounted 120° apart on the outside of the COBE cryostat containing the FIRAS and DIRBE. A shield surrounding the aperture plane protects all three instruments from solar and terrestrial emission. The 31 GHz system operates at room temperature while the 53 and 90 GHz systems are passively cooled to 140 K.

The antennas are wavelength-scaled corrugated horns that were chosen for their low sidelobe response, low insertion loss and compactness. The main beam response is approximately Gaussian with a 7° FWHM. Each pair of antennas (labeled 1 and 2) feed a Dicke-switched radiometer. The output of the ferrite Dicke switch alternates the signal from the two input antennas at a rate of 100 Hz. This is an essential step in the process of reducing systematic effects by reducing the impact of low-frequency gain fluctuations and $1/f$ noise in the radiometer amplifiers. The output of the Dicke switch is sent through ferrite isolation to a mixer–preamplifier. A local oscillator signal obtained from a Gunn diode oscillator is used to mix the signal down to intermediate frequencies. It is then sent to a lock-in amplifier where the signal is square-law detected, converted to a proportional voltage and amplified with a lock-in that is synchronous to the Dicke switch. The lock-in amplifier includes a circuit which integrates this switch-modulated signal for 0.5 s producing a voltage that is proportional to the brightness difference between the two input signals. The signal is calibrated to antenna temperature by periodically injecting broad-band power of a known amplitude from a noise diode into the throat of each antenna.

MAP

The MAP mission is a follow-up to the COBE mission that is scheduled to launch in the Spring of 2001. MAP will remeasure the anisotropy of the CMB with higher sensitivity and angular resolution than COBE DMR. The MAP instrument consists of a set of passively cooled microwave radiometers with 1.4×1.6 m diameter primary reflectors to provide the desired angular resolution of less than 0.3°. The need to suppress systematic measurement errors led to the following instrument features:

(a) MAP is a differential experiment based on pseudo-correlation microwave radiometers. The instrument measures temperature differences between two points ~141° apart on the sky.
(b) MAP will orbit about the Sun–Earth L_2 libration point which provides for a very stable thermal environment and near 100% observing efficiency since the Sun, Earth and Moon are always behind the instrument's field of view.
(c) MAP will rapidly scan the sky to compare many pixel pairs on many different time scales.

The reflector design incorporates two back-to-back off-axis Gregorian telescopes with 1.4×1.6 m primary reflectors and 0.52 m secondary reflectors. Each primary is a shaped elliptical section of a paraboloid, while the secondaries are nearly elliptical. This arrangement produces two slightly convex focal surfaces on opposite sides of the spacecraft spin (and symmetry) axis with plate scales of ~15′ cm^{-1}. In order to limit diffracted signals to less than 0.5 μK, diffraction shields are employed above, below and to the sides of each secondary. In addition, the deployable solar panels and multilayer insulation guarantee that the secondaries remain in shadow during observing.

The feed design calls for as small an aperture as possible consistent with a primary edge taper requirement

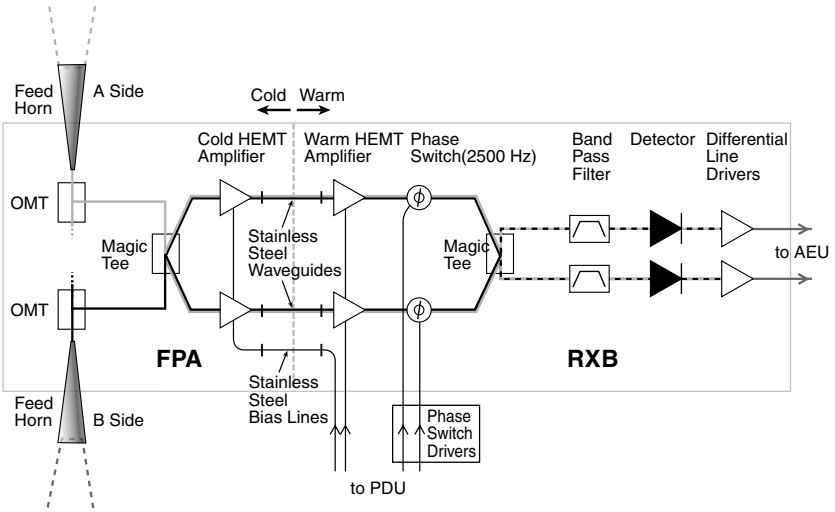

Figure 3. A schematic diagram of a single MAP pseudo-correlation radiometer including the cold focal plane assembly (FPA) and the warm receiver box (RXB).

of −20 dB, and a length that places the throat of each differential feed pair in close proximity to the other. The feed aperture diameters scale inversely with frequency, while the primary is equally illuminated at each frequency, leading to a frequency-dependent beam size. The feeds are corrugated to produce beams with high symmetry, low loss and minimal sidelobes. The phase center of each feed is kept as close as possible to its aperture, resulting in a frequency-independent beam for each feed.

The microwave system consists of ten four-channel 'differencing assemblies', one for each pair of feeds (figure 3). One assembly operates at 22 GHz, one at 30 GHz, two at 40 GHz, two at 60 GHz and four at 90 GHz. This gives the spectral coverage required to separate galactic foreground emission from the CMB and provides roughly equal sensitivity at each frequency. Each feed is attached to a low-loss orthomode transducer which separates the sky signal into two orthogonal polarizations. The A-side signal of one polarization is differenced against the orthogonal polarization, B', from the corresponding B-side feed, and vice-versa. The differencing is accomplished by first combining the two signals A and B' in a hybrid tee to form $(A + B')/\sqrt{2}$ and $(A-B')/\sqrt{2}$, then amplifying each in two cold high electron mobility transistor (HEMT) amplifiers and sending the phase-matched outputs to the warm receiver box (RXB) via a waveguide. In the RXB the two signals are amplified in two warm HEMT amplifiers, phase switched between 0° and +90° or −90° respectively, at 2.5 kHz, then split back into A and B' in a second hybrid tee. At this point, the two signals are square-law detected, amplified by two line drivers, and sent to the analog electronics unit for synchronous demodulation and digitization. The other pair of signals, A' and B, are differenced in the same manner giving a total of four detector channels per differencing assembly. The output in each channel is proportional to the temperature difference between the A- and B-side pixels. The signal is calibrated by fitting the data to the strong dipole signal that was accurately measured by COBE.

The splitting, phase switching and subsequent combining of the signals enhances the instrument's performance in two ways.

(a) Since both signals to be differenced are amplified by both amplifier chains, gain fluctuations in either amplifier chain act identically on both signals and thus cancel upon differencing.
(b) The phase switches introduce a 180° relative phase change between the two signal paths, thereby interchanging which signal is fed to which square-law detector. Thus, low-frequency noise from the detector diodes is common mode and also cancels, further reducing susceptibility to systematic effects.

PLANCK

PLANCK is the third medium-sized mission (M3) of ESA's Horizon 2000 scientific programme. It is designed to image the anisotropy of the CMB over the whole sky, with unprecedented sensitivity and angular resolution. It is now planned to launch in the first quarter of 2007 together with the FIRST (FAR-INFRARED AND SUBMILLIMETRE TELESCOPE) satellite, in a configuration often referred to as the 'Carrier' (because FIRST is 'carried' by PLANCK in the launcher). After launch, PLANCK and FIRST will separate and will be placed in different orbits around the second LAGRANGIAN POINT of the Earth–Sun system. PLANCK will carry two main instruments: the low-frequency instrument (LFI) which covers the frequency range 30–100 GHz, and the high-frequency instrument (HFI) which will cover the frequency range 100–850 GHz. This very wide frequency coverage should provide a wealth of information on both

Space Instrumentation: Imaging Interferometry

Because of the degrading effects of the Earth's turbulent atmosphere, the spatial resolution achieved by ground-based OPTICAL ASTRONOMY is limited to the extent of the SEEING disk—the image of a point source (e.g. a single star), taken through the atmosphere. The size of the seeing disk is independent of telescope diameter, but changes only with wavelength and climatic conditions—about 0.5″ at the best observing sites in good weather. In the absence of atmospheric seeing, e.g. in space, or with a perfect ADAPTIVE OPTICS system, a telescope has a resolution defined by the DIFFRACTION limit, which scales inversely with telescope diameter: the larger the mirror, the sharper the image. For example, the HUBBLE SPACE TELESCOPE with its 2.5 m aperture has a diffraction limit of 0.05″ at a wavelength of 500 nm, 10 times better than the seeing limit, but still not good enough for many areas of astronomical research. Projects such as resolving the immediate surroundings of black holes in external galaxies, or imaging extrasolar planets, require telescope diameters of at least 100 m. To manufacture and launch into space such large apertures is clearly out of reach of present-day technology. Yet, images with such seemingly impossible resolution are feasible. They can be obtained with a method called *synthesis imaging* which can achieve basically unlimited resolution without unreasonably large telescopes. In this article, I discuss the principle of synthesis imaging and the advantages of imaging interferometry from space. I also briefly describe various projects planned for the near future which promise to revolutionize astronomical imaging. While the general discussion of synthesis imaging is valid for the entire electromagnetic spectrum, the degree of difficulty of its realization varies dramatically with wavelength. Here, I will focus solely on the optical regime and ignore the rich and successful history of the RADIO INTERFEROMETER.

The idea of synthesis imaging

Figure 1(*a*) shows a simple star cluster as it would be seen by a (hypothetical) diffraction-free 10 m telescope in space. Imagine its primary mirror covered by an opaque mask with a set of holes along a line. Obviously, most of the image information would be lost—but not all of it. The image produced through such a mask shows a set of INTERFERENCE fringes—alternating stripes of high and low intensity (figure 1(*b*)). These fringes contain information about the structure of the object. Different rotation angles of the mask produce additional fringe patterns. All patterns can be recorded and combined later to obtain the complete source image, as demonstrated in figures 1(*c*) and 1(*d*). In fact, there is no need for the full 10 m telescope mirror: the fringe patterns can be obtained with just a set (at least two) of small mirrors by combining their beams in a common focus. This is the elegant principle behind synthesis imaging: to mimic a large telescope with a number of smaller ones.

There is, however, one caveat which in the past has prevented the successful realization of synthesis imaging at optical wavelengths. In order to produce the all-important interference fringes, the beams from the individual APERTURES must be combined coherently. This means that the difference in their pathlengths to the common focus must not exceed the coherence length of the light. Combining the two signals coherently requires accurate control of the pathlengths between the two telescopes and the beam combination optics. The enormous technological difficulties associated with controlling optical pathlengths to the required levels of a few wavelengths are described elsewhere (see INTERFEROMETRY: GROUND).

How does it work?

The mathematical framework of synthesis imaging is based on the theory of wave diffraction. The basic result is summarized in the van Cittert–Zernike theorem:

> the complex degree of coherence is equal to the normalized Fourier transform of the source intensity distribution[1].

The degree of coherence is a complex quantity, the observables measured in practice are its amplitude and phase. They can be derived from the interference pattern (the fringe) which appears on the detector when scanning the delay between the two beams.

An imaging interferometer measures the degree of coherence across the (u,v) plane. Because, in essence, this measures the Fourier transform of the source structure, the vector between the two telescopes—the baseline $\vec{B}$—is usually measured in the spatial frequency domain, i.e. in units of wavelengths, $u = B_x/\lambda$ and $v = B_y/\lambda$. The plane in which the source wavefront is sampled is therefore called the (u,v) plane. Different baseline vectors are achieved by moving the individual telescopes with respect to the source, thus sampling different (u,v) points. According to the van Cittert–Zernike theorem, this allows the full reconstruction of the source structure via an inverse Fourier transform, provided that the (u,v) coverage is complete. However, the (u,v) coverage of any real interferometer will have gaps, resulting in ambiguity in the source reconstruction. The ring-like residuals in figure 1(*d*) are one example of such ambiguities, also

[1] Strictly speaking, this formulation of the van Cittert–Zernike theorem is correct only for the case of an incoherent light source. Also, both the source size and the baseline length must be much smaller than the distance to the source (the far-field approximation). However, astronomical sources at optical wavelengths always meet all of these conditions.

and Institute of Physics Publishing 2001

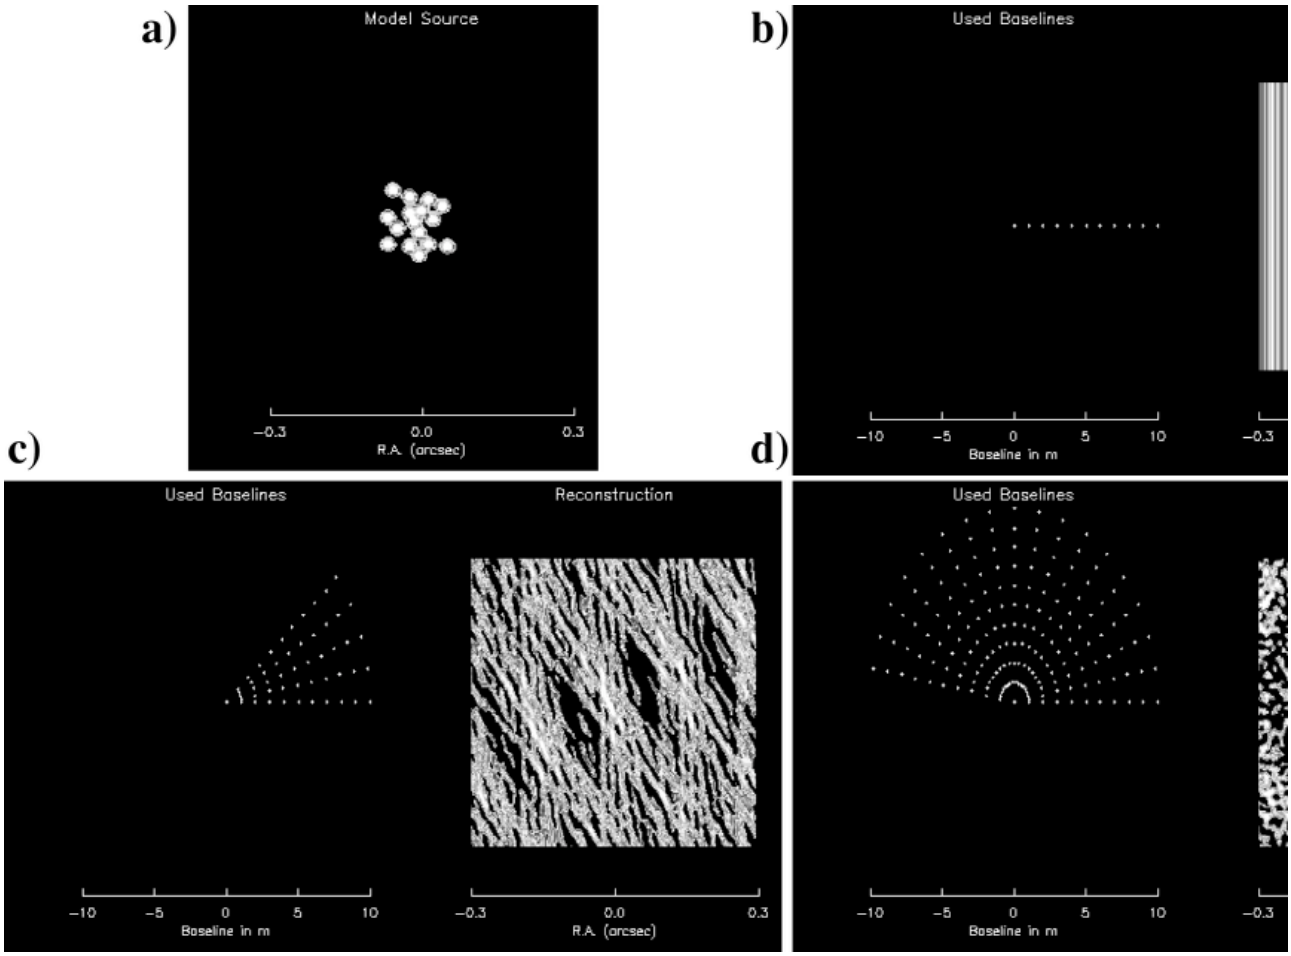

Figure 1. Illustration of the principle of synthesis imaging: (*a*) model source to be imaged; (*b*)–(*d*) image reconstructions (right) for various baseline distributions (left). The ring-like residuals around the central source image are called grating rings. They are a consequence of the regularly spaced gaps in the (*u*,*v*) coverage and can be removed to a large extent by numerical image restoration algorithms.

known as grating rings. The completeness of the (*u*,*v*) coverage is therefore a critical design parameter for imaging interferometers.

Spatial resolution

To first order, the resolution of an imaging interferometer is defined by the longest baseline. However, in contrast to the diffraction limit of a filled aperture, the spatial resolution of a synthesis imaging observation is not uniquely defined. By varying the weighting of the data obtained at different (*u*,*v*) coordinates, or even removing some baselines completely, one can put more or less emphasis on certain spatial frequencies in the reconstruction and thus change the effective resolution, even after the data are taken. This fact is regularly exploited at ground-based telescopes in aperture masking observations of bright sources for which collecting area is not an issue but the highest possible resolution is required.

Field of view

The FIELD OF VIEW (FOV) of an imaging interferometer is limited by the coherence length of the light, $l = \lambda^2/\Delta\lambda$, where λ and $\Delta\lambda$ are the wavelength and the bandwidth of the observation. While the pathlengths from the two interferometer elements ideally are equal in the center of the field, an angular separation Θ from the center necessarily produces a path difference ΘD. As long as this difference is small compared with l, the fringe contrast will not be affected. Thus, $\Theta \leq (\lambda/D)\lambda/\Delta\lambda$, or $\Theta < R_{\mathrm{spatial}}R_{\mathrm{spectral}}$. The maximum FOV of an interferometer thus can be estimated from its spatial and spectral resolution. In practice, however, the FOV is likely to be limited by the effects of the incomplete (*u*,*v*) coverage (see figure 1).

Synthesis imaging in space

All that has been said so far about synthesis imaging applies equally to space- and ground-based interferometers. There are, however, important differences between the two environments in a number of aspects.

(u,v) coverage

Most interferometer arrays will consist of relatively few elements because of cost constraints. In order to overcome the intrinsically sparse (u,v) coverage of such systems, many employ movable apertures. In addition, all ground-based arrays use the Earth's rotation during the course of the night to sample many different (u,v) points. The achievable (u,v) coverage therefore depends on both the geographical location of the array and the source position with respect to the Earth's rotation axis.

In contrast, an interferometer in space cannot rely on the Earth's rotation. It therefore must have movable apertures to fill the (u,v) plane. On the other hand, the (u,v) coverage can be chosen freely. This allows a uniform resolution which can be valuable in survey programs which study the statistical properties of large numbers of similar objects.

Aperture size

The size of the individual apertures of a ground-based interferometer is limited to the size of an atmospheric turbulence cell—about 30 cm at optical wavelengths. In principle, the use of adaptive optics can overcome this limit, but the need for a bright reference source (a 'guide star') within the isoplanatic patch severely limits the number of suitable targets.

In space, on the other hand, there is no turbulent atmosphere. Therefore, the size of interferometer elements is limited only by our technical and financial ability to manufacture—and bring into space—large mirrors.

Frame time

Another important obstacle for interferometry on the ground imposed by the Earth's atmosphere is the need to record the complex visibility within a coherence time of the atmosphere—about 20 ms at a good site for optical wavelengths. Together with the above limit on aperture size, this severely constrains the target brightness: it has to be bright enough to overcome the noise associated with the detection system, from both the detector and the read-out electronics.

Even with a perfect adaptive optics system, the integration time at each (u,v) point is limited because of the Earth's rotation: the measurement has to be completed before the baseline has changed noticeably in order to avoid (u,v) smearing.

In space, the available integration time for each (u,v) coordinate is in principle unlimited, so that much fainter objects can be observed. This assumes, however, that structural vibrations or slow drifts are perfectly corrected.

Passbands

Astronomy from the ground is limited to a number of small regions of the electromagnetic spectrum over which the Earth's atmosphere is transparent. In space, no such limitations exist, and important wavebands such as the ultraviolet or the mid-infrared become accessible.

Environment

Clearly, operating an interferometer in space to the extreme precision required for successful fringe tracking is an extremely challenging task. In the case of single spacecraft with a number of apertures on a connecting truss, the mechanical vibrations of the structure must be minimized, and, even for low-noise structures, residual motions must be actively corrected. In principle, however, space is a favorable environment because it is intrinsically much quieter than the geologically active surface of the Earth. Because of this and the limitations of a truss with regard to the achievable baseline length, future synthesis imaging in space is likely to be realized with a suite of free-flying apertures which are positionally controlled with respect to each other and the beam combining optics by reference laser beams.

Ongoing and planned projects

The technology that makes the ambitious methods of active pathlength control and fringe tracking feasible has only recently become available, mostly through the development of ever faster computers that allow real-time control of mechanical instabilities. While the principles of synthesis imaging are well understood, and the technique has been demonstrated on the ground, interferometry in space has yet to be realized. Today, a number of space-based interferometer projects capable of performing synthesis imaging are in the development or planning stages in the United States and Europe.

StarLight is intended to demonstrate the feasibility of precision control for free-flying spacecraft. It consists of two spacecraft: one that serves as a light collector, and one that comprises a second collector, delay line and beam combining optics. Launch is planned for 2005. The primary goal of StarLight is to demonstrate the technological readiness for subsequent science missions.

The Space Interferometry Mission (SIM) consists of a single spacecraft with three interferometer pairs along a 12 m truss. The individual telescopes have a diameter of about 30 cm. The primary science goal of SIM is to perform high-precision astrometry for a number of key programs. Because SIM will allow the truss structure to be rotated and will cover a yet to be determined range of baseline lengths, it will have some potential for synthesis imaging of simple astronomical sources. SIM is scheduled for launch in 2009.

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

Terrestrial Planet Finder (TPF) in its current design comprises four free-flying 3.5 m telescopes and a fifth spacecraft with the beam-combining optics. The design allows maximum baselines of about 1 km for a resolution of less than 0.001″ at wavelengths around 3 μm. The main scientific goal of TPF is the detection and characterization of Earth-like planets at infrared wavelengths by means of interferometric nulling of the light from the host star. A tentative launch date for TPF is 2012.

DARWIN is a mission concept within the cornerstone program of the European Space Agency (ESA) with a launch after 2014. Much like TPF, it will use free-flying telescopes as the interferometer elemetns. It has a similar design concept and scientific goals to TPF.

While the basic technological tools for these ambitious missions appear to be in hand or within reach, their successful implementation will occur in steps and will require time, effort and money. On the way to the ultimate goal of taking images of other Earths, major advances in many other aspects of astronomy are almost certain because of the dramatic increase in spatial resolution that only synthesis imaging can provide.

Space Interferometry Mission (SIM)

Proposed NASA astrometry mission and the first to use optical interferometry. Launch is planned for June 2005. The spacecraft will drift away from the Earth at approximately 0.1 AU per year, reaching a maximum communication distance of about 95 million km after five years. In this orbit, it will receive continuous solar illumination. It will carry a science interferometer and two guide interferometers with a 10 m baseline. Used to determine the position and distances of stars to extremely high accuracy and to detect brown dwarf stars and planets. It will also pioneer a technique to block out (null) the light of bright stars. Possible angular resolution of 10 milliarcseconds—four times better than the Hubble Space Telescope.

Space Probe

An uncrewed spacecraft designed to investigate the interplanetary medium or conditions on or in the vicinity of another celestial body. A space probe travels along an orbit around the Sun or on a trajectory that takes it from the vicinity of the Earth to the neighborhood of its target (for example, a planet, comet or asteroid). In order to reach interplanetary space, a space probe has to exceed the escape velocity of the Earth. In order to enter a closed orbit around its target planet, a space probe has to reduce its speed relative to that planet, usually by firing onboard rocket motors (if no action of this kind is taken, the craft will fly past its target on a hyperbolic trajectory and recede into interplanetary space). The first space probe to leave the vicinity of the Earth and enter an independent orbit around the Sun was Luna 1, a Soviet probe that passed by the Moon at a range of 6000 km on 4 January 1959, and continued on into interplanetary space.

Space Research Institute

The Space Research Institute (IKI), located in Moscow, is one of the leading organizations in Russia in space research. The main fields of research are astrophysics, space plasma physics and solar system exploration. During its history, from its foundation in 1965, IKI has fulfilled many experiments and missions, including investigations of the Moon, Venus, Mars, Comet Halley (VEGA mission) and Phobos (PHOBOS-2 mission); and, during the last decade, the MIR-KVANT and GRANAT space observatories (astrophysics) and the INTERBALL program (space plasma research). Main sources of funding are the Russian Academy of Sciences and the Russian Space Agency.

Space Research Organization Netherlands

The Space Research Organization Netherlands (SRON) initiates, develops and exploits outstanding instruments for research in and from space. SRON is responsible for the national space research program, which is carried out by the two laboratories for space research in Utrecht and Groningen. Activities comprise the design, development and manufacture of space instruments, as well as the processing and interpretation of the data.

Its principal contributions to astrophysics are: Reflection Grating Spectrometer on XMM; Low Energy Transmission Grating Spectrometer for Chandra; Wide Field Cameras aboard BeppoSAX; Heterodyne Instrument for ESA's Far-Infrared and Submillimeter Space Telescope; and ISO Short-Wavelength Spectrometer.

Space Telescope European Coordinating Facility (ST-ECF)

The ST-ECF, which was established in 1984, is jointly operated by the EUROPEAN SPACE AGENCY (ESA) and the EUROPEAN SOUTHERN OBSERVATORY (ESO). It is located at the ESO headquarters in Garching, near Munich.

The facility supports the European astronomy community in exploiting the research opportunities provided by the Hubble Space Telescope. It provides detailed technical information about the HST and its science instruments, and supports European astronomers in the preparation of HST observing proposals. It also coordinates the development of computer software to meet the specific data analysis needs of HST users, operates and maintains an archive of all the scientific data collected by HST, and acts as a European center for associated meetings and workshops.

ST-ECF staff maintain close contacts with the SPACE TELESCOPE SCIENCE INSTITUTE (STScI) in Baltimore, which is charged with the scientific operation of the HST observatory. ST-ECF also provides a contact point for European media and public information.

Space Telescope Science Institute (STScI)

Located on the Johns Hopkins University Homewood campus, Baltimore, Maryland. The institute is responsible to NASA's GODDARD SPACE FLIGHT CENTER for the scientific operations of the Hubble Space Telescope (HST). It was established by NASA, following a recommendation by the National Academy of Sciences, and is operated by ASSOCIATION OF UNIVERSITIES FOR RESEARCH IN ASTRONOMY (AURA) under contract to NASA.

STScI's main role is to maximize the scientific productivity of HST and to serve the astronomical community in its operation. The institute solicits and reviews observation proposals and selects observations to be carried out. It schedules observations and assists guest observers in their work. It also generates an integrated science and engineering timeline to support all spacecraft activities and provides the facilities and software to calibrate, analyse and archive HST data.

STScI also monitors the HST and its science instruments for characteristics such as instrument performance, pointing accuracy and telescope focus. As part of the planning and scheduling system, the STScI Guide Star Selection System provides reference stars and other bright objects so that the HST's fine guidance sensors can point the telescope accurately.

The institute also played a key role in the early mission concept studies for the Next Generation Space Telescope (NGST) and has been selected by NASA to manage the science and mission operations for this successor to the HST.

STScI is staffed by astronomers, computer scientists, technicians and administrative staff from AURA, the European Space Agency (which is a partner with NASA on the Space Telescope Project), and the Computer Sciences Corporation. Of its combined staff of approximately 500, approximately 100 are astronomers and scientists.

Spacetime

A four-dimensional geometrical framework that unites the three dimensions of space and the dimension of time. A point in spacetime (identified by four coordinates) is called an event (or 'world-point'). The history of a particle (a line in four dimensions connecting all the events at which it is present) is called a world-line.

The concept of spacetime was devised in 1907 by Hermann Minkowski (1864–1909). Whereas Newton regarded time as being independent from the three dimensions of space, Minkowski contended that they are intimately related. Four-dimensional spacetime was adopted by Einstein as the framework within which to develop his general theory of relativity. According to that theory, spacetime is curved in the presence of matter and the paths of rays of light and particles of matter are determined by the curvature of spacetime.

Spanish Astronomy

Astrophysics is a very recent development in Spain, but its spectacular evolution in itself constitutes a singular phenomenon that has aroused the interest of sociologists and historians of science alike.

Historical background

It is well known that, during the Middle Ages, the Iberian peninsula was the European center of astronomical knowledge. Not only were the works of classical and oriental astronomy rediscovered and made available to the world at large (especially through the School of Translators at Toledo), but it was here also that new instrumentation was developed and advances were made in the scientific understanding of the heavens, contributing decisively to the empirical and conceptual foundations of the Renaissance astronomical revolution. In the 15th and 16th centuries the art of navigation, which opened up ocean routes to the advantage of Spanish and Portuguese mariners, derived its base in the astronomy developed in Spain. Significantly, the Prime Meridian, the origin of longitude, was first defined to pass through Toledo and later through the island of Hierro—it was only in the 19th century that it was finally settled to pass through the Royal Observatory, Greenwich.

It was not until the Enlightenment that astronomy once more flourished in Spain. The dedication of the mariner-astronomers of Cadiz, led by Jorge Juan and Antonio de Ulloa, played a decisive role in bringing the new science and technology to Spain, and not only in the field of astronomy.

The observatory of Cadiz was founded in 1751 and published its first astronomical ephemerides (the third oldest in the world) in 1792. The Observatory of Madrid was created at the end of the century.

Spanish Enlightenment astronomers were fully aware that the most advanced instrumentation was needed in order to pursue modern astronomy. That is why the observatories of Cadiz and Madrid have in their possession two of the finest instruments of the period. A further indication of this was the commissioning of a giant telescope, 25 ft long with a primary mirror 2 ft in diameter, from William Herschel, who was the foremost telescope maker of his time. Unfortunately, before it could enter into service this optical marvel was destroyed by Napoleonic troops garrisoned at Madrid Observatory.

Slow progress began to be made in Spanish astronomy by the beginning of the present century. The obervatories of San Fernando and Madrid were refurbished, and in 1904 the new obervatories of Fabra (in Barcelona) and Cartuja (Granada) were built. However, the Spanish Civil War (1936–9) and its aftermath led to a further halt in the progress of Spanish astronomy, which stagnated into the more routine aspects of 'positional astronomy' and 'celestial mechanics'.

After the Second World War European astronomers began to seek new telescopic locations in southern regions with more favorable climates.

In 1958 the path of totality of a solar eclipse passed through the Canaries and astronomers from all over the world traveled to the islands. This occasion served to recall the 19th-century Tenerife observations of PIAZZI SMYTH (who later became Astronomer Royal for Scotland). Piazzi Smyth made his observations at several different heights ranging from sea level to the peak of Mount Teide and confirmed Newton's prediction that the stars would be better viewed at greater heights. For this reason, Piazzi Smyth's expedition to Tenerife has come to be regarded as the precursor of present-day mountain observatories.

Also, in 1910, Jean Mascart, an astronomer from the Paris Observatory, went to Tenerife to observe the return of COMET HALLEY, this expedition forming part of a wider undertaking by the World Health Organization to study the effects of the toxic gases in the tail of the comet, which on this occasion would sweep past the Earth. He made his observations at Piazzi Smyth's site and, apart from deducing that the toxic gases of comets' tails were undetectable, he concluded that the Canarian skies were of great purity and offered exceptional conditions for astronomical observing. Unfortunately, the resulting Franco–German initiative to create a European observatory on the flanks of the Teide was to come to nothing with the advent of the First World War.

Today, Piazzi Smyth's Canarian astronomical adventure is commemorated by the lunar features (christened by Piazzi Smyth himself) *Montes Tenerife* and *Pico* (after the peak of the Teide).

In the light of these memories of past expeditions, it eventually came to be realized that the Canaries might offer one of the sites sought after by modern astronomers, particularly in the branch of astrophysics. The Spanish authorities, in response to international pressure, decided to take action and in 1959 the National Ministry of Education created the OBSERVATORIO DEL TEIDE, under the responsibility of the Rector of the University of La Laguna, with the express aim of establishing whether the heights of Tenerife could provide the conditions demanded by modern astronomical observing and, if so, of promoting the setting up of an observatory there.

Astronomical site testing was undertaken by Spanish astronomers in the 1960s and the first telescopes were built at the Observatorio del Teide. They were of small aperture and were dedicated to the photometry of extended sources and solar physics. This led European astronomers to think that the Canaries might be a good site for setting up their telescopes and they eventually completed the site testing.

During the 1970s, formal agreements were drawn up with various European countries concerning the setting up of advanced telescopes in Spanish territory: in 1972, the Hispano–German Astronomical Centre (CAHA), which runs the CALAR ALTO OBSERVATORY (in Almeria), was intituted, and in 1979 several European countries signed the 'Agreements on Cooperation in Astrophysics', through which the observatories of the INSTITUTO DE ASTROFÍSICA DE CANARIAS (IAC) are made available to the international scientific community. It was during this period that the

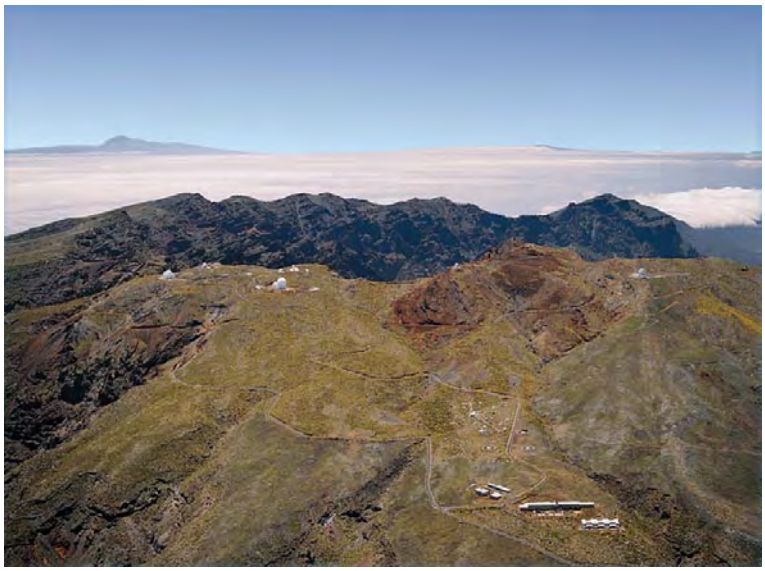

Figure 1. Aerial view of the Observatorio del Roque de los Muchachos, on the island of La Palma. It is at this Observatory, at a height of 2400 m and bordering the Caldera de Taburiente National Park in the muncipality of Garafia, that the 10 m GTC (*Gran Telescopio Canarias*) will be built.

Figure 2. Partial view of the Observatorio del Teide, on the island of Tenerife. Astrophysics in the Canaries began on this island in this observatory, situated in the district of Izaña at a height of 2400 m, where the municipalities of La Orotava, Fasnia and Güímar meet. It has the most complete array of solar instrumentation in the world.

infrastructure was provided for the setting up of the most advanced group of European optical–infrared telescopes of their time.

Radio astronomy began to be developed in parallel with these activities. In 1977 the Yebes Observatory (Guadalajara) was created, and in 1982 the INSTITUT DE RADIO ASTRONOMIE MILLIMETRIQUE (IRAM) installed a 30 m millimetric radio telescope at Pico Veleta (Granada). These were followed by NASA space-tracking dishes in Robledo and Cebreros (Madrid).

From the 1980s onwards, this train of circumstances provided Spain, which had not hitherto developed a base in astrophysics and had been lacking in any kind of modern astronomical instrumentation, with the most wide-ranging panoply of optical and radio telescopes in Europe. By agreement, the Spanish scientific community was to receive between 10% and 25% of the the observing time on all foreign instruments.

The vision, enthusiasm, tireless energy and perseverance of a small group of individuals led eventually to the creation of the necessary internal conditions to enable full use to be made of this incredible wealth of facilities in

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

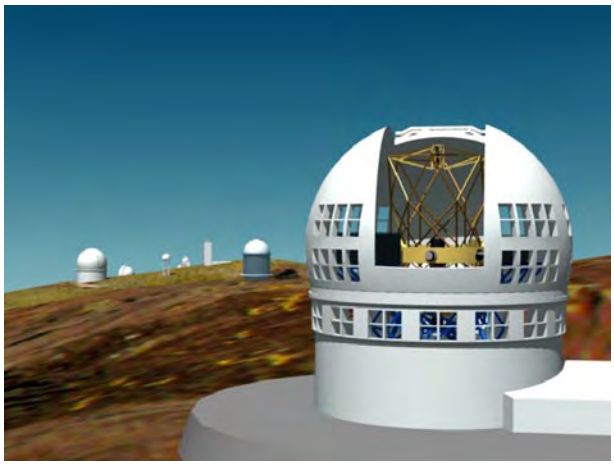

Figure 3. Three-dimensional view of the building and dome of the GTC (*Gran Telescopio Canarias*). Its primary mirror will consist of 36 hexagonal segments, each with a largest diameter of 1.9 m and together forming the equivalent of a conventional monolithic mirror of 10 m diameter. Its size and design innovations will make the GTC the most advanced instrument of its generation when it sees first light in the year 2002. The IAC is leading the construction of this advanced telescope, to be located at its Observatorio del Roque de los Muchachos, on the island of La Palma.

Figure 4. June 1985 saw the official inauguration of the Canarian astrophysical observatories, presided over by the Spanish Royal Family and royalty and heads of state from Denmark, the Federal Republic of Germany, Great Britain, Ireland, the Netherlands and Sweden. Among the representatives of the international scientific community were five Nobel Laureates in physics.

the form of the birth and vigorous development of astrophysics in Spain. The new influx of foreign instrumentation served as a lever to raise Spanish astronomy in record time to a par with the most scientifically advanced countries. A useful illustration of the activity of the nascent science of astrophysics in Spain is given by the fact that the 4.2 m Anglo–Dutch William Herschel Telescope is five times oversubscribed by Spanish applications for observing time.

The present quantity and quality of scientific production, the number of Spanish groups heading lines of research and the construction of instrumentation have together won the admiration of the international scientific community, especially when the rapidity and determination with which this high level of achievement has been reached are taken into account. Some even speak of 'Spain's astronomical miracle'.

The present situation

In order to gain an overall view of present-day Spanish astronomy, it would be useful to follow its main lines of development in terms of the recent flood of new instrumentation into Spain, the training of researchers, the creation of new administrative structures, an open policy of fostering public awareness of astronomy and the building of new instrumentation.

However, before entering into these aspects it might be opportune to mention the fields in which Spanish astronomy has made important contributions. Among these I cite, in alphabetical order and with no attempt at being comprehensive, active galaxies, astrometry, brown dwarfs, circumstellar dust shells, cool stars, the cosmic microwave background and the large-scale structure of the universe, interstellar molecules, nebulae and H II regions, neutron stars, normal galaxies, relativistic astrophysics, solar physics, star formation and stellar populations, white dwarfs and x-ray binaries.

A deluge of new instruments

Table 1 summarizes the main astronomical resources at present located on Spanish soil. Only the collecting area has been highlighted since it is a telescope's diameter that determines its resolving power and light-grasping capacity (as well as its cost).

Special mention must be made of the IAC's international observatories, in which more that 30 scientific institutions from 14 countries participate, and which effectively constitute the European Northern Observatory (ENO). There are nine telescopes with mirrors of diameter over 1 m, not counting the 10 m *Gran Telescopio Canarias* (GTC) now under construction (figure 3). The observatories were inaugurated in 1985 by the King and Queen of Spain in the presence of six other heads of state and a distinguished selection of scientists (figure 4).

The excellence of the Canarian skies is specifically protected as an 'astronomical reserve' by Spanish law.

The training of researchers

The training of astrophysicists was begun in the 1960s, opportunities being provided for young researchers to travel to foreign research centers. It was necessary for Spain to have its own investigators if it was to derive any benefit from the numerous instruments set up in its territory. The training of good astrophysicists was then, and continues to be, a prime objective.

Table 1. Main astronomical resources.

	Collecting surface (m^2)
Observatorio del Teide (Tenerife)	
4 solar telescopes	1.20
1 infrared telescope	1.77
3 general-purpose telescopes	1.48
Various radiotelescopes for CMBR	
Various helioseismological instruments	
Total	4.45
Participating countries: Belgium, Germany, France, Italy, Spain, Taiwan, United Kingdom, United States of America	
Observatorio del Roque de los Muchachos (La Palma)	
2 solar telescopes	0.48
1 meridian circle	0.03
6 general-purpose telescopes	34.46
Multiple cosmic-ray detectors	
Total	34.96
(With the coming into service of the GTC this total will rise to 113.46 m^2.)	
Participating countries: Denmark, Finland, Germany, Holland, Ireland, Italy, Norway, Portugal, Russia, Spain, Sweden, United Kingdom	
Centro Astronómico Hispano-Aleman (Almeria)	
1 Schmidt camera	0.50
4 general-purpose telescopes	16.31
Total	16.81
Participating countries: Germany, Spain	
Observatorio de Sierra Nevada (Granada)	
2 general-purpose telescopes	2.40
Total:	2.40
Participating country: Spain	
Observatorio de Pico Veleta (Granada)	
1 radio telescope	706.50[a]
Total:	706.50
Participating countries: France, Germany, Spain	
Centro Astronómico de Yebes (Guadalajara)	
1 radio telescope	153.86[a]
1 astrograph	0.13
Total:	153.86
Participating country: Spain	

[a] The collecting area of a radio telescope is not comparable with that of an optical telescope.

In 1975 Spain's Ministry of Education and Science granted the IAC the facilities to pursue 'a national program for the training of researchers in astrophysics' that was to last for 4 yr and produced the first small group of PhDs in astrophysics. Since then, the IAC has run a postgraduate school that continues to generate an average of nine PhDs each year.

However, this educational undertaking is also shared by other astrophysics centers and university departments throughout Spain, bringing the mean annual total of new doctorates in astrophysics up to about 20.

Hence, today it may be said that Spain's main 'astronomical resource' is not only the telescopes installed in its territory but also its highly competitive workforce of young astrophysicists, who have already earned international recognition and prestige. In 1998 there were 462 astronomers in Spain, 305 of whom had doctorates (data provided by the Sociedad Española de Astronomía).

New administrative structures

The successful creation of centers adapted to confront new situations and conceived to derive the fullest benefit from international cooperation has undoubtedly been a decisive factor in the development of astrophysics in Spain.

In 1959, the National Ministry of Education set up the Observatorio del Teide in the Canaries. In 1972, the first chair in astrophysics was created at the University of La Laguna, which, in 1973, inaugurated the 'University Institute of Astrophysics'. Soon after, in 1975, the University of La Laguna, the National Research Council (*Consejo Superior de Investigaciones Científicas*, CSIC) and the Association of Local Governments (*Mancomunidad de Cabildos*) of the province of Santa Cruz de Tenerife (which includes the island of La Palma) jointly created the present Instituto de Astrofísica de Canarias (IAC). In 1982, this institute gained the legal status of a 'public consortium', made up of the State Administration, the Canarian Autonomous Community, the University of La Laguna and CSIC; the Observatorio del Teide (on Tenerife) and the OBSERVATORIO DEL ROQUE DE LOS MUCHACHOS (on La Palma) are in turn governed by the IAC.

In Andalusia, the Instituto de Astrofísica de Andalucía (IAA) was set up in 1975 by CSIC. The IAA had its first headquarters in Almeria and later in Granada. The creation of the IAA was the culmination of the combined efforts of the Cartuja Observatory and the University of Granada. In 1982, a chair and a department of astrophysics were created at the University of Granada. In its turn, the IAA built the Sierra Nevada Observatory in the 1990s.

CSIC also has astrophysicists in other institutes and at the Centre d'Estudis Avançats de Blanes (Catalonia); it also participates in other centers such as the Instituto de Astronomía y Geodesia of Madrid's Complutense University and the Instituto de Física of Cantabria University.

The Instituto Geográfico Nacional (which runs Madrid Observatory) created the Centro Astronómico de Yebes, an observing station at Calar Alto and, more recently, an astronomical center at Alcalá de Henares.

The Royal Institute and Naval Observatory (in San Fernando) participates in the Meridian Circle at the Roque de los Muchachos Observatory; in 1997, it became a key institution in astrometry when it set up its own meridian circle at El Leoncito (Argentina).

The Instituto de Técnica Aeroespacial (INTA) became involved in astrophysics in 1972 and, together with scientists at the *Consejo Nacional de Investigaciones Espaciales* (National Council of Space Research), created the Laboratorio de Astrofísica Espacial y Física Fundamental (LAEFF) in Villafranca de Castillo.

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

Other Spanish universities eventually followed suit and joined in the astronomical 'boom'. At the present time the following universities are, to a greater or lesser degree, active in astrophysics: Alicante, the Balearic Islands, Barcelona (Autonomous), Barcelona (Central), Barcelona (Polytechnic), Cantabria, Granada, La Laguna, Madrid (Autonomous), Madrid (Complutense), Murcia, the Basque Country, Santander, Santiago de Compostela, Seville, Tarragona, Valencia, Valladolid, Vigo and Saragossa.

Promoting public awareness of astronomy

Spain's new astronomy has been nurtured with a deep commitment towards fostering a public awareness of astronomical knowledge. Astrophysicists play a prominent role in the popularization of astronomy throughout the country, the IAC's participation in the events of the Seville 1992 *Exposición Universal* and the Science and Cosmos Museum (Tenerife) being clear examples of this commitment.

Interest in the universe around us is growing fast in Spain, especially among the young, a fact that is reflected in the frequent media coverage of astronomical topics. Astronomy is always mentioned in popular science magazines, some of these being exclusively devoted to astronomy.

However, perhaps the clearest evidence of social assimilation of astronomy is given by the burgeoning of active AMATEUR ASTRONOMICAL SOCIETIES. Here there has also been a boom, from a mere handful in the 1960s to the creation of organized amateur groups in nearly all the cities (indeed, there are several societies in some cities).

The construction of astronomical instrumentation

The first instruments built in Spain were simple, but little by little these have evolved in their complexity and refinement. Today, there are highly sophisticated Spanish-built focal-plane instruments mounted on some of the most advanced telescopes in the world.

Also outstanding in this regard are Spain's recent efforts in space-borne instrumentation. In 1995 ISO (Infrared Space Observatory) was launched by ESA and SOHO (Solar Heliospheric Observatory) by NASA; both observatories carried on board instruments built by Spanish industry led by the IAC. Later, the University of Valencia provided instrumentation for MINISAT (INTA). In the CASSINI and ROSETA missions the IAA led Spain's participation; in the very near future, the University of Valencia and LAEFF will play the leading role in the INTEGRAL satellite.

Instrumentation for the forthcoming ESA–NASA PLANCK and FIRST missions will be provided by groups of Spanish astrophysicists.

However, the culmination of all Spain's endeavors in the building of new astronomical instrumentation is the *Gran Telescopio Canarias* (GTC), with its latest-generation 10 m diameter segmented mirror, for which the segment blanks have already been ordered. There is now funding to complete the construction of the telescope and, consequently, the participation of other countries has now been limited to a maximum of 30%. The project is running to schedule and first light is expected for 2002, with the GTC entering into service in 2003.

Future prospects

Observation is, and will continue to be, a key element in the development of models and theories that aid our understanding of the universe. After the spectacular advances made in this century, astrophysics is now at the threshold of new enigmas, whose unraveling will require the use of large telescopes located in the best sites on the planet. Spain possesses one such site: the Observatorio del Roque de los Muchachos. For all these reasons, and for its direct impact on Spanish science, technology and industry, the IAC has spearheaded the initiative to build the *Gran Telesopio Canarias* (GTC) and will continue to commit itself to the large telescopes of the future.

The take-off of astronomical research in Spain has been greatly favored by access to advanced instrumentation. In order to consolidate these gains it will be necessary for Spain to bolster its theoretical element while at the same time reinforcing its observational capacity. It will also be necessary to dedicate manpower and means to opening and exploiting all windows of observation, both ground and space based.

The high human potential available to Spanish astronomy and the astronomical quality of its observatories and the inevitable growth of research and development investment in Spain together promise an extremely productive future in this science.

Special Astrophysical Observatory, Russia

The Special Astrophysical Observatory (SAO) of the Russian Academy of Sciences was organized in 1966 as a managing institution for operating the 6 m mirror optical reflector BTA (Bolshoj Azimuthal Telescope) and the 600 m aperture radio telescope RATAN-600. The observatory is located near the valley of Zelenchuk river (North Caucasus). The 6 m telescope site is at the altitude of 2100 m above sea level. In addition to the BTA telescope, a few smaller instruments of 0.6 to 1.0 m diameter are based at the site. Radio observations are made with the RATAN-600, situated on the southern outskirts of Zelenchukskaya village, about 20 km to the north from BTA. An administrative center, library, scientific laboratories and dwelling houses are located in Nizhnij Arkhys settlement, which is about halfway between the SAO main instruments.

Both telescopes were built in 1975, but regular observations started two years later. The observational time at the telescopes is scheduled by international allocation committees. Today SAO is the main Russian center for ground-based astronomical observations. About one-third of scientific programs at the telescopes are carried out in cooperation with European astronomers.

BTA was the world's largest telescope till the beginning of 1990s. First use of the alt-azimuth mounting for the giant telescope became an example for further large instrument projects. The radio telescope RATAN-600 was designed as an antenna with a changeable surface, allowing application of the method of aperture synthesis.

The activity of the observatory is supported by the Russian Academy of Sciences and the Ministry of Science and Technology. Staff of the Observatory numbers 480 people. There are two members of the Russian Academy, 14 ScD and 60 PhD among 114 SAO researchers. Research activity includes the space distribution of galaxies, active galactic nuclei and quasars, stellar atmospheres and magnetic fields, study of binary and multiple stars, relativistic objects, interstellar medium structure, and solar radio astronomy.

Special Relativity

The special theory of relativity (SR), developed by ALBERT EINSTEIN in 1905, represents a revolutionary change in the human conception of the nature of space and time. According to SR, space and time are not absolute but must be viewed as components of a single entity, SPACE-TIME. This idea has numerous important implications, both conceptual and practical.

SR provides a framework for formulating the laws of physics in the absence of gravitational fields. When gravity is included, the GENERAL THEORY OF RELATIVITY (also developed by Einstein) must be employed. Because gravity is a very weak force, SR is adequate for most problems.

A central role is played in SR by the *inertial frame*, defined as a frame of reference in which Newton's law of inertia holds: a body subject to no external forces moves with constant velocity. Whenever two such frames move rapidly relative to one another, SR departs markedly from Newtonian physics.

SR is based on two postulates:

(a) (principle of relativity) every law of nature has the same form in any two inertial frames;
(b) the speed of light in a vacuum, c, is the same in all inertial frames.

A principle of relativity had been proposed many years earlier by GALILEO, but was long believed to apply only to mechanical phenomena; Einstein's first postulate extends Galileo's principle to encompass *all* physical laws. The second postulate is contrary to intuition, which suggests that the measured speed of a light beam (like that of any moving body) should depend on the motion of the observer.

SR is by now supported by a vast body of experimental evidence. Some of its major implications are discussed in the following paragraphs.

Simultaneity. Observers in different frames will in general assign different times to a given event. Two events that are simultaneous in one frame of reference occur at different times according to observers in another frame.

Time dilation. A clock that is moving in a given frame runs slow when compared with clocks that are stationary in that frame. The ratio between recorded time intervals is $(1 - V^2/c^2)^{-1/2}$, where V is the velocity of the 'moving' clock.

Length contraction. A body is shorter when measured in a frame in which the body is moving than it is in its own rest frame. The ratio between the measured lengths is again given by the factor $(1 - V^2/c^2)^{-1/2}$. Only the dimension in the direction of motion is contracted.

Velocity transformation. Let $\boldsymbol{v}$ be the velocity of a body in frame S and $\boldsymbol{v}'$ be its velocity in frame S′, which moves at velocity $\boldsymbol{V}$ relative to S. Let $v_\parallel$ and $v_\perp$ be the components of $\boldsymbol{v}$ parallel to and perpendicular to the direction of $\boldsymbol{V}$. The components transform as follows:

$$v'_\parallel = \frac{v_\parallel - V}{1 - (v_\parallel V/c^2)} \tag{1a}$$

$$v'_\perp = \frac{v_\perp (1 - V^2/c^2)^{1/2}}{1 - (v_\parallel V/c^2)}. \tag{1b}$$

In pre-Einsteinian relativity, the corresponding relations are simply

$$v'_\parallel = v_\parallel - V, \tag{2a}$$

$$v'_\perp = v_\perp. \tag{2b}$$

Relativistic beaming. Consider a transformation in which V is close to c. Equations (1) imply that if $v_\parallel$ and $v_\perp$ are of the same order of magnitude, $v'_\perp$ is much smaller than $v'_\parallel$. It follows that if a source moving at almost the speed of light emits either particles or radiation more or less isotropically in its own rest frame, the radiation observed in the laboratory is highly concentrated in the direction of the source's velocity. (Equations (1) apply to radiation as well as to material particles.)

Relativistic Doppler effect. SR leads to a modification in the classical formula for the change in wavelength detected when the source of a light wave moves relative to the observer. The relativistic Doppler formula is

$$\frac{f}{f_0} = \frac{\lambda_0}{\lambda} = \left(\frac{1 \mp \beta}{1 \pm \beta}\right)^{1/2} \tag{3}$$

where λ and f are the observed wavelength and frequency and λ_0 and f_0 are the corresponding values when source and observer are at rest with respect to one another. The upper signs apply when source and observer are receding, the lower ones when they are approaching. (For oblique relative motion, a somewhat more complicated formula applies.)

Mass–energy relation. When a body's energy changes by an amount ΔE, its mass (inertia) changes by an amount $\Delta m = (\Delta E)/c^2$. A rest energy $E_0 = mc^2$ can be associated with a body of mass m.

Relativistic energy and momentum. Conservation of momentum holds in SR provided momentum is defined as $p = \gamma m v$, with

$$\gamma = (1 - v^2/c^2)^{-1/2}. \tag{4}$$

Relativistic kinetic energy is given by

$$K = (\gamma - 1)mc^2. \tag{5}$$

The total energy of a body with velocity v is $E = \gamma mc^2$. In the limit $v \ll c$, momentum and kinetic energy reduce to their Newtonian forms $p = mv$, $K = \frac{1}{2}mv^2$. Momentum and total energy satisfy the useful relation

$$E^2 = p^2c^2 + (mc^2)^2. \tag{6}$$

Newton's law of motion holds in the form $F = \mathrm{d}p/\mathrm{d}t$ (but not in the form $F = ma$).

Photons, electromagnetic waves and particles. Maxwell's equations of electromagnetism are consistent with the principle of relativity: they have the same form in all

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

inertial frames and can therefore be used to calculate the radiation emitted by an accelerated charge of any speed.

Photons (light quanta) can be incorporated into the theory provided their mass is taken to be zero. The energy–momentum relation for a photon is $E = pc$, consistent with equation (6) if $m = 0$.

Particles can be created and annihilated, subject to the appropriate conservation laws (energy, momentum, charge, lepton number, baryon number, etc). For example, an electron and a positron can annihilate into two or more photons. (One-photon annihilation is forbidden by conservation of momentum.)

The role of c as a limiting speed. If the relative velocity between two frames were greater than c, the second postulate could not be satisfied. According to equation (1), $v_\parallel = 0$ and $v_\perp = c$ implies $v'_\parallel = V$; if $V > c$, v' cannot equal c.

Equation (4) shows that as $v \to c$ the kinetic energy of a body approaches infinity. Hence a body of non-zero mass cannot be accelerated to speed c.

The velocity transformation implies that if $v < c$ and $V < c$, then $v' < c$. The hypothesis that c is a limiting speed is therefore consistent with the first postulate: if a body's speed is always less than c in one inertial frame, the same is true in all frames[1].

Relativity and causality. An intriguing consequence of SR is that the time order of spatially separated events can differ in two inertial frames. If that were true of events between which a cause-and-effect relation exists, observers in some frame would detect the effect before its cause. This logical catastrophe is avoided by the hypothesis that no signal can propagate faster than c. If event E_1 is the cause of E_2, a signal of some kind must travel between them. If the speed of the signal is bounded by c, the time interval between the events must be at least L/c, where L is their spatial separation. It can be shown that whenever that condition is satisfied, the time order of the events is absolute: the cause precedes the effect in every frame. A 'superluminal' signal could lead to violation of causality and would have other bizarre consequences.

Applications to astronomy and astrophysics

The presence in the cosmos of relativistic particles (i.e. of particles whose speed is very close to c) is confirmed by detecting either the particles themselves (in cosmic rays) or the radiation they emit. Most non-thermal sources of radiation are interpreted as being due to relativistic electrons.

[1] One can show also that if $v > c$ and $V < c$, then $v' > c$: a body moving faster than light in one frame moves faster than light in all frames. During the 1960s physicists investigated the possibility that faster-than-light particles, named tachyons, might exist. A consistent theory can be constructed if the tachyon's mass is assumed to be imaginary. A tachyon's energy then becomes infinite as its speed approaches c from above; hence it cannot be slowed below c. All experimental searches for evidence of tachyons proved unsuccessful, however.

Cosmic rays

Particles with energies as high as 10^{20} eV have been detected in COSMIC RAYS. The cosmic-ray flux has both a Galactic and an extra-Galactic component; except for those of the very highest energies; however, most cosmic rays are believed to originate within the Galaxy, probably from supernovas.

The characteristic signature of a high-energy cosmic ray is the *extensive air shower*. The primary particle emits a gamma-ray photon by bremsstrahlung in the electric field of an atom in the atmosphere. The photon subsequently creates an electron–positron pair, each member of which emits more photons. A cascade thus develops; in addition to electrons and photons the shower can contain muons, pions, neutrinos and other particles. Showers containing as many as 10^9 particles have been detected. They can extend over several square miles; because of relativistic beaming, however, most of the shower is confined to a small central core.

Synchrotron radiation

A charged particle in a magnetic field follows a helical path, with the field direction as axis. Being accelerated, the particle radiates. At low velocity the radiation is primarily at the gyrofrequency $\nu_0 = qB_\perp/2\pi\gamma mc$. At relativistic velocity, however, the emission is dominated by high harmonics of ν_0 and is effectively a continuum, peaked at the frequency $\nu_m \cong 0.45\gamma^3\nu_0 \cong 10^6\gamma^2 B_\perp$. (The numerical expression is for electrons, with B in gauss and frequency in Hz.) The radiation is emitted preferentially in the forward direction, within a cone of opening angle $1/\gamma$, and is strongly linearly polarized. The spectrum falls off exponentially for $\nu \gg \nu_m$. The radiated power varies as $E^2 B_\perp^2$.

Many acceleration mechanisms lead to a power-law distribution of electron energies, $N(E) \sim E^{-n}$. The synchrotron spectrum from such a source likewise follows a power law, $I_\nu \sim \nu^{-\alpha}$; the spectral index of the radiation, α, is related to the index of the electron energy spectrum by $\alpha = (n-1)/2$ and the degree of linear polarization is $\Pi = (n+1)/(n+7/3)$.

Power-law spectra, at frequencies from radio to x-rays and even gamma rays, are observed from a variety of Galactic and extra-Galactic sources and are generally interpreted as SYNCHROTRON RADIATION. Typical spectral indices range from about 0.2 to 1.5. In some sources the spectrum steepens in the optical and x-ray regions.

In the CRAB NEBULA, a supernova remnant, the magnetic field is estimated to be a few times 10^{-4} G. If the observed luminosity is synchrotron radiation, the energy contained in relativistic electrons is $\sim 10^{48}$ ergs, about 10^{-4} times the energy released in a typical supernova explosion. Electrons that emit in the x-ray band have energies about 10^{13} eV.

The radiative lifetime of a particle emitting synchrotron radiation varies as $E^{-1}B^{-2}$. For electrons emitting x-rays in the Crab, the lifetime is only about 20 years, much less than the age of the remnant; hence the electron

Dirac House, Temple Back, Bristol, BS1 6BE, UK

energy must be continuously replenished. The mechanism responsible for the replenishment was a puzzle until the discovery of the PULSAR (a rotating neutron star) within the nebula. The loss in kinetic energy associated with the observed decrease in the pulsar's rotational speed is enough to accelerate the electrons.

The pulsar's own radiation is also interpreted as being synchrotron radiation in a much higher magnetic field, estimated to be 10^6 G or more. Some high-energy electrons escape from the remnant entirely, accounting for at least part of the cosmic- ray electron flux.

Other sources of synchrotron radiation include radio galaxies and quasars, as well as the non-thermal radio emission from our own Galaxy. The presence of relativistic electrons indicates violent activity in a source.

Inverse Compton radiation

In the Compton effect, a photon scatters from a stationary electron and is slightly degraded in energy. If a photon collides with a relativistic electron, the process can be described as Compton scattering in the electron rest frame. When the collision is transformed to the laboratory frame, the photon's lab energy is multiplied by a factor of roughly γ^2.

The inverse Compton process is quite similar to synchrotron radiation. An electron's energy loss is proportional to γ^2 times the energy density of either the local photon field (inverse Compton) or the static magnetic field (synchrotron); in each case a power-law distribution of electron energies leads to a power-law spectrum of radiated energy, with the same relation between spectral indices.

The inverse Compton effect plays an important role in X-RAY and GAMMA-RAY ASTRONOMY. Relativistic electrons interact with photons in the microwave background as well as with optical photons in starlight. A 100 MeV gamma ray can be produced by a 4 GeV electron scattered off an optical photon or by a 150 GeV electron scattered off a photon from the microwave background.

The interaction with the microwave background is strong enough to exclude a metagalactic origin for high-energy cosmic-ray electrons: because of Compton losses an electron with energy $\sim 10^{11}$ eV cannot reach the solar system even from the nearest radio galaxy, at a distance $\sim$4 Mpc.

When a cloud of relativistic electrons emits synchrotron radiation, the electrons lose energy by Compton scattering off the synchrotron photons. This effect sets an upper limit on the possible intensity of synchrotron sources.

Cerenkov radiation

Although no material particle can travel faster than light *in vacuo*, the speed of light in a medium is only c/n, where n is the index of refraction of the medium. Hence a charged particle can exceed the speed of light in the medium. The particle then emits a characteristic radiation called Cerenkov radiation; it is analogous to the shock wave emitted by a body traveling faster than sound in a medium. Cerenkov radiation is emitted within a cone of opening angle $1/\gamma$; it is commonly used to detect high-energy particles.

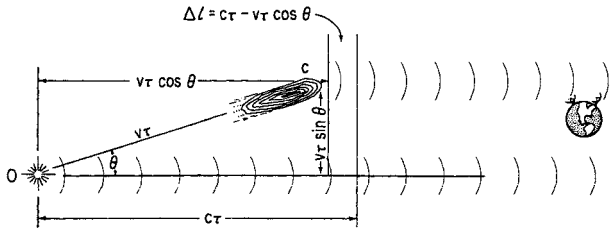

Figure 1. Model for superluminal emission.

Limitation on source dimensions

If a cosmic source exhibits substantial variation in intensity over a time T, one can argue from causality that its dimensions cannot be much greater than cT. This argument has been used to infer upper limits on the sizes of QUASARS and other active regions, whose intensity has been observed to vary over months or even less. Care must be taken in making such arguments, however.

Superluminal effects

In recent years an interesting phenomenon has been observed in several extra-Galactic compact RADIO SOURCES: material appears to be ejected from a central core at a speed that exceeds c, sometimes by a factor as high as 10. If matter were actually moving that fast, SR would be violated. What one observes, of course, is the angular separation between the ejected material and the core; if one determines the distance of the source from its red shift (assumed to be cosmological), the inferred transverse velocity exceeds c.

The commonly accepted explanation of the effect is shown in figure 1. If a source of radiation moves at a small angle θ to our line of sight, at speed v close to c, the source nearly keeps up with its own radiation. The sketch shows two pulses of radiation emitted at times separated by an interval T. When it emitted the second pulse, the source was closer to us by $vT\cos\theta$. The interval between arrivals of the two pulses is therefore $T[1-(v/c)\cos\theta]$. The transverse displacement of the source during the interval between the two emissions is $vT\sin\theta$; hence its apparent transverse velocity is

$$v_{\rm app} = v\sin\theta/[1-(v/c)\cos\theta]. \qquad (7)$$

The maximum of this function, for $\theta = \sin^{-1}(1/\gamma)$, is $v_{\rm app} = \gamma v$, which is arbitrarily large.

Although the *a priori* probability that a source moves nearly in the direction of our line of sight is small, the relativistic beaming effect, described above, increases the probability that such a source will be detected.

Speckle Imaging of Binary Stars

In addition to their ability to detect faint and distant objects in the universe, large telescopes can, in principle, resolve fine detail in celestial objects. The theoretical limit of resolution for a telescope is linearly related to the APERTURE (or diameter of the primary light-collecting mirror or lens of the telescope) and by the wavelength at which an observation is made (see RESOLVING POWER). Hence larger apertures and shorter wavelengths enhance resolution. Unfortunately, for telescopes beyond 10–20 cm apertures, atmospheric turbulence thwarts the attainment of the full diffraction-limited performance otherwise permitted by theory. This turbulence reveals itself in the form of 'twinkling' of starlight to the unaided eye. However, when a star is observed through a telescope of modest or larger aperture, one sees a boiling distribution of intensities which spread the starlight out in a blurred and distorted 'seeing disk' typically 1 arcsec in angular extent, many times larger than would otherwise by the case.

In 1970, the French astronomer Antoine Labeyrie announced an elegant new technique for analyzing these so-called 'speckle' images from large telescopes to extract information about the structure of the object being observed on scales down to the theoretical limit. Labeyrie's method of 'speckle interferometry', which was diversified by Labeyrie and others to become more generally known as 'speckle imaging', involved the analysis of snapshot exposures (approximately 0.01 s in duration) of stars taken at high magnification and relatively narrow spectral bandwidths using power spectrum or autocorrelation methods (see also CORRELATION FUNCTION AND POWER SPECTRA IN COSMOLOGY). The observing requirements limit the method to relatively bright objects in most cases.

While speckle imaging has been applied to a variety of objects at visible and infrared wavelengths, the greatest successes of the technique have been in the field of binary star studies. Binary stars are pairs of stars gravitationally bound in mutual orbits (see BINARY STARS: OVERVIEW). The majority of the stars exist not as single objects like the Sun but in binary or higher-order gravitational systems. The measurement of the orbital period of a binary system and the linear size of the orbit provides a direct determination of the mass of the components of the binary. This is the only observational means available to astronomers for measuring the masses of stars, and much of our understanding of how stars form, evolve and die is ultimately tied to how well we know the masses of stars. Unfortunately, although some 100 000 binary star systems have been discovered, most have long orbital periods, and hence their orbits are poorly known.

The enhanced resolution of speckle imaging, when carried out at telescopes with apertures larger than 2 m or so, allows the resolution of binaries that otherwise appear as single stars when observed through the turbulent atmosphere. Classical methods for resolving binaries utilize the human eye and have led to the discovery of pairs

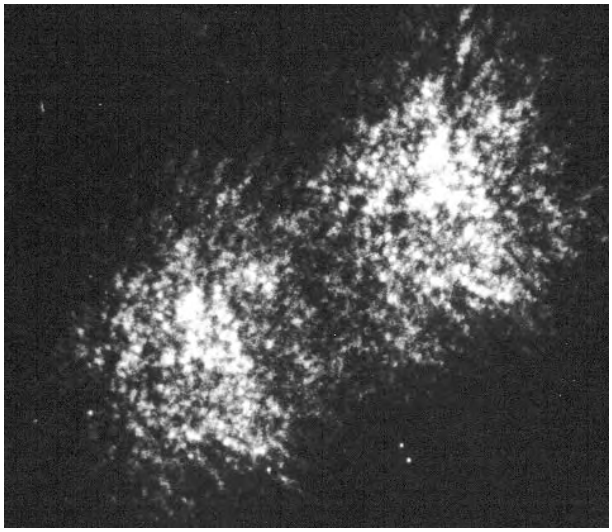

Figure 1. The double star 57 Cancri, with an angular separation of 1.5 arcseconds, is shown here. Note the similarity between the speckle patterns of the two stars in this speckle image taken with the 4 m telescope on Kitt Peak, Arizona.

with angular spacings on the sky as small as 0.15 arcsec. Speckle imaging extends this down to 0.03 arcsec, or even smaller when one of the few existing telescopes larger than 4 m is utilized. This increase in resolution coupled with the much higher measurement accuracy of speckle imaging very significantly improves the quality of binary star orbit determinations. Furthermore, where classical methods tended to select binaries with orbital periods of decades or centuries, speckle imaging can resolve systems with periods of years or decades, permitting the determination of the orbit within a reasonable timescale. More than 20 000 measurements of several thousand binary stars have resulted from speckle imaging, including the discovery of several hundred bright binary systems.

Speckle imaging of binary stars has now made obsolete the visual study of these systems. The most active center for speckle imaging at present is the US NAVAL OBSERVATORY in Washington, DC, which also serves as a clearing house and archive for all types of measurements for resolved binary star systems.

While speckle imaging techniques are applicable to single telescopes, related 'interferometric' methods employing two or more telescopes separated by baselines up to hundreds of meters in length permit the resolution of binaries much closer than those accessible to speckle imaging (see INTERFEROMETRY: GROUND). Several interferometric arrays of telescopes are operational and others are coming on line. The current generation of such instruments will resolve systems with angular spacings as small as 0.0001 arcsec, corresponding to orbital periods on the time scales of hours and days. As with speckle imaging at single telescopes, these telescope arrays must also cope with atmospheric turbulence, but interferometric arrays promise a very substantial contribution to the imaging of binary

Spectrographs: Fiber-fed Spectrographs

Fiber-fed spectrographs exploit the unique properties of optical fibers to increase the performance of astronomical instruments. The most important applications are in multi-object spectrographs which enable simultaneous observations of many astronomical targets, as image reformatters for area spectroscopy, and as a means to feed high-stability bench-mounted spectrographs.

Optical fibers are cylindrical glass light guides of small diameter (typically 10–300 μm). The most common type used in ASTRONOMICAL SPECTROSCOPY are known as multi-mode step-index fibers which rely on total internal reflection at the boundary between the fiber core and a lower refractive index cladding. The critical angle $\theta_{\rm crit}$ for total internal reflection defines the *numerical aperture* (NA) of the fiber which depends on the refractive indices of the core and cladding as $\mathrm{NA} = \sin\theta_{\rm crit} = \sqrt{n_{\rm core}^2 - n_{\rm cladding}^2}$. Commercially available fibers have numerical apertures typically in the range 0.15–0.35 which imply a minimum input focal ratio $F_{\rm min} \approx \sqrt{1-\mathrm{NA}}/2\,\mathrm{NA}$ for light to be efficiently transmitted. Silica glass fibers have excellent transmission in the optical (0.4–2.0 μm) range and lengths of several tens of metres can be employed without significant internal absoption. In the ultraviolet these losses increase rapidly (as λ^{-4}) due to Rayleigh scattering by density and composition variations within the fiber. At longer wavelengths the transmission of silica drops dramatically due to hydroxyl ion absoption, but heavy-metal fluoride (e.g. zirconium fluoride) and chalcogenide glasses with improved infrared transmission are now becoming available.

An important property of optical fibers for the design of astronomical spectrographs is the decrease in FOCAL RATIO of the transmitted beam known as *focal ratio degradation* (FRD). The degree of FRD depends on several factors, the most important of which is internal stresses within the fiber. The relative change in focal ratio is proportional to the input focal ratio F, so that optical fibers work best with fast (small F-ratio) beams (so long as $F > F_{\rm min}$).

Multi-object fiber spectrographs

One of the most successful applications of optical fibers in astronomy has been the development of multi-object spectrographs which can obtain the spectra of many objects simultaneously. Single optical fibers are positioned in the telescope focal plane so that each acquires the light from a separate target object. On passing through the optical fiber, any spatial information about the target is largely scrambled (at least azimuthally) so entrance diameters of 1–2 arcseconds are usually chosen to match the mean angular sizes of the objects of interest (limited by the SEEING for point sources). The output ends of the fibers are aligned to form a long slit which then feeds a conventional dispersive spectrograph.

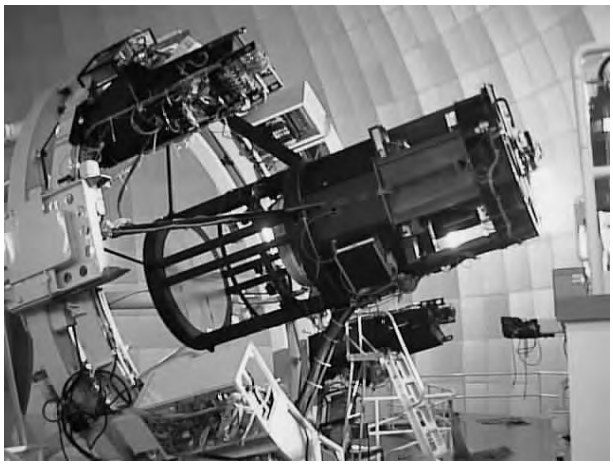

Figure 1. The 2dF multi-fiber spectrograph can deploy up to 400 optical fibers across a 2 degree diameter field at the prime focus of the 3.9 m Anglo-Australian Telescope. At the core of the instrument, seen here at the top of the telescope tube, is an advanced robotic positioner capable of repositioning an individual fiber to an accuracy of a few μm in < 10 seconds. To maximise efficiency, two sets of 400 fibers are available so that observations can continue using one of them whilst the second is being reconfigured. Changeover between fields takes only a few minutes. The fibers feed two spectrographs which are equipped with CCD detectors and are also mounted on the top of the telescope. ©Anglo-Australian Observatory

Most of the engineering difficulties are associated with accurately positioning the fibers in the focal plane (typical requirements being 20 μm accuracy across a 200 mm diameter field). The first multi-object fiber-fed spectrographs, developed in the late 1970s, used a manual plug-board approach but these have now mostly been replaced by automated robotic positioning mechanisms. The latter fall into two main classes: (i) multiple positioner devices where individual fiber probes are actively controlled using stepper motors; (ii) single positioner devices where the fiber probes are moved sequentially by a single pick-and-place robot and held in position passively (usually by a permanent magnet on the base of the probe). The first method allows very rapid ($<$ 1 minute) reconfiguration of the field but is limited in multiplex capability by the size of the active control mechanisms (typically to 20–50 fibers). Using the second approach, multi-object fiber-fed spectrographs have been constructed (see figure 1) which can obtain spectra for several hundred astronomical targets simultaneously, at the cost of some limitations in reconfiguration time.

The tremendous gains in observing efficiency, when a sufficient density of targets is available, have ensured that multi-object fiber-fed spectrographs have been developed for most of the world's major observatories. Currently around 30 systems have either been built or are in the design phase. Calibration observations which monitor individual fiber throughputs are required when using these systems to observe faint targets. Unlike multi-slit spec-

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

trographs (see SPECTROGRAPHS: MULTISLIT SPECTROGRAPHS), the sky-background signal cannot be sampled contiguously with the object. The sky spectrum is therefore usually derived from separate fiber probes which may take very different optical paths through the spectrograph making sky-subtraction difficult. However, close to Poisson-noise limited spectra have been demonstrated by 'beam-switching' of objects between close pairs of fibers.

Integral-field fiber spectrographs

Fiber-fed integral-field spectroscopy is a means to obtain area spectroscopy of extended targets using optical fibers to dissect the image. The simplest systems use dense packs of bare fibers at the input, but the efficiency is limited (typically to $\leq$ 60%) by the packing fraction achievable with a given core/cladding ratio. The most effective method is to use a high fill-factor hexagonal or square microlens array to couple the input light into a matrix of individual fibers. These input optics can simultaneously condition the input focal ratio to an optimum value (F/3–F/5) for propagation down the fiber with minimal FRD. The spatial coverage and spectral resolution of such instruments are largely determined by detector size, with devices containing 1000+ spatial elements now becoming available. Their advantages relative to other forms of imaging spectrographs (e.g. Fourier transform, Fabry-Perot) are the relatively wide spectral coverage, fixed format on the detector, and the efficient use of detector pixels.

High-stability fiber spectrographs

The use of flexible fibers as optical feeds from the telescope focal plane to the spectrograph presents the opportunity to remove the spectrograph from the telescope entirely and mount it on a stationary platform. Although limiting the throughput at ultraviolet wavelengths, the advantages of doing so are increased stability (and decreased cost) due to the stable gravity vector, and the absence of flexure during telescope motion. In addition, the image scrambling properties of optical fibers can be used to advantage to remove the wavelength errors associated with focal plane image motion (from seeing or telescope guiding errors). Although the radial scrambling of light in an optical fiber is incomplete, particularly at fast F-ratios, the azimuthal scrambling leads to an order of magnitude improvement in centroid stability compared to that of a conventional slit spectrograph. Because they are sited off the telescope, fiber-fed high-stability spectrographs can also be kept in a controlled environment to minimize thermal effects. Using these techniques, wavelength precisions of 1 part in 10^6 are achievable, comparable to that required to detect Jupiter-size planets around solar-type stars via their reflex Doppler motions (see also EXOPLANETS).

Conclusions

Over the past two decades, optical fibers have made a major impact on the design and use of astronomical spectrographs. With the continuing development of new types of optical fiber with improved performance, for the telecommunications and fiber sensor markets, it appears likely that this trend will continue for the forseeable future. Extending their range of operation into the thermal infrared using cooled fibers, and combining the advantages of integral field spectroscopy with the efficiency gains of multi-object spectroscopy via deployable mini-integral field units (see SPECTROGRAPHS: INTERNAL FIELD UNITS), are areas currently under active study.

Spectrographs: High-Resolution Spectrographs

Definitions

A **spectrum** (plural: spectra) is the wavelength or frequency distribution of radiation emitted by any radiant source. Visually, it is the familiar band of colors seen through a prism or in a rainbow. When the spectrum is observed by eye the instrument used is a '**spectro*scope***'. If recorded on a photographic emulsion, the instrument is a '**spectro*graph***'. When the photometric precision is high the process is called '**spectro*metry***' and the instrument is a '**spectro*meter***' or '**spectro*photometer***'. The term '*spectrograph*' has been extended to mean any instrument that uses any image detector to record the spectrum.

Spectral **resolving power** or **resolution** is the power of a spectrograph to distinguish between adjacent spectral features, or lines. Numerically, it is the ratio of the wavelength of a spectral line, λ, and the separation $d\lambda$ between two just-resolved lines:

$$R = \frac{\lambda}{d\lambda}.$$

In this article we will deal with the history, design principles, and implementation of *high-resolution astronomical spectrographs*.

The role of spectroscopy in astronomy

Radiation from astronomical sources spans the full spectrum from low-energy long-wave radio emissions to highly energetic hard x- and gamma-rays. Only a narrow band of wavelengths visible to the human eye was accessible to astronomers of the 18th and earlier centuries. With the invention of photography in 1839 and its application to astronomy in 1840 we could detect light into the near ultraviolet and the near infrared. The discovery of radio waves from space, by Karl Jansky in 1933 at Bell Laboratories, revealed the existence of very-long-wavelength radiation from astronomical sources. The far ultraviolet blocked by the Earth's atmosphere was first detected by high-altitude balloon and rocket experiments. Ultraviolet light and x-rays originating in far distant sources are now routinely observed from space-borne telescopes.

Throughout most of history, objects seen in the night sky could only be understood in terms of human interpretation of their visual appearance and motions. With the invention of spectroscopy the physical nature of the stars became a subject of legitimate investigation—thus the term 'astrophysics'. It became possible to determine not only the chemical composition of the stars, but their atmospheric temperatures and pressures as well as their velocities through space and orbital motions about previously unseen companion stars, from which we could measure their masses. The spectrograph could distinguish between spectral features due to separate stars in otherwise unresolved multiple-star systems. The large spectrographic survey known as the *Henry Draper Catalog* revealed that hydrogen—not iron—is the dominant chemical element in the universe. Spectroscopy permitted, for the first time, an unambiguous distinction between the two primary types of *nebulae* (Latin: clouds)—those that are composed primarily of rarefied gases such as the great nebula M42 in Orion, and unresolved stellar systems such as the Andromeda galaxy M31. This gave science its first unequivocal proof that a universe filled with galaxies extends far beyond the borders of our home Milky Way Galaxy. That view was further reinforced by Edwin Hubble and Milton Humason, in 1929–1930, when they discovered the expansion of the universe through spectroscopy of extra-Galactic nebulae.

The next step in understanding the nature of the universe has taken place in the last third of the 20th century, through high-resolution spectrographic revelation of the fine details of spectral lines. Its most recent and famous application has been the detection and measurement of the minute changes in the motions of nearby stars indicating that unseen planets are in orbit about them. High-resolution spectrography is critical to studies of the abundances of specific isotopes of the chemical elements, from which much is being learned of the evolution of the chemical elements in stellar interiors.

History of astronomical spectroscopy

Sir Isaac Newton (1643–1727) founded the science of spectroscopy in about 1665 with his investigations of the nature of light, published in 1704. A century later, in 1802, chemist William Wollaston discovered dark lines crossing the spectrum of the Sun; he thought that these were gaps separating the colors. JOSEPH FRAUNHOFER disputed this assumption when he observed, in 1814–1815, that the solar spectrum is marked with large numbers of dark lines *superimposed on an otherwise continuous gradation* of color. He saw some 600 lines and cataloged the positions of 324 of them (see FRAUNHOFER LINES). He designated the more prominent lines by letters of the alphabet and some of these designations are still in use. In 1859 GUSTAV KIRCHHOFF demonstrated that the dark lines are due to absorption of light of certain wavelengths in an overlying atmosphere of the Sun and he stated his three laws of spectral analysis.

(1) *A luminous solid or liquid emits light as a continuous spectrum.*
(2) *A rarified luminous gas emits a bright-line spectrum.*
(3) *Certain wavelengths are absorbed from the light of a source of a continuous spectrum when passed through a rarified gas, resulting in a dark-line or absorption spectrum.*

An important characteristic of any rarified gas is that its *dark* lines due to law (3) correspond in wavelength to its *bright* lines due to law (2). For the first time in history, science began to realize the possibility of identifying the chemical elements in the Sun, through spectroscopy.

Kirchhoff's work marked the *origin of the science of astrophysics*. In the 1860s he and Robert Bunsen first demonstrated that the chemical elements in the *Sun* are

the *same as those found on Earth*. By 1864 British astronomer SIR WILLIAM HUGGINS identified spectral lines in the *stars* with those of known chemical elements found on Earth, and he discovered that some nebulae have pure emission spectra and must therefore be gaseous. This series of events heralded an understanding of the commonality of the chemical nature of stars everywhere in the universe. Huggins had attempted photographing the spectrum of the bright star Vega, in 1863, but he was unable to photograph the Fraunhofer absorption lines. It was left to HENRY DRAPER (1837–1882) to obtain the first successful stellar spectrograms.

Draper's father, American scientist John W Draper, was among the first to experiment with photography and in 1840 obtained the first photographs of the Moon showing the lunar 'seas', on Daguerreotype plates. He successfully photographed the solar spectrum with a prism spectroscope. Being dissatisfied with the wavelength scale of the Fraunhofer lines, he had a *diffraction grating* ruled on a tiny speculum metal mirror and succeeded in obtaining useful solar spectrograms[1].

Draper encouraged his son Henry to continue these investigations, and in 1858 Henry began construction of an observatory complete with a 71 cm reflecting telescope with silvered glass mirror. He abandoned speculum metal on the advice of Sir John Herschel. On 1 August 1872, Henry Draper obtained the first photographic spectrum of a star—Vega—complete with Fraunhofer lines. Following the death of Henry Draper at age 45, in 1882, his wife and scientific collaborator Anna carried a number of his stellar spectra to Harvard College Observatory, where director Edward Pickering had offered to reduce the plates. This led to a scientific collaboration that eventually resulted in the *Henry Draper Catalog of Stellar Spectra*, which together with the *Henry Draper Extension* cataloged the spectra of over 350 000 stars. This was one of the most important contributions to the science of astrophysics in modern times. Among other discoveries resulting from the *Henry Draper Catalog*, Miss Cecilia Payne in her PhD thesis research (1921–1924) recognized that the strengths of the spectral lines indicated an abundance of hydrogen in stellar atmospheres that was a million times greater than that of the metals, in particular iron. This discovery forever exploded the contemporary belief that iron was the most abundant element in the universe.

In the meantime German astronomer HERMANN VOGEL (1841–1907) was experimenting with photographic spectroscopy at the Potsdam Astrophysical Observatory, where he was director. He was the first to observe radial velocities of stars with sufficient precision to discover spectroscopic binary stars, and with Julius Scheiner he was the first to accomplish the spectroscopic determination of stellar diameters and masses. They proved in 1889, through its radial velocity changes, that the variable star Algol is an eclipsing binary.

A common problem in early photographic spectrography was the difficulty of obtaining reliable exposures. This was blamed on degradation of the quality of the emulsion on the wet collodion plates during long-time exposures and on instability of the image on the plate due to flexure of the instrument. The stability question was solved when Walter S Adams built large stationary prism spectrographs at the *coudé* (French: elbow) foci of the Mt Wilson 1.5 m (1911) and 2.5 m (1925) telescopes. The spectrographs were mounted solidly on the concrete structure of the coudé room, where it became practical not only to use very long focal lengths but also to support large lenses and prisms free of flexure. At the 2.5 m telescope a series of increasingly improved spectrographs culminated in 1934 in the coudé spectrograph of Theodore Dunham, using large diffraction gratings. His was the first use of the Schmidt camera to photograph the very wide angular extent of high-dispersion spectra.

In the meantime work had been proceeding on the art of making finely ruled diffraction gratings. In 1785 Rittenhouse had experimented with a diffraction grating made with 53 *slits* in a width of 1.2 cm. Fraunhofer had ruled a grating with 4000 grooves on a 1.2 cm mirror as early as 1823 and in 1846 Nobert generated a grating of 6000 grooves over a width of 2.5 cm. Lord Rayleigh used Nobert's gratings in his experiments on the physics of light. By 1870 L M Rutherford had made a grating with 35 000 grooves over a width of 5 cm. This was the first diffraction grating to actually equal the resolution of the available glass prisms.

About 1882 Henry A Rowland, at Johns Hopkins University, built ruling engines with which he made 15 cm gratings having more than 100 000 grooves and resolving power exceeding 150 000. This earned him the distinction of 'father of the modern diffraction grating'. Additional ruling laboratories were set up at Mt Wilson Observatory and at the University of Chicago, where gratings were made with up to 15 cm ruled width, giving resolving power up to 350 000. These three laboratories produced the world's supply of large gratings through the 1930s. Michelson's engine at Chicago made one grating of width 24 cm with resolving power 600 000.

Early reflection gratings were ruled in speculum metal, an alloy of tin and copper, with a diamond tool. Speculum metal had been widely used for telescope mirrors (e.g. by Sir William Herschel). It is brittle and somewhat granular and the diamond tools tended to wear out during the ruling, limiting the size of grating that could be made. In 1933 John Strong, at Johns Hopkins University, introduced vacuum deposition of aluminum on glass. This made a soft, smooth surface on which larger gratings could be ruled, enabled by much longer diamond life, and it made for brighter reflection and lower scattered light.

A major loss of efficiency in gratings is due to diffraction of light into multiple orders of interference. Wood, Babcock and others experimented with methods

[1] A diffraction grating is a reflective or refractive surface on which is ruled a multitude of parallel, closely spaced grooves which break up the reflected or refracted light into separate wavelets. Through mutual interference, the directions of propagation of the transmitted rays are redistributed according to their wavelengths.

of controlling these losses. In 1944 they succeeded in controlling *groove shape* by shaping the diamond ruling tool. This allowed directing as much as 60% of the light into a selected spectral order. The term 'blazed gratings' was coined by George R Harrison to describe this effect. By 1949 Harrison was ruling the first gratings working in very high spectral orders and optimized at very large 'blaze angles', a type of diffraction grating he named an '*echelle*'. Typical echelle blaze angles are 60° and greater. He built the MIT B and C ruling engines and, with interferometric control of the screw used to define the groove spacing, these have become the standards of excellence for gratings up to 30 cm ruled width and echelles up to 40 cm. The B engine is now at the Richardson Grating Laboratory of Spectronic Instruments, Inc, and the C is at the National Optical Astronomy Observatories (NOAO).

Theory of high-resolution spectrography

Definition of high resolution

For the purposes of astrophysical research, resolving power is considered 'high' if all the detail in the spectral lines can be distinguished. This can be achieved if the resolution of the spectrograph is somewhat sharper than the widths of the narrowest lines in the source spectrum:

$$R_{\text{spectrograph}} \equiv \frac{\lambda}{\mathrm{d}\lambda} \geq \frac{c}{V}$$

where c is the speed of light (300 000 km s^{-1}) and V is the combined thermal and microturbulence velocity of the atoms constituting the star's atmosphere. For the vast majority of stars, the range of thermal velocities is between 3 and 15 km s^{-1} with microturbulence lying between 1 and 7 km s^{-1}, so that *high* resolving power ranges from 20 000 to 120 000. For cool planetary atmospheres and cold interstellar medium, resolving power of 500 000 to 1 000 000 has been found useful.

Principles of high-resolution grating spectrograph design

There are many excellent optical texts describing diffraction of light by parallel slits. From these we derive the *grating equation*; the parameters are illustrated in figure 1. Light of wavelength λ is diffracted from a reflection grating with d^{-1} grooves mm^{-1} in accordance with

$$\lambda = \frac{d}{m}(\sin\alpha + \sin\beta)\cos\gamma \qquad (1)$$

in which m is an integer $(0, \pm1, \pm2, \ldots)$ giving the *order of interference* and α and β are angles of incidence and dispersion relative to the normal to the grating's ruled surface[2]. The angle γ is the orthogonal component of the angle of incidence and is usually near zero; we will neglect γ in what follows. The *reciprocal angular dispersion* is the derivative of equation (1):

$$\frac{\mathrm{d}\lambda}{\mathrm{d}\beta} = \frac{d}{m}\cos\beta \ (\text{Å rad}^{-1}) \qquad (2)$$

[2] In the sign convention used for these equations, the angles α and β both have the same numerical sign if both incident and dispersed rays lie on the same side of the normal.

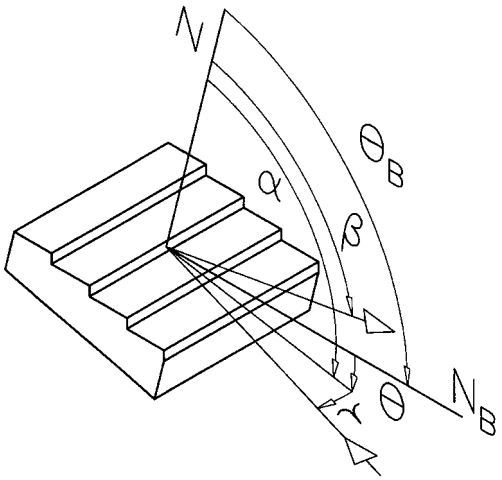

Figure 1. Segment of an echelle grating with blaze angle θ_B, the tilt of the active side of the grooves. Parameters used in the text (equations (1)–(4)) are
- angle of incidence of the rays (the arrow pointing *toward* the echelle), α,
- orthogonal component of the angle of incidence, γ,
- angle of dispersion of the rays (arrow pointing *away*), β,
- distance between the adjacent grooves, d.

since α is normally constant. The reciprocal *linear* dispersion is

$$\frac{\mathrm{d}\lambda}{\mathrm{d}x} = \frac{d}{mF}\cos\beta \ (\text{Å mm}^{-1})$$

where F is the focal length of the spectrograph camera in millimeters and d is the spacing between grooves in Å (1 Å $= 10^{-10}$ m). In most gratings, d is comparable with or somewhat greater than the wavelength of the light; in echelles it can be greater than the wavelength by factors of order 30–100.

A more illuminating relation results if we divide the dispersion equation (2) by the grating equation (1), eliminating m and d:

$$\frac{\mathrm{d}\lambda}{\mathrm{d}\beta} = \frac{\lambda\cos\beta}{\sin\alpha + \sin\beta}. \qquad (3)$$

This equation shows that dispersion by a grating at wavelength λ is a function only of the angles α and β. The spectral order m and the groove width d have been eliminated. Particularly for an echelle grating, m and d are freely selectable to meet any desired geometry in the spectrograph design.

We can rewrite equation (3) to obtain the spectral resolving power:

$$R \equiv \frac{\lambda}{\mathrm{d}\lambda} = \frac{\sin\alpha + \sin\beta}{\cos\beta\,\mathrm{d}\beta}.$$

The image at the detector is the *monochromatic* image of the spectrograph slit, of angular width $\mathrm{d}\beta$. This can be

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

expressed in seconds of arc on the *sky* if we incorporate the telescope and spectrograph apertures:

$$R\varphi = \frac{\sin\alpha + \sin\beta}{\cos\beta}\frac{D_{\rm C}}{D_{\rm T}} \times 206\,265. \qquad (4)$$

This is the *throughput equation* for a grating spectrograph. Here, φ is the width of the object in the sky or of the spectrograph entrance slit, in seconds of arc. The constant 206 265 is the conversion factor from radians to seconds of arc; $D_{\rm C}$ and $D_{\rm T}$ are the apertures of the collimated beam and of the telescope. The equation is general and serves for any grating spectrograph. The throughput equation is the critical relationship for the design of any spectrograph in which the resolving power is controlled by the size of the stellar image due to seeing or to the width of the entrance slit, whichever is smaller. The product $R\varphi$ is a useful figure of merit for any spectrograph. Typically, if we select $R = 60\,000$ as the required resolving power then it is useful to design so that $R\varphi = 60\,000''$. In this case the slit is $1''$ wide, letting through most of the stellar image under typical atmospheric conditions. The main parameters of the spectrograph, the size and blaze angle of the grating, are completely determined by equation (4). The remaining tasks are selection of the number of grooves $\rm mm^{-1}$, which controls the free spectral range between adjacent orders, and the focal length of the camera. This should match the image of the spectra to the size of the CCD and the spectral resolution to the pixel spacing on the image detector.

The modern era

New detectors for spectrography

From its first use in stellar spectrography in 1872 until 1974, the dominant detector was the photographic plate. However, with a maximum detective quantum efficiency of only 4%, *96% of all photons that managed to reach the photographic emulsion failed to darken a grain of silver*. Furthermore, in high-resolution spectrography the light of the star image is spread over a large number of pixels, greatly diluting the total photon count per pixel. As a consequence, high-resolution photographic spectrography was limited to long exposures on relatively bright objects, and the use of large telescopes for high-resolution spectrography experienced a lull during the 1960s. At the same time renewed interest in extra-Galactic research fueled by the newly discovered QUASARS and PULSARS took up much of the large telescope time.

A renaissance in high-resolution spectrography began with the completion of the McDonald Observatory's Harlan J Smith 2.7 m telescope and coudé spectrograph in March 1969. These instruments were funded primarily for ground-based support of NASA's planetary research programs. A computer-controlled photoelectric spectrum scanner was added in May 1969 and a high-resolution echelle in 1971. These were applied to research on atmospheres of the planets and stars. With the echelle in double pass, resolving power of 600 000 was achieved in studies of the extremely narrow lines in stellar spectra due to the intervening interstellar medium. With a Data General Nova™ computer in place, the time was ripe for the first application of solid-state image detectors to astronomical spectrography, in 1973. The first device was a Reticon™ linear array of 256 pixels on a silicon integrated circuit chip. These devices have peak quantum efficiencies of about 70%, greatly exceeding those of photographic plates. A low-resolution spectrograph was built (see SPECTROGRAPHS: LOW-RESOLUTION SPECTROGRAPHS), and spectrographic and imaging observations were made with the Reticon on the 0.9 m and 2.1 m telescopes. Development of an intensified Reticon array, which worked by photoelectron bombardment of the silicon chip, followed. This was an image amplification technique to overcome the high read-noise level characteristic of Reticon arrays. The first successful device was put into routine operation in high-resolution spectrography at the 2.7 m coudé spectrograph in 1974. This device had a single linear array of 1024 pixels. The intensified Reticon was dubbed the self-scanned Digicon, following Edward Beaver's pioneering work at San Diego on the parallel-readout Digicon later used on the Goddard High-Resolution Spectrograph (GHRS) on the Hubble Space Telescope. Self-scanned digicons remained in service at McDonald Observatory until 1988. In 1976 a bare Reticon array was put into operation alongside the self-scanned digicon, advantage being taken of the high quantum efficiency of the silicon integrated circuit chip. It exhibited a particularly great advantage in the near infrared, where photoemissive devices have poor sensitivity. The Reticon array became the most widely utilized image detector in high-resolution spectrography at McDonald Observatory until CCDs phased it out in 1992. The Reticon was adopted at many observatories worldwide during the decade immediately preceding application of the first fully successful CCDs.

In the mid-20th century, a wide variety of electronic devices capable of single-photon image detection came under development, largely to meet the needs of astronomical research from space-based telescopes. These included TV cameras, image tubes with photographic output, and a variety of techniques for direct readout of amplified photoelectronic images. Parallel development efforts led, in the 1980s, to availability of high-quality 'science grade' CCDs of large area and high resolution. These activities have led to the nearly complete replacement of the photographic plate in astronomy. In parallel with all this, a renaissance of ground-based telescope construction began in the early 1980s when a series of conferences sponsored by ESO, NOAO and SPIE pointed the way to the 1990s construction boom in telescopes with apertures up to 10 m. *All* of these have included high-resolution spectrographs as part of their initial suite of instrumentation. This has led directly to the first-ever confirmed discoveries of planets outside the solar system—some 29 now known through their gravitational tugs on their parent stars, detected through high-resolution spectrography and precision stellar radial velocities (see EXOPLANETS).

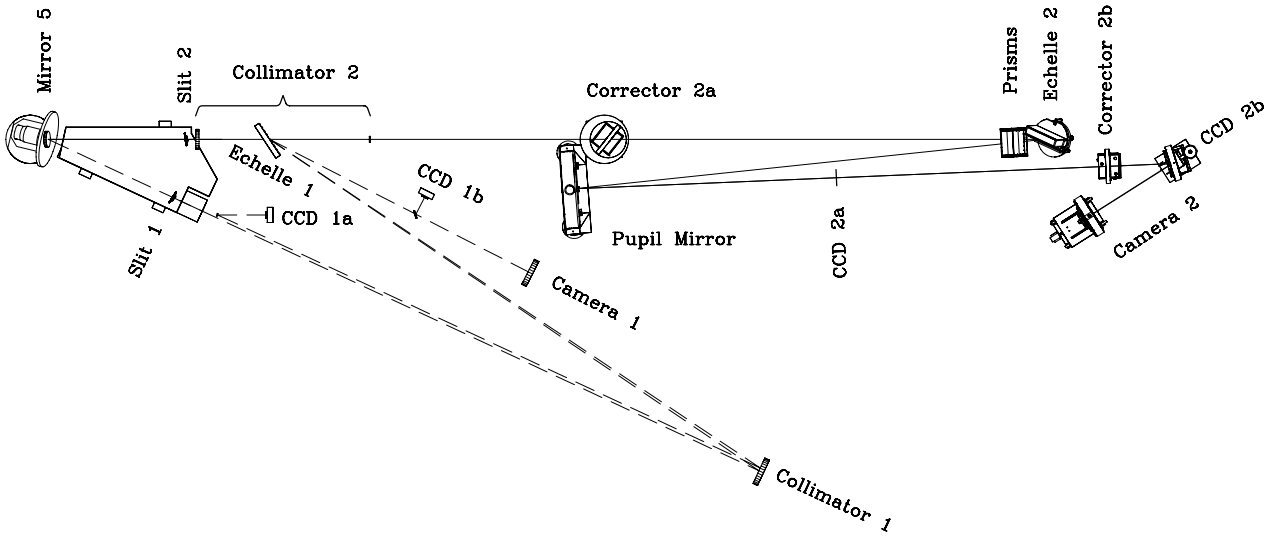

Figure 3. The coudé spectrographs of the 2.7 m H J Smith telescope at McDonald Observatory. ***Optical path 1*** (dashed rays): 2.7 m coudé spectrograph, completed by Robert G Tull in 1969; shown without its photographic cameras, which were removed in 1988. Available foci are as follows: auto-collimated focus of collimator 1 (CCD 1a) ($R_{\max} = 600\,000$), echelle in double pass); Newtonian focus of camera 1 (CCD 1b) ($R_{\max} = 200\,000$). ***Optical path 2*** (solid rays): 2dcoudé spectrograph, completed in 1992 by Robert G Tull, Phillip J MacQueen and John Good. Access is obtained by removing the grating 'echelle 1'. Available foci are as follows: focal surface of the pupil mirror (CCD 2a) ($R_{\max} = 200\,000$); folded Schmidt camera focus (CCD 2b) ($R_{\max} = 70\,000$).

New spectrographs for very large telescopes

Four technological advances characterize the modern high-resolution astronomical spectrograph: (1) electronic image detectors with two-dimensional formats and high quantum efficiency, (2) efficient echelle gratings well matched to detector formats, (3) computer-controlled automation and data retrieval and (4) computerized optical design methods and new optical glasses. The dispersion of light by an echelle is much greater than that of a conventional diffraction grating, owing to its high blaze angle. For that reason the resolving power can be high even though the slit is wide open, yielding greatly improved efficiency. The echelle disperses the spectrum in a narrow ray-fan of width typically 6°–7° containing many overlapping spectral orders. Cross-dispersion with a prism or grating separates these orders and the resulting stack of spectra is imaged on a large-format CCD, exposing many spectral orders simultaneously. These advances have vastly increased overall efficiency, pushing the limits of research to much fainter sources. A typical echellogram is illustrated in figure 2. In some cases the classical Schmidt is not the best camera choice. The CCD may be too large to fit inside a Schmidt camera without excessive blockage of the incident light. Recent developments in optical design combined with a broad range of newly available optical glasses have led to refractive cameras with fast focal ratio and flat, aberration-controlled external focal surfaces well matched to large-area CCDs over a broad spectral range (see CAMERAS). Examples of spectrographs using these techniques will be given here.

Hubble Space Telescope (HST) On 25 April 1990 the HUBBLE SPACE TELESCOPE and GHRS were launched into low Earth orbit aboard the space shuttle Discovery. With a selection of five first-order gratings and one echelle giving resolving powers of 2000–80 000, extensive programs of spectrography were carried out over a period of 7 yr, with observations on stars as faint as 14th magnitude. Two Digicon intensified linear diode-array image detectors, each with 512 photon-counting pixels, served to record the spectrum. The spectral range was in the ultraviolet, a region totally inaccessible from ground-based observatories. Being above the influence of the Earth's atmosphere, the telescope delivered nearly diffraction-limited stellar images to the spectrograph, greatly improving its resolving power and efficiency.

During a service mission in February 1997 the GHRS was removed from the Hubble Space Telescope and replaced by the Space Telescope Imaging Spectrograph (STIS). STIS has a CCD for use in low- and intermediate-resolution spectrography from far ultraviolet into the infrared and two MAMA (multianode microchannel array) imaging detectors, each with 1024 × 1024 pixels which operate at 2048×2048 in high-resolution mode. When used for high-resolution echelle spectrography with the four echelles, these photon-counting detectors have broader ultraviolet spectral coverage per exposure than could be obtained with GHRS, at higher resolving power.

McDonald Observatory 2.7 m H J Smith Telescope A spectrograph completed in 1992 and operating in parallel with the original coudé spectrograph has been named

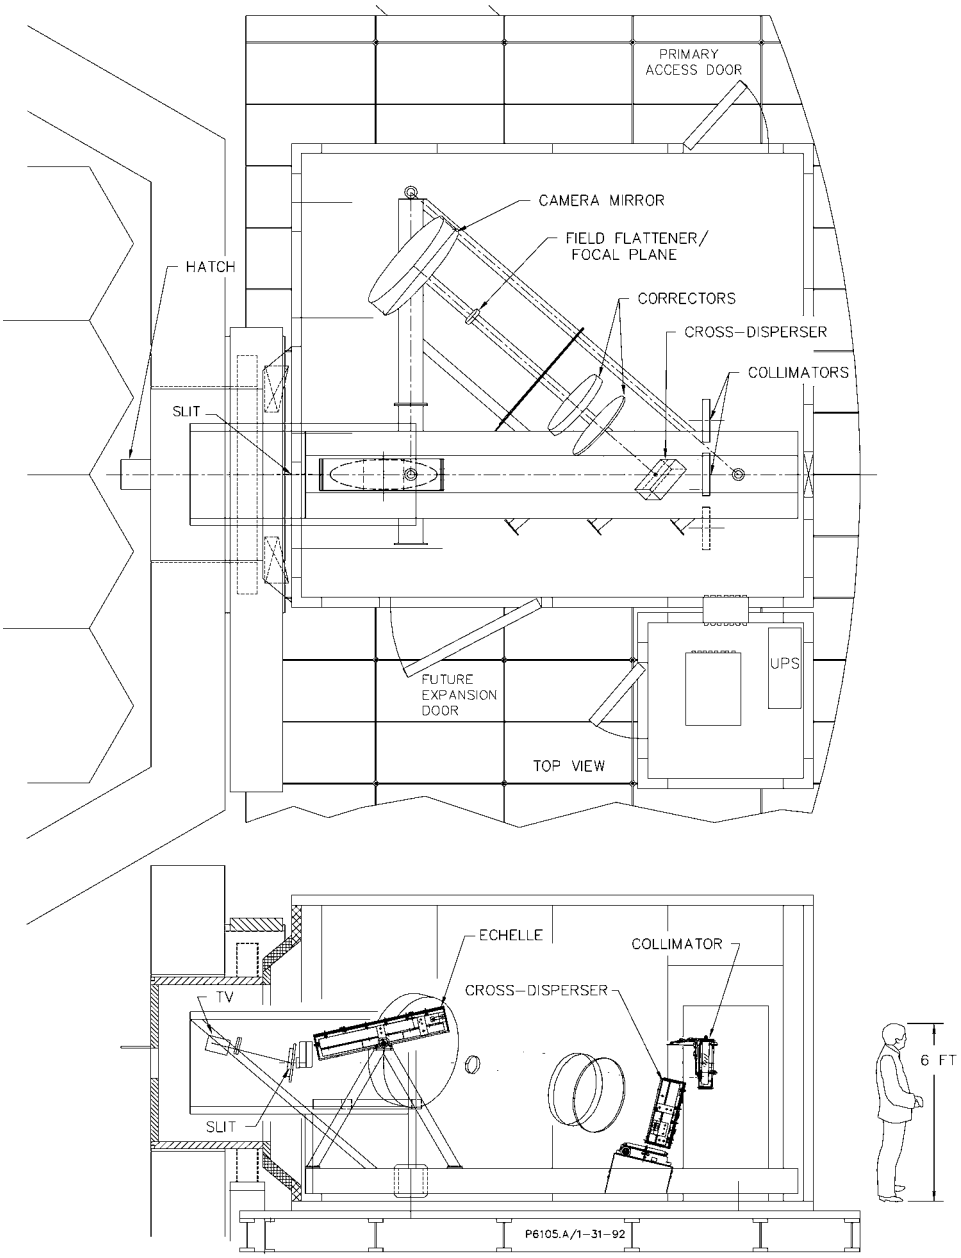

Figure 4. HIRES spectrograph of the 10 m Keck I telescope on Mauna Kea, Hawaii. Its resolving power is about 60 000. Built by a team headed by Steven S Vogt, it came into operation in 1993. Figure reproduced from Vogt *et al* 1994. HIRES: the high resolution echelle spectrometer on the Keck ten-meter telescope *Instrumentation in Astronomy VIII Proc. Soc. Photo-Opt. Instrum. Eng.* **2198** 362, by permission of Steven Vogt.

'2dcoudé' (figure 3). It uses a 79 grooves mm^{-1} echelle with blaze angle 63.9° (R-2) which is interchangeable with a 52 grooves mm^{-1} echelle blazed at 65.3°. Cross-dispersion is accomplished by a train of four 15° fused silica prisms in double pass, directly in front of the echelle. The collimator aperture is 19 cm. The detector is a Tektronix CCD with 2048 × 2048 24 μm pixels. Resolving power at the folded Schmidt camera is 70 000. There is an intermediate focus with resolving power of order 200 000. Stars of magnitude $V = 11.2$ can be recorded at $R = 60\,000$ with an exposure time of an hour at signal-to-noise ratio 100, in average seeing conditions.

Keck HIRES The best-known example of a modern high-resolution spectrograph on a very large telescope is HIRES, built by Steven Vogt on the 10 m Keck I telescope on Mauna

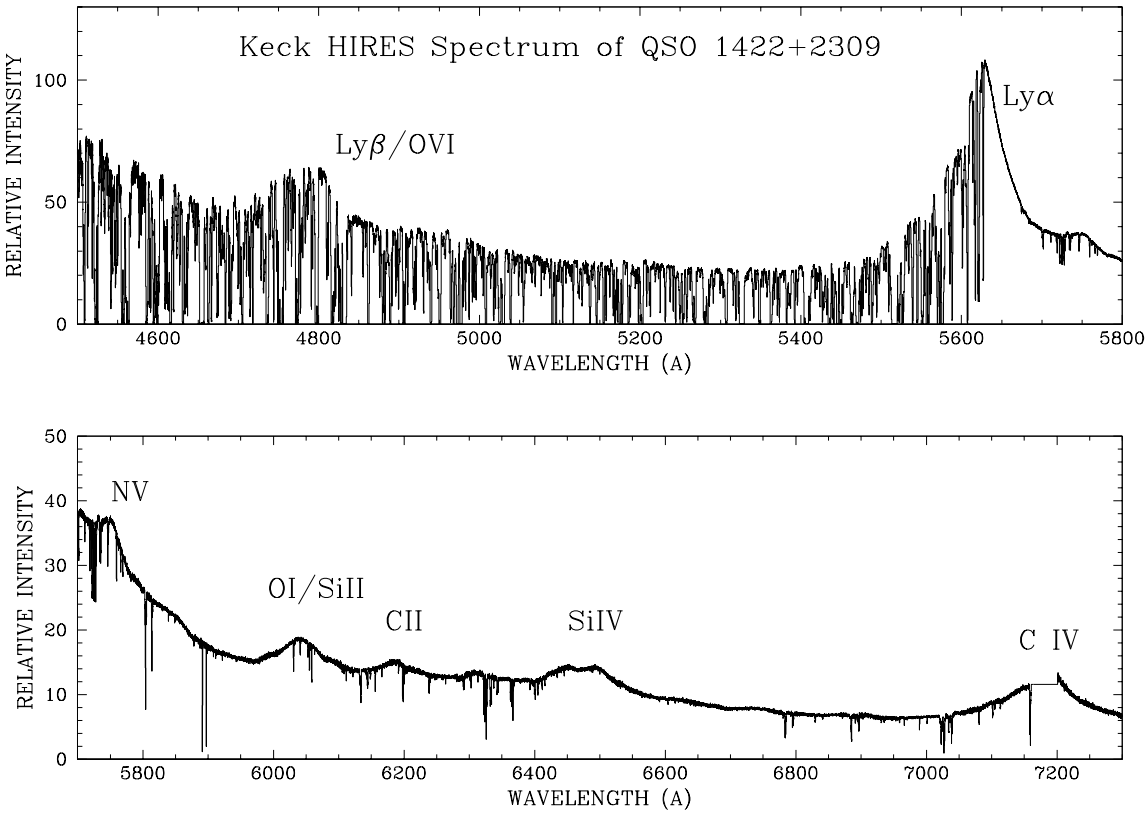

Figure 5. High-resolution spectrum of the quasar QSO 1422 + 2309. This spectrum was obtained in a 7.5 h exposure using the Keck HIRES spectrograph by Wallace L W Sargent. The resolution is 45 000. This figure demonstrates the power of a modern high-resolution spectrograph on a very large telescope. The broad emission line at wavelength 5605 Å is due to the far ultraviolet Lyman α line of hydrogen in this heavily redshifted $Z = 3.61$ quasar (the line is shifted 3.61 times its rest wavelength of 1216 Å). Nearly all the spectral absorption lines to the left (blue) of the emission peak at 5605 Å are due to Lyman α absorption in intervening intergalactic hydrogen clouds at redshifts distributed from 0 to 3.61 by the expansion of the universe. Such a distribution of absorption lines has become known as the 'Lyman α forest'. Note the nearly complete absence of absorption lines with wavelengths greater than 5605 Å. This quasar, with total brightness $V = 16.2$, is among the most distant objects known in the universe. Figure reproduced by permission of W L W Sargent, with thanks to the Keck observatory.

Kea (figure 4). It uses a mosaic of three echelles with blaze angle 70.5° and total ruled width 1.2 m cross-dispersed by a mosaic of two first-order diffraction gratings. The $f/1$ catadioptric camera designed by Harland Epps has a 1.1 m diameter image-forming mirror and 75 cm aberration-control lenses at its entrance aperture. Its 30 cm beam diameter is adequate to ensure minimal light blocking at its internal CCD housing. This spectrograph went into operation in 1993 and quickly demonstrated its power in research on extra-Galactic objects as faint as magnitude 19.6. Its spectra of the 'LYMAN ALPHA FOREST' seen against background quasars are well-known examples (figure 5).

ESO VLT The Ultraviolet–Visible Echelle Spectrograph (UVES) is on a Nasmyth platform of one of the four 8 m telescopes constituting the European Southern Observatory's Very Large Telescope (VLT) on Cerro Paranal in Chile. Built by Hans Dekker and Bernard Delabre, it combines two independent spectrographs, enabling simultaneous exposures in the red and blue ranges of the spectrum. Each utilizes an echelle with blaze angle 75°. The ruled width of each echelle is 84 cm, and each is a mosaic of two replications on a single Zerodur blank. Made at the Richardson Grating Laboratory, these are the largest diffraction gratings currently in existence for visible light spectroscopy. The beam diameter is 20 cm. The two channels are separated by means of a *dichroic beam-splitter* (a mirror that transmits red light and reflects the blue). Each uses a grating for cross-dispersion. Because of the very high dispersion of the echelles, UVES is a highly compact instrument for its resolving power of 120 000. With the excellent seeing conditions at the site in Chile, this spectrograph should see very little loss due to the slit width.

Robert Tull has built a single-channel adaptation of the UVES, called simply HRS. It is at the 9.2 m Hobby–Eberly Telescope at McDonald Observatory. It differs from UVES in that the starlight is conducted to the spectrograph

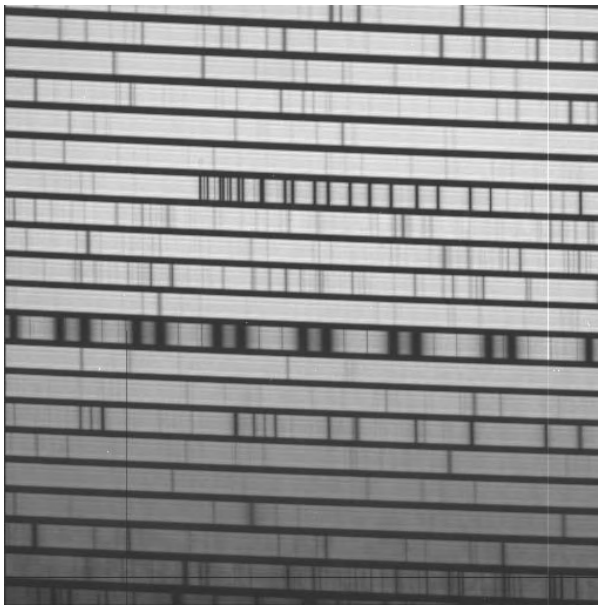

Figure 2. A typical echelle spectrogram: sunlight at the 2dcoudé spectrograph of the McDonald Observatory 2.7 m telescope. The resolving power is $R = \lambda/d\lambda = 200\,000$. The spectrum was exposed on a 2048 × 2048 Tektronic, Inc, CCD. The image covers a fraction of the observable spectrum in echelle spectral orders 56–36 (top to bottom) covering parts of the wavelength region 6126 Å–9550 Å in the red and near infrared. The strong, broad lines in order 45 (near the centre of the figure) and the strong sharper lines in order 50 are the 'A' and 'B' bands of molecular oxygen in the Earth's atmosphere. Atmospheric water vapor produced the strong lines in order 42.

by an optical fiber originating at the telescope focus.

The future of high-resolution spectrography

It is risky to attempt predictions too far into the future. Changes over the second half of the 20th century have been surprising and dramatic; we are not sufficiently wise to out-guess the route technological progress will take 50 yr hence. There are, however, two emerging technologies to watch.

Adaptive optics

Star images are degraded by atmospheric turbulence ('SEEING'), typically to a second of arc or greater diameter. The equations in the section on the theory of high-resolution spectography show that heroic measures must be taken to build spectrographs with large enough slit to accept most of the light and at the same time to maintain high spectral resolution, when used on telescopes as large as 10 m. ADAPTIVE OPTICS, an artificial means to shrink the diameter of the star image, has been proven effective on a number of telescopes, notably the 1 m ESO NTT, the 2.5 m Hooker telescope on Mt Wilson and the 10 m Keck II on Mauna Kea. With adaptive optics, there is hope to concentrate the star image diameter by a factor of 20. This in turn allows design of far more compact diffraction-limited spectrographs, yielding a gain in efficiency at much-decreased cost for the spectrograph.

Direct energy detection

There are under development solid-state image detectors capable of recording not only the time and location of arrival of a photon but also its energy (i.e. its optical frequency). It would be tempting to speculate that some day the energy resolution for such devices could be high enough that a single chip of silicon might replace the entire optical system now needed for high-resolution spectrography.

Spectrographs: Integral Field Units

Most astronomical objects display extended structures. For example, the bulge of a spiral galaxy looks quite different from its spiral arms. Indeed multicolor imaging, which is no more than very-low-resolution spectroscopy, shows us that the disk is bluer than the bulge, indicating that young stars form preferentially within the spiral arms. This, however, does not tell us how stars are moving within the spiral arm and what are the composition, temperature and pressure of the interstellar medium in various parts of the galaxy. Acquiring spectra at different locations will help us in answering these questions. More generally, understanding the chemical composition and kinematics of extended objects relies on obtaining spatially resolved spectrographic information.

The spectrophotometric information content of an extended object is inherently of three dimensions: two dimensions for the sky plane and one dimension in wavelength. Present detectors are unfortunately of a two-dimensional nature only. This makes it a major problem to pack this three-dimensional spectrophotometric information content of celestial objects on the detector plane. This, in turn, explains the still very prevalent use of classical long-slit spectrographs because of their perfect match with available digital detectors (figure 1) and despite their total loss of one spatial coordinate (across the slit width).

For simple objects, one can generally obtain enough information using multiple exposures with judicious slit orientations. However, for a complex object this rapidly becomes difficult as the geometry of the object rarely matches the geometry of the slit, not to speak of the increasing cost in telescope time. In ground-based telescopic observations, the non-simultaneity of the long-slit observations lead to inhomogeneous data as SEEING and weather conditions usually change between two successive exposures. It is then strictly impractical to cover completely and homogeneously a given field of view with a number of long-slit exposures.

Three-dimensional spectrographs are intended to give three-dimensional data for a fully sampled field of view. There are two general classes of instruments: scanning spectrophotometers and integral field units (IFUs).

In a scanning spectrophotometer, time scanning is used to provide the missing third dimension. This type of instrument has a large FIELD OF VIEW, every detector pixel being a spatial element, but its use is restricted to relatively bright objects because of the need for time scanning. At the end of the observation the data cube is obtained by a concatenation of all individual exposures. As for multiple-slit exposures, time of variation of the weather or instrumental conditions may cause inhomogeneities in the data.

The most famous example of a scanning spectrometer is the scanning Fabry–Pérot INTERFEROMETER. It is based on a two-parallel-plates etalon, whose separation can be tuned via a piezoelectric system. Such an instrument allows scanning in wavelength by making successive exposures at different separations of the etalon plates. To scan the complete free spectral range generally requires a large number of exposures (up to 50). The scanning Fabry–Pérot is limited to a small wavelength range, which restricts their use practically to the kinematical study of a single emission line. There are a number of such devices in operation throughout the world, such as Taurus at RGO (Taylor and Atherton 1980), HIFI at University of Hawaii (Bland and Tully 1989) and CIGALE at Marseille (Boulesteix *et al* 1980).

Another approach is to use an imaging Fourier transform spectrometer (FTS). This instrument is a Michelson-like interferometer, which allows the recording of interferograms by a step-by-step scanning of the path difference between the two arms. Increasing the path difference increases the spatial resolution. While there are many FTSs in operation, most of them have only one

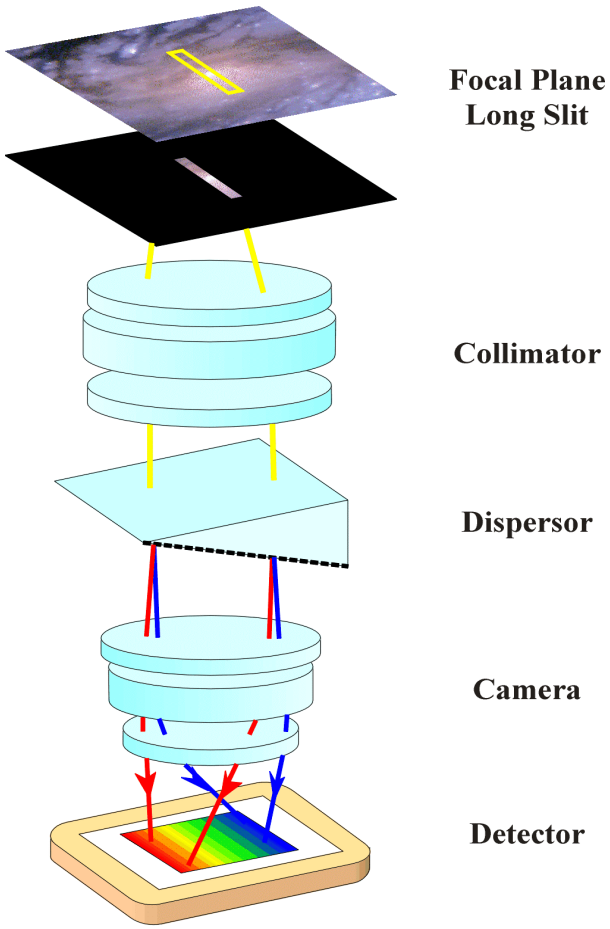

Figure 1. Basic principle of a long-slit spectrograph. A slit aperture, located at the telescope focal plane, masks everything of the observed object except along the slit. The slit orientation matches the orientation of the detector, so that each point of the object along the slit gives a spectrum on the detector. This simple technique avoids spectral overlap because neighboring points are located perpendicularly to the slit.

spatial dimension and are generally used for high spectral resolution spectroscopy in the infrared. An exception is the imaging FTS called Bear operated at CFHT (Maillard 1995).

Basic principle of an integral field unit

In contrast to scanning spectrophotometers, IFUs manage to cram the full three-dimensional data in a single exposure on the detector. An IFU is made of two successive stages: the spatial stage whose function is to reformat the field of view and the spectral stage whose function is to disperse and focus the light on the detector. The latter is nothing else than a classical spectrograph that deserves no special comment (but see SPECTROSCOPE/SPECTROGRAPH). The spatial stage is the most critical part. There are currently three types of IFU (figure 2): lenslet unit, fibers unit and slicer unit. They differ in the geometrical arrangement of the spatial elements.

An important parameter of an IFU is the packing efficiency: this is the number of spatial elements multiplied by the length of a spectrum in pixels divided by the total number of pixels of the detector. An ideal IFU will have a packing efficiency of 100%. For example with a detector of 2048^2 pixels, one is limited to 45×45 spatial elements if each spectrum covers a full column or line of the detector. This explains why IFUs usually have a relatively small spatial field of view, even with the large detector format available nowadays. In the real world, however, packing efficiency is limited by the geometrical packing and the optical quality of the spatial and spectral stages.

Lenslet IFU

Lenslet IFUs use an array of lenses to sample the field of view. The light intercepted by each lenslet is focused in a spot called the micropupil which is an image of the telescope pupil. Micropupils are then dispersed by the spectrograph in a conventional manner. The ratio of the lenslet diameter to the micropupil diameter must be large (typically 50). It is this demagnification that saves space on the detector to store the spectral dimension. A slight rotation between the dispersion direction and the microlens array orientation avoids spectral overlap in one dimension. In the other dimension, a wide-band interference filter limits the spectral range to a finite length to prevent overlap. The lenslet size is typically of the order of mm which does not generally match the sampling scale at the telescope focal plane (for example, the lenslet size should be as small as 14 μm to sample 0.1 arcsec at the focal plane of a 3.6 m $f/8$ telescope). An enlarger, preceding the lens array, is thus added to adapt the spatial sampling to the expected spatial resolution. Throughput of this type of IFU is generally good: square or hexagonal lenslet shapes provide a 100% covering efficiency and the lenslet can be made in optical glass and coated. A drawback is that a significant fraction of spectra are truncated if spectra are too long: in practice, the maximum spectral length should be less than 25% of the detector format in the dispersion direction to minimize this effect. The total packing efficiency on the detector is limited by the need to separate each spectrum from its neighbors as neighboring pixels do not share the same wavelength. When using a low spectral resolution grating at the order n, the $n+1$ and $n-1$ orders could cause some overlap with other spectra. In that case using a prism should be considered, especially at blue wavelengths where this effect is more pronounced.

The first lenslet IFU was called TIGER (Bacon *et al* 1995) and has been operated at the Canada–France–Hawaii 3.6 m telescope (CFHT) between 1987 and 1996. Starting in 1997 it has been replaced by OASIS (figure 3): a lenslet IFU with 1600 hexagonal lenses dedicated to the CFHT adaptive optics bonnette. Since TIGER, a few other instruments have been realized with the same design: one for the SAO 6 m telescope (Afanasiev and Sil'chenko 1991), another for the Kyoto three-dimensional spectrograph for the 1.88 m Okayama telescope (Ohtani 1995) and recently the SAURON spectrograph for the 4.2 m William Herschel Telescope.

Fiber IFU

Fiber IFUs use optical fibers arranged in a close-packed bundle at the telescope focal plane and then reformatted into a pseudo-slit, which is then fed into the spectrograph. This presents an advantage compared with lenslet IFUs in the sense that the spectra can be as long as the detector format allows. On the other hand, fiber IFUs suffer from a lower efficiency owing to limited packing efficiency at the entrance (generally less than 75% owing to geometrical loss and cladding) and FOCAL RATIO degradation. The latter is due to diffusion by imperfections within the fiber and diameter variation along it. This effect introduces some light loss and becomes more important with large f numbers. This strongly constrains the designs of the spectrograph and the spatial stage. Fiber IFUs need to be calibrated carefully to control the fiber-to-fiber point spread function and transmission variations.

The first fiber IFU that has been extensively used at a telescope was SILFID at CFHT (1986) (Vanderriest and Lemonnier 1988), later replaced by MOS-ARGUS (1993). Other development took place at the Kitt Peak 3.5 m telescope with DensePak (1988) (Barden and Wade 1988) and at the William Herschel 4.2 m telescope with Hexaflex (1989) (Arribas *et al* 1991), 2D-FIS (1994) (Garcia *et al* 1994) and INTEGRAL (Arribas *et al* 1997). All of these instruments worked in the visible.

Adding lenses in front of the fibers helps to increase the packing efficiency and to solve the problem of focal ratio degradation. Each lenslet forms an image of the telescope pupil at the entrance of each fiber in the bundle. At the output, a linear array of lenslets forms a pseudo-slit fed to the spectrograph. Working examples are the SMIRFS at the 4 m UK infrared telescope (Haynes *et al* 1998) and SPIRAL at the 4 m Anglo-Australian telescope (Kenworthy *et al* 1998). There are a number of fiber IFUs in development for the 8–10 m class telescope (e.g. VIRMOS IFU for VLT, GMOS IFU for Gemini); most of them include lenslets.

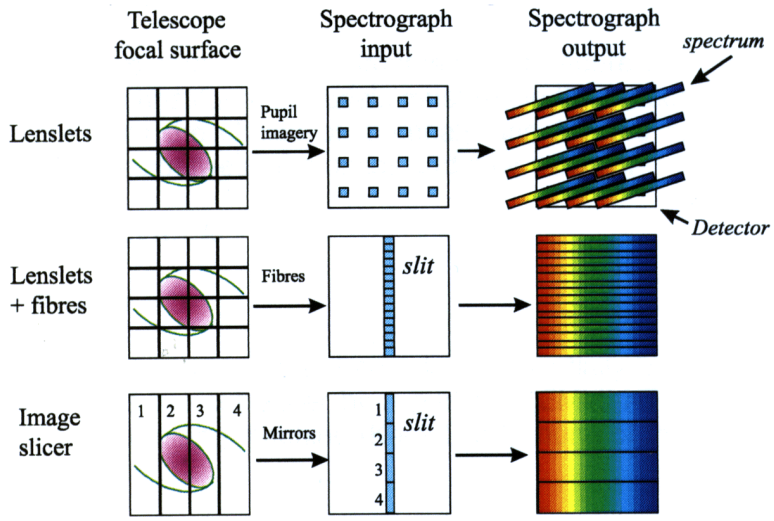

Figure 2. Schematic of IFU types (from Content 1997).

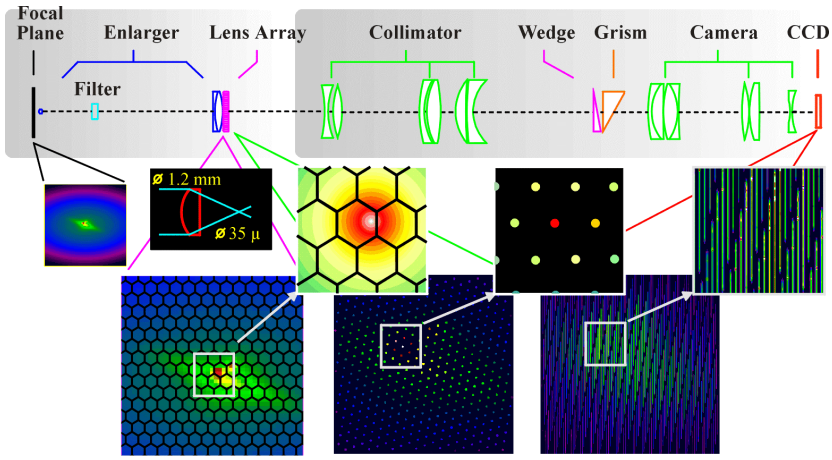

Figure 3. OASIS optical layout.

Slicer IFU

The slicer IFUs use mirrors in the telescope focal plane to cut the field of view into a number of strips which are then rearranged into a one-dimensional long strip. The slicer is composed of two sets of mirrors: the first set slices the field of view in a number of strips and reflects them into different directions while the second set rearranges the strips and aligns them into one continuous long strip. Slicer IFUs are comparable with fiber IFUs in terms of spectral coverage, but they are more efficient in terms of packing efficiency as the spatial sampling is continuous along each strip. The tilt of each submirror produces a defocus between the two edges of each slice. This defocus translates into losses in spatial resolution and throughput. This gives a practical limit to the maximum number of slices that can be accommodated by such an IFU as defocus increases with the number of slices.

The only working slicer IFU in operation today is the three-dimensional instrument built at MPE (Weitzel *et al* 1996). It operates in the near infrared (H and K band) and has been successfully used on a number of 4 m class telescopes.

A variation of this principle which limits the defocus has been proposed by Content (1997) (figure 4): the mirrors have curved surfaces to allow the pupil-relay mirrors to be reduced in size. The tilt of each component is then reduced and consequently the defocus aberrations are decreased.

Applications

IFUs have been successfully used on a large variety of objects, from the study of PLANETARY SURFACES to the most distant QUASARS.

A good example of IFU possibilities is given in the study of the Einstein cross, the gravitationally lensed

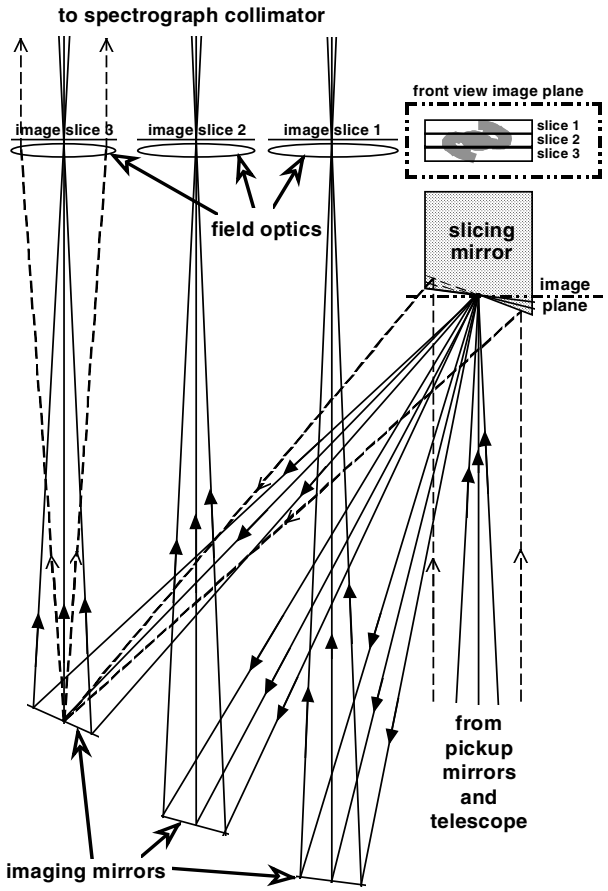

Figure 4. Principle of the slicer IFU (from Content 1997).

system 2237 + 0305. An exposure taken with the IFU TIGER (lenslet type) gave 400 spectra covering the central part of the galaxy with a 0.4 arcsec sampling. The spectra (figure 5, panel A) at the four quasar image locations show a mixture of galactic light and quasar light. One can see indeed the strong line emission of C III] 1909 Å redshifted to 5200 Å as well as stellar absorption lines typical of a galaxy. Integrating the flux over the whole spectral range for each spectrum allows the reconstruction of the equivalent of a direct image within that wavelength range. This image (panel B) shows the well-known cross shape of this object with five maxima, the central one being the nucleus of the galaxy. This image is obviously dominated by the continuum, which is an unknown combination of the quasar and galaxy fluxes. However, it is quite easy to properly subtract the continuum independently for each spectrum. The continuum-free C III] reconstructed image, displayed in panel C, is now free from most of the galactic contribution and it no longer shows the galaxy nucleus. Using simultaneously spectral and spatial information, it was thus possible, in this example, to disentangle the contributions of the quasar and of the galaxy (Fitte and Adam 1994).

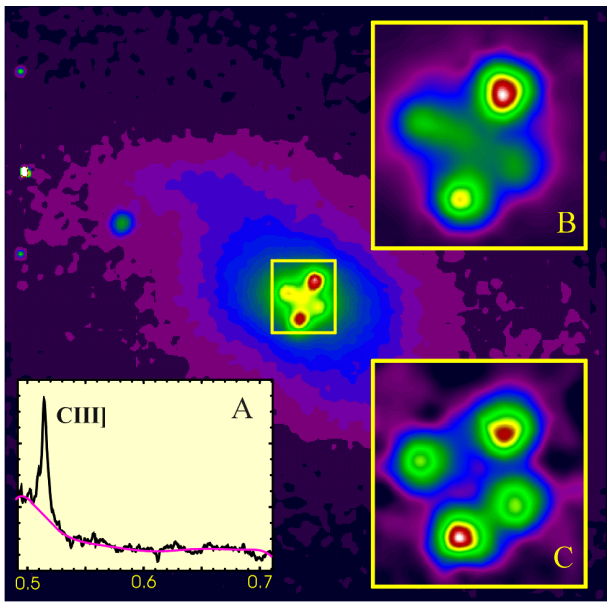

Figure 5. IFU study of the Einstein cross. Panel A: spectrum at one of the quaser image locations. Panel B: reconstructed image with the whole spectral range. Panel C: reconstructed image of the continuum-free C III] emission.

Prospects

Integral field spectrographs in operation are not very common yet, but a number are being designed for the new 8 m class telescopes. In parallel with multiobject spectrographs, which are ideally suited to the study of large collections of objects, IFUs will become more and more popular for the detailed study of individual objects, or alternatively for very dense fields such as GLOBULAR CLUSTERS.

The success of adaptive focus on ground-based telescopes and the launch of large-aperture space telescopes has emphasized the need for high spatial resolution spectroscopy. Decreasing the slit width is no longer a valid solution and IFU capabilities then become essential to understand the physics and the complex morphology generally displayed by astronomical sources at high spatial resolution.

Recently the first three-dimensional detector, with direct measurement of the photon energy, has been tested on a telescope (Peacock *et al* 1998). These superconducting photon-counting cameras have an excellent quantum efficiency over a broad wavelength range (UV to IR). Although their spectral resolutions are still very modest (∼20) and their number of pixels quite small (8 × 8), they have the potential to replace most of the existing spectrographs in the future.

Spectrographs: Low-Resolution Spectrographs

Low-resolution spectrographs typically record the spectrum of astronomical objects at resolution ($\lambda/\Delta\lambda$) in the range 10^2–10^4. This resolution is adequate to reveal many strong absorption lines in stellar spectra, or emission lines in nebular spectra, and to resolve the typical range of velocities exhibited within a galaxy, for example, but it is not sufficient to resolve the intrinsic line profiles of solar-type stars or individual interstellar clouds. Low-resolution spectroscopy is particularly applicable to faint objects where photon noise from the source and sky places a practical limit on the resolution which can be achieved while maintaining an adequate signal-to-noise ratio.

Overview

A spectrograph contains four parts: the slit or entrance aperture, a collimator which converts the cone of light emerging from the slit to a parallel beam, a prism or grating which disperses the parallel beam through a range of angles which depends on wavelength and the camera, which focuses the parallel beams into new images of the slit at a corresponding range of positions. The detected intensity as a function of position is then a measure of the spectrum, or intensity as a function of wavelength. The same arrangement is used for spectrographs in the UV, optical and IR portions of the spectrum.

The development of optical spectrographs through the mid-1960s was driven largely by the characteristics of photographic plates, which were the typical detectors of the time (see DETECTORS: PHOTOGRAPHY). The photographic speed of the spectrograph camera was critical, so that the image of the spectrum would be bright enough to produce a useful photographic exposure in a reasonable period of time. Low-dispersion instruments with particularly fast CAMERAS were called nebular spectrographs because of the low intensity of nebular images compared with stellar images. Even for nebular spectrographs the limiting photographic magnitude was sufficiently bright that the effect of sky background was modest.

The advent of more modern detectors, initially image intensifiers and more recently CHARGE-COUPLED DEVICES (CCDs), has resulted in a gain of more than 100 in the effective limiting brightness of low-dispersion spectrographs. One consequence of this change is that modern spectra are often dominated by sky background, and the spectrograph must be designed to maximize the contrast of the object against sky and to provide accurate calibration and subtraction of the sky background.

Most modern optical spectrographs being built for large ground-based telescopes are imaging spectrographs. The collimator and camera have a significant field of view, typically equivalent to several arcminutes on the sky. Without a disperser the detector can make a direct image of the spectrograph field of view. The scale of the final image is reduced by the ratio of the focal length of the collimator to the focal length of the camera. Often this scale results in a better match between the image size and the pixel size, and a larger field of view, than would be obtained with the same detector placed directly in the telescope focal plane. Within the field of view there may be many objects of interest brighter than the limiting spectroscopic magnitude. In place of a single slit, an aperture plate can be inserted with a number of small slits cut at the locations of interesting objects (see SPECTROGRAPHS: MULTISLIT SPECTROGRAPHS). When viewed through the disperser, the image contains a spectrum for every slit. Care must be taken in placing the slits so that the dispersed spectra do not overlap. In some cases even larger fields of view are covered by employing several spectrographs, each of which images a separate portion of the telescope focal plane in what is sometimes called a fly's-eye arrangement.

An alternative approach to multi-object spectroscopy is to use a number of optical fibers, positioned in the telescope focal plane at the locations of interesting objects. The other ends of the fibers, which are flexible, can be lined up in place of a long slit in an imaging spectrograph, producing a separate spectrum for each object (see SPECTROGRAPHS: FIBER-FED SPECTROGRAPHS). In some cases the size of the field accessible to fibers can be much larger than the size of the field for a multi-slit spectrograph.

When observing an extended object, a conventional slit spectrograph produces a one-dimensional series of spectra, spatially resolved in the direction along the slit. In some cases it is desirable to extend the spatial sampling to two dimensions, in order to cover the entire area of the object. This can be accomplished by using an array of closely packed fibers, a modified optical slit assembly called an image slicer, or an array of field lenses which spatially re-sample the image. Such a spectrograph is called an integral-field spectrograph (see SPECTROGRAPHS: INTEGRAL FIELD UNITS).

Detailed considerations

The slit serves two purposes. (1) Sky background adjacent to the object (and the associated photon noise) is rejected by the slit jaws. (2) In the case where the slit is narrower than the telescope image, the wavelength resolution in the final spectrum is determined by the width of the slit rather than by the distribution of light across the source. Single-object slits are sometimes made from two jaws with a mechanical adjustment for changing the slit width, or else by machining or etching a number of discrete slits with a selection of widths. In single-object spectrographs it is common to polish the surface of the slit jaws and tilt the slit at an angle to the incident beam, so that an auxiliary TV camera can be used to view the reflected image of the telescope focal plane in order to check the placement of an object on the slit. Multiple slits for imaging spectrographs have been made using multiple mechanical slit jaws, by machining custom aperture plates using mechanical tools or high-powered lasers, or by making photographic images on very fine-grained emulsions.

Typical collimated beam diameters for low-dispersion spectrographs are in the range 5–20 cm. Larger diameter

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

is achieved by increasing the focal length of the collimator, resulting in higher resolution for a given slit width because the range of angle subtended by the slit decreases. Larger size also makes the optical design problem more tractable by reducing the angular field of view required of the collimator in order to image a field of a given diameter, and of the camera in order to illuminate a CCD array of a given size. Cost and mechanical flexure, however, increase rapidly with size, and the available rulings for DIFFRACTION GRATINGS become increasingly limited.

Usually the prism or grating is placed near the exit pupil of the collimator, where an image of the primary mirror is formed by the collimator optics. For a single-object spectrograph the small entrance aperture tends to form a pinhole image of the primary at a range of positions along the parallel beam. However, for an imaging spectrograph with a wide-angle field of view, the location of the exit pupil is critical. Reflecting collimators have the disadvantage that the exit pupil is reflected back toward the slit, and an off-axis or folded design must be used in order to extract the collimated beam to an accessible location. Refractive collimators have the advantage of more easily producing an external pupil, but must contend with chromatic aberration which is absent in reflecting designs. In a wide-field imaging spectrograph the design of the collimator can be considerably more challenging than the design of the camera, because the required control of the pupil position does not permit the arbitrary use of a field flattener in the collimator image plane (see also WIDEFIELD CCD IMAGERS).

The disperser can be either a prism or a diffraction grating. Prisms have the potential advantage of very high efficiency but suffer from a number of disadvantages. The dispersive power of a prism is relatively low compared with a diffraction grating, and dense glasses with the highest dispersion do not transmit well at the blue end of the spectrum. The dispersion of a prism is highest in the blue while most astrophysical sources are brighter in the red, resulting in a very uneven exposure. The optical homogeneity of glass is difficult to maintain through a sufficiently long optical path, and reflection losses at strongly oblique surfaces can also be difficult to control.

For these reasons most spectrographs make use of either transmitting or reflecting diffraction gratings. The gratings must be blazed in order to concentrate the diffracted light efficiently into a single diffracted order. Transmission gratings are blazed by cutting each groove into the face of the grating at an angle so as to create a tiny prism which refracts light at approximately the angle of diffraction. Reflecting gratings are blazed by cutting each groove at an angle so as to form a tiny mirror which reflects light at approximately the angle of diffraction. Because refraction for typical optical materials is weaker than reflection, the angular dispersion achievable with transmission gratings is a factor of two or so lower than with reflecting gratings.

When using a diffraction grating to cover a wide range of wavelengths, care must be taken to avoid overlapping spectra from different orders of diffraction. An order-separating filter may be required. In some cases a dichroic mirror is used to direct red and blue wavelengths into two separate spectrographs. Each side of such a double spectrograph can be optimized for maximum performance over a more limited wavelength interval. Sometimes a weak cross-disperser is introduced in order to separately detect spectra in several low orders of diffraction. Such a spectrograph is said to be working in echellette mode (see SPECTROGRAPHS: HIGH-RESOLUTION SPECTROGRAPHS).

In a spectrograph which uses transmission gratings the optical axis will be bent through some angle which depends on the grating being used. In order to avoid having to pivot the camera of the spectrograph to various angles (in particular to allow the camera to be fixed in the straight-through position where a direct image of the telescope field can be made by removing the grating) the transmission grating is often replicated on a prism which compensates for the diffraction angle of the grating. The combination is often called a grism.

A variation of the reflecting grating which can achieve still higher angular dispersion illuminates the ruling through the substrate. This allows the diffraction to occur in the resin with which the grating was replicated, rather than in air. The wavelength is shorter in the resin in proportion to the index of refraction, and the angular dispersion is correspondingly higher. The disadvantage of such immersion gratings is that the reflective coating is typically less efficient when illuminated from inside the material than it is when illuminated from air.

Typically some angle is introduced between the incident and diffracted beams of a reflecting grating spectrograph, in order to separate the collimator and camera optics. Order zero of a reflecting grating always emerges at the angle of reflection (for this order the grating is acting as a mirror). Diffraction of increasing order can occur on either side of the zero-order image. Orders which emerge on the same side of the zero-order image as the incident beam are called interior orders. Orders which emerge on the opposite side of the zero-order image are called exterior orders.

A critical property of such a spectrograph is the anamorphic factor, r (for a diffraction grating, the ratio of the cosine of the angle of incidence to the cosine of the angle of diffraction). The anamorphic factor can become substantial for gratings with high angular dispersion. For interior orders the anamorphic factor is less than 1 and the angular width of the slit is reduced in the diffracted beam by the factor r, but the physical size of the diffracted beam is increased (in one direction) by $1/r$. Interior orders have the advantage that the wavelength resolution is higher because the projected slit is narrower, but the optics must be larger in order to accept all of the diffracted beam, which can make the optical design problem significantly more challenging. Exterior orders are subject to light loss on the back facet of each groove and are generally used only under special circumstances.

The spectrograph camera can be either reflecting (typically using Schmidt-type optics) or transmitting. The reflecting designs again suffer from the difficulty of separating the image plane and the pupil plane. Prime-focus Schmidt cameras require a special dewar to suspend a cooled detector in the middle of the optical system. Folded Schmidt cameras use a flat mirror to extract the final image to an external location. In either case, optical performance is limited by the field flattener which is required in order to match the curved focal plane to a flat detector. Cassegrain Schmidt designs produce a flat focal plane, but the light loss caused by obscuration on the secondary mirror can be substantial. Refracting cameras can produce wide, flat fields, but must contend with chromatic effects which usually require the incorporation of special low-dispersion glasses or other low-dispersion materials, such as calcium fluoride.

The entire optical assembly of the spectrograph must be mounted in a mechanical framework with adequate structural and thermal stability, in order to minimize drift of the spectrum on the detector. Drift causes a loss of spectral and spatial resolution, as well as changes in the intensity calibration of the detector. This is especially true for thinned CCD arrays which are subject to high-frequency fringing effects caused by optical interference within the thickness of the array. The intensity calibration is particularly critical when subtracting sky determined at one location along a slit from the spectrum of a faint object at another location. For large spectrographs it can be particularly difficult to achieve adequate stability, and various measures have been considered, including active optical compensation and distributed mechanical flotation.

Recent developments

The most ambitious low-resolution spectrographs built in recent years have aimed to maximize the advantages of multi-object spectroscopy. Fiber systems capable of observing from 300 to 600 objects at one time, in some cases incorporating multiple spectrographs or double (dichroic) spectrographs, have been constructed, typically in order to measure galaxy redshifts and large-scale structure, to survey faint quasars and to study stars in the halo of the galaxy. Multi-slit systems are under construction incorporating multiple spectrographs or large CCD mosaics, generally with the intention of studying the evolution of more distant samples of galaxies.

A new type of diffraction grating, called a volume-phase holographic grating, has begun to attract attention. These gratings work by introducing periodic high-frequency modulations of the index of refraction in a layer of suitable transparent material. Volume-phase gratings can be somewhat more efficient than surface-relief gratings, and may be especially useful if they can be produced in larger sizes than conventional diamond-ruled gratings.

Spectrographs: Multislit Spectrographs

A multislit spectrograph is similar to a standard-slit spectrograph, except that the FIELD OF VIEW on the sky is greatly expanded to allow placement of entrance slits on many objects in the field.

This instrumental field of view on modern large telescopes is typically 5–20 arcmin and a considerable advantage is gained over single-slit spectrographs when there are many possible targets in this size of field.

Access to even larger fields of view (for example several degrees) is limited by the cost and design complexity of large optical elements; in this regime the preferred solution is to use fiber-fed spectrographs which use fibers to reformat light into a smaller entrance slit (see SPECTROGRAPHS: FIBER-FED SPECTROGRAPHS). In contrast in a multislit spectrograph the contiguity of the image of the full field is preserved throughout the optical train, although it is dispersed in wavelength. This of necessity involves greatly expanding the size of the optics, even when working at a low spectral resolution, to accommodate the size of the beam. Multislit spectrographs are also sometimes referred to for this reason as 'beam-fed spectrographs' to distinguish them from fiber-fed systems.

The particular niche occupied by multislit spectrographs in astronomy is the spectroscopy of very faint objects in crowded fields, especially the measurement of REDSHIFTS of very distant galaxies. By retaining the use of a slit which measures the background adjacent to the object much better subtraction of night sky emission can be obtained than by using fibers; this is critical because targets are usually much fainter than the sky. Because of the orientation towards faint targets simple designs are generally employed with the minimum number of optical elements in order to maximize the throughput of light through the instrument. A direct imaging capability is also common which gives rise to a very versatile instrument; because of this a multislit spectrograph is almost a standard facility on the largest telescopes.

Modern examples of multislit spectrographs are the Low Dispersion Survey Spectrographs (LDSS-1 and LDSS-2) on the Anglo-Australian and William Herschel 4 m telescopes and the Low Resolution Imaging Spectrograph (LRIS) on the W M Keck 10 m telescope. These have all been used for progressively fainter and more distant redshift surveys; the current state of the art is redshift 4–5 galaxies and quasars from LRIS.

Optical layout

The typical layout is shown in figure 1 which illustrates the LDSS spectrograph on the Anglo-Australian Telescope.

The focal plane of the telescope is occupied by a *slit mask*; this is a piece of opaque material (usually metal or carbon fiber) in which multiple slits have been cut. The positions of the slits on the mask correspond to the relative positions of the images of the targets formed at the telescope focal plane. A provision is made for swapping slit masks and removing them completely to give a clear aperture for imaging (for LDSS-2 this is accomplished by mounting them on a wheel).

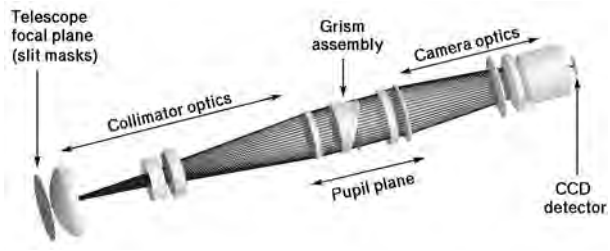

Figure 1. Optical diagram of the *Low Dispersion Survey Spectrograph* (LDSS), a multislit spectrograph on the Anglo-Australian 3.9 m telescope. A collimator re-images the telescope focal plane (where the slit masks are located) into a pupil which accommodates a dispersing element (a grism) and/or filters. The dispersed spectra are then re-imaged by the camera optics on to the CCD detector.

A requirement for observing is to prepare the slit masks in advance; various technologies have been used for making slits such as photo-etching, cutting with a mechanical drill bit and laser cutting.

Next in the optical train comes a *collimator* which is usually the largest optical element. This usually consists of several lens elements which takes light from each point in the focal plane and produces parallel rays (for more details see SPECTROSCOPE/SPECTROGRAPH).

Behind the collimator these rays form a real pupil (where there is an image of the telescope entrance aperture) and at this point in the optical train are put optical filters for wavelength range selection and diffraction gratings to disperse the light into spectra. The LDSS case uses a *grism* which consists of a prism bonded to a transmission grating; the prism refracts the spectra so they stay on axis. Thus removing and inserting the grism into the pupil allows one to instantly swap between imaging and spectroscopy of the full field, a very convenient feature.

After the pupil comes the *camera*, another optical element assembly which focuses the spectra (or direct images) onto a second focal plane where a detector of some kind is placed. Usually the camera includes some kind of focal reduction to shrink the image of the field down on to a small detector.

The standard modes of operation are imaging in various filters and slit spectroscopy by inserting a mask and a grism and/or grating. It is also possible to do 'slitless spectroscopy' by just using the grism and/or grating with a clear aperture; however, in this case the background emission is greatly enhanced so it is not commonly used for faint targets.

Design variations

Many variations are possible. For example, LRIS uses reflection gratings rather than grisms. In this case to swap

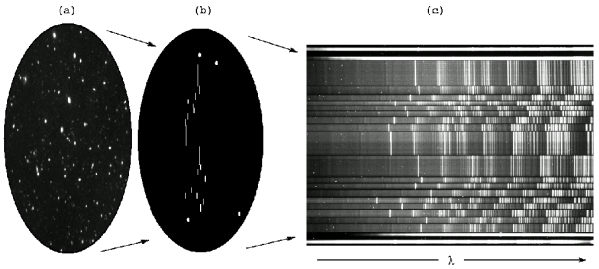

Figure 2. Stages of image formation in a multislit spectrograph (data shown are for LDSS-1). (*a*) An image of the sky is formed at the telescope focal plane. (*b*) A slit mask selects objects for spectroscopy via position in the focal plane. (*c*) Each slit in the mask forms a spectrum of object + sky on the detector. (Note that the holes at the top and bottom of the mask are for alignment of the mask on reference stars in the field; this is done in direct imaging mode.)

between imaging and spectroscopy one must remove the grating and insert a flat mirror. LRIS also uses a reflective collimator mirror; it would also be possible in principle to also have a reflective camera. Another variation could be to have multiple channels; for example the beam could be split by a dichroic after the pupil and sent to multiple cameras (to optimize for blue and red wavelength range).

Data and reduction

Images are formed on a large detector such as a CHARGE-COUPLED DEVICE (CCD). Figure 2 shows a typical raw data image, illustrating spectroscopy through a slit mask. Each slit forms a rectangular spectrum, its position on the detector corresponding to the position of the slit on the mask and hence the object on the sky. This leads to a design constraint in the making of the mask: objects must be chosen for slits so that their resulting spectra do not overlap. This geometric effect can be seen in the figure.

In a typical setup with faint objects either unresolved or a few arcseonds in size a slit would be about 10 arcsec in size. Thus with a typical 10 arcmin field of view up to 60 spectra could be obtained in a tier. If the spectra are short compared with the detector multiple tiers can be used giving an increased multiplex advantage. One way of achieving this is to use a bandwidth limiting filter to reduce the wavelength range of the spectra; another is to simply observe at a very low resolution so even the full spectrum is short.

For data reduction the individual slit spectra must be located, then they can each be reduced as a single-slit spectrum (although each will have a wavelength scale offset by the departure of the slit from the field center in the direction of the dispersion). As for a single slit the background is subtracted by interpolating the data values either side of the object on the slit. Some example spectra from the LDSS-2 redshift survey (Glazebrook *et al* 1995) are shown in figure 3.

Technological developments

Multislit spectrograph technology is far from static and several developments are actively being pursued.

Infrared instrumentation

The same optical principles can be applied to infrared instruments. To operate out to a wavelength of 1.6 μm the only fundamental change required is the use of an infrared sensitive detector (see also INFRARED ARRAYS). To go redder than this it then becomes necessary to cool the entire instrument in a dewar to avoid too much thermal radiation, especially from the mask. This causes a problem because masks need to be accessed to be changed, which necessitates removing them from the dewar. A proposed solution to this is use of a separate, smaller, fore-dewar just for the masks and which can be thermally cycled much more quickly. Thermal radiation from outside the telescope aperture must also be blocked; this is done by placing a cold aperture stop in the pupil space. Multislit spectrographs based on this concept are being built for the Anglo-Australian and Kitt Peak 4 m telescopes and are being proposed for the new large telescopes.

Microslits

The number of objects one can fit on a mask is limited by the size of the slits. If they can be made smaller the multiplex can be increased; ideally one want small apertures (often called 'microslits') which are just big enough to cover the objects.

This leaves the problem of how to do the sky-subtraction. In principle one can take separate sky observations through the slits. One problem with this is that the sky brightness can change in minutes while with a CCD one must take much longer exposures to overcome noise. Research in progress at the Anglo-Australian Observatory has demonstrated that this limitation can be overcome via a special CCD controller mode known as 'charge shuffling' where spare pixels on the detector are used to store the sky signal. Using microslits fields of up to 200 objects have been observed at once with large spectral ranges. This is a powerful technique for very dense fields.

Larger fields

Going to larger fields than the normal limit of about 10 arcmin requires fabrication of large and expensive optical components. Nevertheless there are proposals to do just that. For example the US National Optical Astronomical Observatories has designed an 8 m telescope with a 1.5° field of view which will feed four large multi-slit spectrographs.

Future mask technologies

The flexibility of the multislit design has led to the desirability of having a multislit spectrograph on the Next Generation Space Telescope (NGST) due to be launched in 2008 (see SPACE INSTRUMENTATION: NEXT GENERATION SPACE TELESCOPE). However, for a space instrument which will never be serviced after launch there is a problem in the

provision of slit masks; because of this new technologies are being researched to provide mechanically *configurable* slit masks, which can be operated remotely.

Two such technologies are being developed at the Goddard Space Flight Center using microelectromechanical devices which are arrays of mechanical devices made on a silicon substrate. One possibility is a 'micromirror array': a 4096×4096 array of tiltable mirrors is envisioned which could move between an ON position, which would direct light into a spectrograph, and an OFF position which would be virtually opaque. Every position in the array would be rapidly configurable to form a series of slits. A related concept is 'microshutter arrays'; these are arrays of small shutters which open and close, operating in transmission like a conventional slit mask. At the time of writing the size of test arrays is of order 3×3 elements.

A more conventional proposal for NGST, from the Dominion Astrophysical Observatory, is to use a stack of mechanical slits, up to 75, which are scrollable side to side on metal rolls. Similar ideas have been implemented before on the ground; for example the 'multislit mechanism' on the Multiple Mirror Telescope in Arizona provides eight configurable slitlets in a 3 arcmin field of view.

Spectroheliograph/spectrohelioscope

An instrument that allows the Sun to be studied in light of one particular wavelength (by imaging the Sun photographically, or electronically, in the case of a spectroheliograph, or by direct vision in the case of the spectrohelioscope). Basically, the instrument consists of a spectrograph, or spectroscope, which is used to isolate one particular spectral line (e.g. one of the hydrogen or calcium lines), combined with a mechanical or optical means of scanning the disk of the Sun. In the case of a spectrohelioscope, provided that the solar disk, or the region of interest, can be completely scanned at least ten times a second, persistence of vision allows the observer to see a stationary monochromatic (single-wavelength) image. The instrument enables features such as prominences and filaments to be studied

The amount of detail that can be seen increases as the width of the slit is decreased. By isolating different parts of a particular spectral line (a spectral line has a finite width) an observer can observe to different depths within the solar atmosphere.

Spectroscope/spectrograph

A device that enables the spectrum of a light source to be viewed directly (spectroscope) or recorded by photographic or electronic means (spectrograph). A basic spectrograph consists of the following principal elements: a narrow slit, through which light is admitted to the instrument, a collimator, a dispersing element, an imaging system, and a detector. Light from the source (for example, a star) falls on the slit, which is placed at the focal plane of the telescope. Light diverging from the slit is brought into a parallel beam by the collimator which, like the imaging element, may consist of lenses or mirrors. The beam of light then encounters the dispersing element, which separates the light into its constituent wavelengths, or colors. The dispersing element may be a prism (or series of prisms) or a diffraction grating (a finely ruled grating which transmits or, more usually, reflects light and splits it into its constituent wavelengths). A system that uses reflecting optics and a reflection grating permits the study of wavelengths that cannot pass through glass. Finally, the imaging system focuses the spectrum (the spread-out band of wavelengths) onto the detector, which may be a photographic emulsion, an image tube or a CCD. In a spectroscope used for visual observation, a small telescope, with an eyepiece, is placed after the dispersing element.

The focused spectrum consists, in essence, of a very large number of overlapping monochromatic images (each corresponding to a different wavelength of light) of the entrance slit. In order to produce a sharply focused spectrum, the slit should be as narrow as possible. However, the narrower the slit, the fainter the spectrum, and the longer the exposure time that is needed in order to record the spectrum. Because the spectrum of a point-like source such as a star would consist of a thin strip of light, too narrow to analyze effectively, a further optical component, called a widener, is usually placed between the slit and the collimator. This broadens the spectrum at right angles to its length. Alternatively, the observer can achieve the same effect by moving the telescope during the exposure so as to trail the image of the star a little way up and down the slit.

Two key factors that characterize the performance of a spectrograph are dispersion and spectral resolution. Dispersion is a measure of the extent to which the constituent wavelengths are spread out, the linear dispersion being the change in wavelength over a given physical length of the spectrum. Dispersion is normally quoted in nanometers per millimeter (nm mm^{-1}), a dispersion of 1 nm mm^{-1} corresponding to a change in wavelength of 1 nanometer over 1 millimeter of the imaged spectrum's length. Spectral resolution (R) is a measure of the instrument's ability to reveal fine detail in the spectrum and is defined by $R = \lambda/\Delta\lambda$, where λ denotes the wavelength of interest and $\Delta\lambda$ the smallest wavelength interval that can be distinguished within the spectrum. For example, when used to study light with wavelengths of around 500 nm, a spectral resolution of 500 would correspond to being able to distinguish two idealized spectral lines that were separated in wavelength by 1 nm. The dispersions of astronomical spectrographs range from about 100 nm mm^{-1} to about 0.01 nm mm^{-1} and their resolutions from about 10 to about 100 000.

Spectroscopic Binary Stars

Historically, spectroscopic binary stars were binary systems whose nature was discovered by the changing DOPPLER EFFECT or shift of the spectral lines of one or both of the component stars. The observed Doppler shift is a combination of that produced by the constant RADIAL VELOCITY (i.e. line-of-sight velocity) of the center of mass of the whole system, and the variable shift resulting from the orbital motion of the component stars about that center of mass. If the variable orbital component is large enough and the two stars are comparable in luminosity, then two spectra are periodically seen and can be measured, although the system appears as a single star in even the largest telescopes. (Sometimes only one star is bright enough for its spectrum to show in the combined light, but still the variable radial velocity of that one star can be measured. Extreme examples of such 'single-spectrum' systems are provided by the planetary systems discovered in recent years around several stars other than the Sun.) Spectroscopic binaries, therefore, are distinguished from visual binaries, the components of which can be resolved, often by quite small telescopes.

Astronomers were not able to detect spectroscopic binaries until astronomical spectroscopy had been developed sufficiently for reliable measurements of radial velocity to be possible. This, in turn, depended on the application of photography to such measurements, so that no spectroscopic binaries were known until late in the 19th century. In 1889, Pickering in Harvard and Vogel in Potsdam independently published radial-velocity studies of Mizar and ALGOL, respectively, which thus became the first two known spectroscopic binaries. Visual binaries, on the other hand, were known at least from the late 18th century, and their study became a significant part of astronomy after the publication in 1803 of an important paper by Sir William Herschel in which he announced that the two components of Castor which he recognized were in orbital motion about their center of mass (see VISUAL BINARY STARS). Herschel, in fact, coined the term 'binary star' to describe this kind of association of two stars. Interestingly, we now know that each of those visual components of Castor is itself a spectroscopic binary, and these two bright binaries are also accompanied by a more distant faint spectroscopic binary, YY Geminorum. The first 'binary' system to be discovered, therefore, is in fact a sextuple system.

A third kind of binary—ECLIPSING BINARY STARS—has also long been recognized. John Goodricke, again in the late 18th century, suggested that the light variations in Algol might arise from periodic eclipses of the primary star by 'a large body'. His conjecture was not confirmed until Vogel's work showed it to have been correct, so the serious study of eclipsing binaries began at about the same time as that of spectroscopic binaries. It should be immediately obvious that the distinction between these two classes is quite artificial. All eclipsing binaries are potentially spectroscopic binaries, although it is hard to observe spectroscopically, at adequate dispersion, the faintest ones known—and that was especially true when we were completely dependent on photographic emulsions for recording spectra. Similarly any spectroscopic binary would display eclipses, if its orbit were so oriented that each component star passed between us and the other one, once in each orbital period. The methods of observation and analysis are very different for spectroscopic and eclipsing binaries, however, and it is often convenient in text-books and encyclopedias to treat them as two distinct classes. Nevertheless, whenever possible, spectroscopic and photometric observations should be discussed together in the analysis of any given binary system.

It is less obvious whether visual and spectroscopic binaries are really distinct classes or, again, merely appear to be so because of the limitations of the methods of observation. Most visual binaries have orbital periods measured in years, decades or even centuries. The overwhelming majority of spectroscopic binaries have periods less than 100 days and several well-defined subclasses have periods of much less than a day. This large range of periods between visual and spectroscopic binaries corresponds to a similarly large range of separations and suggests that there might be a real physical distinction between close (i.e. spectroscopic and eclipsing) binaries on the one hand, and wide (i.e. visual) binaries on the other (see CLOSE BINARY STARS). The notion of such a distinction gained strength from the fact that, for a long time, few binaries were known with orbital periods in the range between those of the two apparent classes. In recent decades, however, improvements in both the speed and precision with which we can measure radial velocities have permitted the detection of the slow, small- amplitude variations to be expected from binaries in the 'missing' period range. At the same time, the development of, first, speckle interferometry (see SPECKLE IMAGING OF BINARY STARS) and, more recently, interferometry with optical arrays has permitted the resolution of pairs that were previously considered long-period spectroscopic binaries. The apparent minimum in the period distribution is by no means as clear as was once thought. Whether or not there is a real distinction between close and wide binaries is perhaps not finally decided, but evidence against one is mounting and it is this writer's opinion that such a distinction does not exist. Again, whenever possible, spectroscopic observations, that reveal the projection of the orbital motion on the line of sight, and visual or other observations, that reveal its projection on the plane of the sky, should be analyzed and discussed together. We may, perhaps, re-define spectroscopic binary systems as binary systems in which the radial velocity of at least one component can be measured, regardless of whether or not the components are resolved.

Binary systems offer many problems of their own for study, such as their origin, evolution and, in the close pairs, the mutual non-gravitational interactions of the components. Historically, however, the main motive for studying binaries of all kinds has been the opportunities

they provide for the determination of stellar properties, particularly stellar masses. Spectroscopic and eclipsing binaries are specially attractive in this respect, since their relatively short orbital periods enable data to be accumulated much more quickly for them than for visual binaries. For the best results, however, many precautions must be taken to ensure that the measured velocities are as precise as possible and do indeed correspond to the velocities of the centers of mass of the component stars. If observed values of stellar mass are to be of any use in the testing of theories of stellar structure and stellar evolution, the most precise measurements possible must be made of the radial velocities, and the systems chosen for measurement must be free of the complications found in systems in which the components are mutually interacting. For this reason, the best mass determinations come only from the so-called detached binary systems (see BINARY STARS: DETACHED).

Spectroscopic binary systems form a considerable fraction of the stellar population and, contrary to earlier beliefs, there is no particular evidence that their numbers are fewer among the late-type stars than among those of early type. If all known eclipsing binaries were included, the total number of known and suspected spectroscopic binaries would be very large. A compilation of spectroscopic binaries with known orbital elements (see below), published in 1988, contained information for over 1400 systems. Some of these may eventually be found not to be binaries at all, but other known systems were missed in the compilation. The observational effort put into the detection and measurement of new systems since then has greatly intensified and a rough estimate would be that the number of systems with known orbital elements is now double the 1988 number. Stellar multiplicity is not confined to binary systems: many binaries belong to more complex groupings—as already mentioned, Castor is a sextuple system. More common are triple systems, especially those in which a close pair is accompanied by a more distant companion. It is intuitively obvious that such a configuration is relatively stable since, at large distances, the close pair acts gravitationally almost as a mass point. If a visual orbit is known for the distant companion, the total mass of the triple system may be obtained and the individual masses of all three components, even if the close pair is not eclipsing. The existence of multiple systems is of significance for theories of binary formation (see CLOSE BINARY STARS: FORMATION AND EVOLUTION).

The orbital period

It should now be clear that the orbital period is one of the most important things to be determined for any kind of binary system. For spectroscopic binaries, the basic observational data consist of a series of measurements of the radial velocity (usually expressed in km s^{-1}) of one or both components at given times. Unless the orbital period is already known, the times are likely to be arbitrarily spaced. Often, the period is known, at least approximately, either from earlier spectroscopic observations or from photometric observations of an eclipsing binary or from visual observations. If the period is not known, the first step is to determine it. This used to be more of an art than a science, but modern computers have made possible extensive series of trial and error, and most observatories at which binaries are routinely studied have programs available that will search for all possible periodicities in a given set of data and give an estimate of the significance of those found. Sometimes the program will indicate two or more possible periods—in which case future observations can be planned to choose between them. Even with computer aid, however, the investigator must be on guard against possible erroneous periods. A multiple or submultiple of the true period may be found, for example. Confusion is particularly likely if the two components have very similar and almost equally strong spectra, since there may be doubt at any phase at which both spectra can be seen which one is the primary (i.e. more luminous) component. More subtle are the errors that creep in if the true period is close to a sidereal day. Since observations are often made at just such an interval, a spurious (or so-called *alias*) longer period may be found, imposed on the data by the pattern of observing. The same effect can work in reverse, a long-period system appearing to have a period close to a sidereal day.

Once the orbital period, P, has been found (usually it is expressed in days) the phase ϕ of an observation made at time t can be found from the fractional part of the expression

$$(t - t_0)/P$$

where t_0 is some convenient zero of time—it might be the time of the first observation or, for an eclipsing binary, the time of the middle of the deeper eclipse. Clearly ϕ always lies between 0 and 1. It is now possible to plot the observed velocities against the phase to give the velocity curve of the binary. This is a representation of the observed velocity variation as if all the observations had been made in one orbital cycle (similar to the light curve of an eclipsing binary) and is the first step to determining the other characteristics of the system (see figure 1).

It often happens, even for a newly observed binary, that a few older observations of the star exist. They are sometimes useful for refining the value of the orbital period since they give isolated velocities at some time well in the past and can be used to estimate the number of cycles between the two sets of observations and therefore to improve the preliminary value of the period. A word of warning is again necessary, however: orbital periods either can appear to vary or actually do vary. If the binary revolves around its center of mass with a third star (as we have seen, a not uncommon situation) the orbital period will appear to vary cyclically because of the changing light-travel time across the larger orbit. The orbital period of a binary will also appear to vary cyclically if the major axis of the binary orbit (the line of apsides) is rotating because of tidal interaction between the components. Finally, in systems in which the stars are interacting by mass transfer

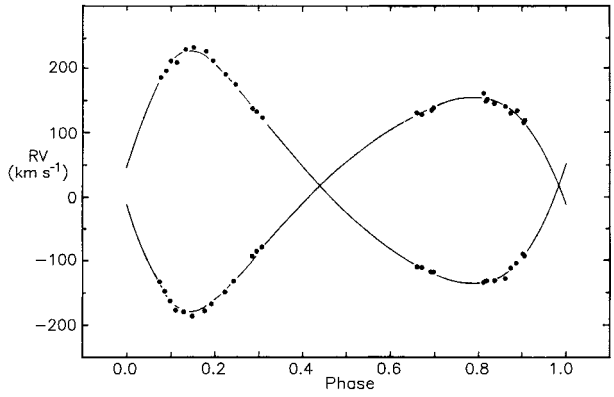

Figure 1. A modern velocity curve of the eclipsing and spectroscopic binary QX Carinae; reproduced with permission from Andersen J *et al* 1983 *Astron. Astrophys.* **121** 271–80. The orbital eccentricity is 0.28 and the longitude of periastron 124° for the primary star.

from one to the other, or in which mass is leaving the system, the orbital period really will change, usually in an irregular fashion. It used to be fashionable to quote orbital periods to very many decimals of a day, but such optimism is rarely justified.

The orbital elements

Once the orbital period is known and the velocity curve has been drawn, we can use the latter to determine the other characteristics of the orbit, which will in turn lead us to the goal of determining the masses of the component stars. As with planetary orbits in the solar system, the orbit is completely known if certain quantities called the ORBITAL ELEMENTS are known. Two angles are needed to define the orientation of the orbital plane in space, a third angle defines the orientation of the major axis of the elliptical orbit in that plane, a quantity e, lying between 0 and 1, defines the eccentricity of the orbit and the major semiaxis, a, gives the size of the orbit. It is also necessary to specify where a star is in the orbit and this can be done if the time of periastron passage is known. In planetary orbits, it is not necessary to specify a and P separately; they are related by KEPLER'S THIRD LAW

$$a^3/P^2 = \text{constant}.$$

The mass of the Sun is overwhelmingly greater than that of any of the planets, so the ratio just given is constant to a very high degree of precision. In binary orbits, however, with two comparable stellar masses moving under their mutual gravitation, we must use the generalized form of Kepler's law:

$$\frac{a^3}{P^2} = \frac{G}{4\pi^2}(m_1 + m_2) \tag{1}$$

where m_1 and m_2 are the masses of the two stars (usually m_2 is less than m_1) and G, of course, is Newton's constant of gravitation. Since m_1 and m_2 are not known in advance, a and P are usually regarded as separate elements. In summary, we seek to know for a binary orbit the following.

- ☊ the longitude of the ascending node (the point in the orbit at which the receding star crosses 'the plane of the sky').
- i the inclination of the orbital plane to the plane of the sky.
- ω commonly called the longitude of periastron, although by strict analogy with the practice in planetary astronomy that term should be reserved for ω+☊. The angle ω is the angle between the direction of the ascending node and the direction of periastron.
- e the orbital eccentricity.
- a the major semiaxis.
- P the orbital period.
- T the time of passage of the two stars through the periastron point.

In addition, for spectroscopic binary systems we usually consider as an element

- V_0 the radial velocity of the center of mass of the system. Note, however, that this quantity is variable in a triple system and that may cause problems if the interval covered by the observations is an appreciable fraction of the longer orbital period.

These quantities refer to the relative orbit of one star with respect to the other. If we are interested in the absolute orbits of either or both stars, relative to the center of mass of the system, we can distinguish the elements for each component by the suffixes 1 and 2. Clearly, P must be the same for each component and ☊, i, e, T and V_0 should be, while ω_1 should equal $\omega_2 + 180°$. In practice accidental and systematic errors in the observations will often lead to slightly different values of these elements for each component. We finally note that

$$a = a_1 + a_2$$

and, by simple moments,

$$\frac{a_1}{a_2} = \frac{m_2}{m_1}. \tag{2}$$

Determination of the orbital elements

The basic equation for the radial velocity, V, of a binary component in its orbit is

$$V = V_0 + Ke\cos\omega + K\cos(v + \omega) \tag{3}$$

where $2K$ is the total observed range of radial velocity and v is the true anomaly in the orbit, i.e. the angle between the radius vector at time t and the direction of periastron. It is simple to compute the mean anomaly, M (in radians), at any time t, since

$$M = \frac{2\pi}{P}(t - T)$$

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

and v and M are related by a well-known series expansion in e or, less directly, by Kepler's equation. It can also be shown that

$$K = \frac{2\pi a \sin i}{P(1-e^2)^{1/2}}. \tag{4}$$

We thus see from equation (3) that radial-velocity observations by themselves give us no information about the angle ☊. (They do, however, when combined with visual or interferometric observations, which define the line of the nodes, tell us which of the two nodes is the ascending one.) We also see that we cannot separate $a \sin i$ since, by eliminating P from equations (1) and (4), we find, for a given eccentricity and total mass,

$$K = \text{constant} \times a^{-1/2} \sin i$$

and we do not know whether a small K arises from a large a or a small $\sin i$. However, if i is known from photometric, visual or interferometric observations, then a can be determined and hence, by equation (1), the total mass of the system. Equation (2) then serves to give us the individual masses.

The earliest methods of determining orbital elements were all graphical, a method devised by Lehmann-Filhés in 1894 being the most popular. Even today, an experienced investigator may roughly estimate the orbital elements from the appearance of the velocity curve. For example, if the latter is sinusoidal, the orbit is circular (and V_0 is then simply the mean observed velocity), and the greater the departure from a sinusoidal curve, the greater is the orbital eccentricity. The condition for finding V_0 if the orbit is eccentric is that the areas between the V_0-axis and the velocity curve lying above and below the former should be equal. If the velocity curve is symmetrical about the maximum observed velocity, then $\omega = 0^\circ$ (by convention, ω is zero when the major axis of the orbit is perpendicular to the line of sight and the ascending node coincides with periastron). If the velocity curve is symmetrical about the V_0-axis, but the ascent from minimum to maximum observed velocity takes longer than the following descent, then ω is 90°. Again, the greater the disparity between the two times, the more eccentric the orbit (see figure 2).

Such visual estimates are, of course, only of use as a rough guide to the investigator, and the graphical methods of determining orbital elements have become of historical interest only. It is important to use a fully objective computational method that will also give realistic values for the uncertainties in the elements. Lehmann-Filhés showed how his method could be adapted to a least-squares solution, although he believed (correctly for his time) that such a solution would rarely be worth the trouble of making it.

Equation (3) cannot be directly adapted to least squares since it is not linear in the unknowns, which are often of very different magnitudes, and the unknowns

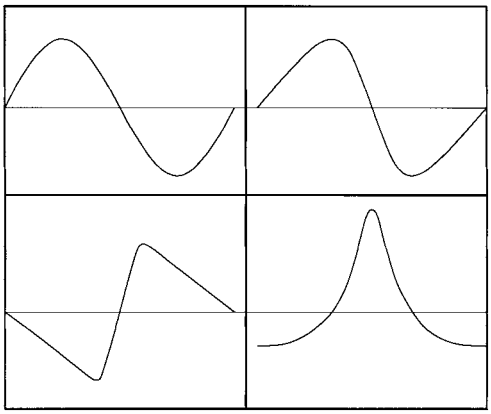

Figure 2. Schematic velocity curves for (upper left) a circular orbit, (upper right) an elliptical orbit with $e = 0.25$ and $\omega = 90^\circ$, (lower left) an elliptical orbit with $e = 0.5$ and $\omega = 270^\circ$ and (lower right) an elliptical orbit with $e = 0.5$ and $\omega = 0^\circ$. The scale of velocity is arbitrary. The horizontal line represents the V_0-axis, velocity of the center of mass of the system. In the first two elliptical orbits, periastron passage occurs when the steeper branch of the velocity curve crosses the V_0-axis, and in the last at the time of maximum velocity.

T and P appear in it only implicitly. Lehmann-Filhés differenced the equation and collected all the corresponding terms together to give

$$\begin{aligned}\Delta V = {} & \Delta V_0 + (\cos u + e\cos\omega)\Delta K - (\sin u + e\sin\omega)K\,\Delta\omega \\ & + \left(\cos\omega - \frac{\sin u \sin v}{1-e^2}(2 + e\cos v)\right) K\,\Delta e \\ & - \sin u(1 + e\cos v)^2 (t - T)\frac{K\,\Delta\mu}{(1-e^2)^{3/2}} \\ & + \sin u(1 + e\cos v)^2 \frac{K\mu\,\Delta T}{(1-e^2)^{3/2}}\end{aligned} \tag{5}$$

where, for brevity, $u = v + \omega$, $\mu = 2\pi/P$. In practice, scale factors are often introduced into the coefficients of Δe, $\Delta\omega$ and ΔT, so that all the unknowns will be similar in magnitude (the solution might give, for example, $100K\,\Delta\omega$). Although, in principle, a correction can be computed to the period (through $\Delta\mu$) that is rarely done (i.e. $\Delta\mu$ is assumed to be zero). Including a correction for the period reduces the weight of the whole solution and, if the period needs refinement, this can often be better achieved by the method already described. To make the solution, one must obviously begin with preliminary values of the elements, and the quantities ΔV are the residuals of the observed velocities from those computed with the preliminary elements, while the other differences are the corrections to be made to the preliminary values of the several elements. In the days of hand-operated, or even electrically driven, calculators, it was worthwhile to spend some time deriving as good a set of preliminary elements as possible by some graphical method, in order to avoid the need to iterate with a second solution to find the final elements. Nowadays, however, since electronic

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

computers can perform several iterations very quickly, rough estimates of V_0, K, e, ω and T are often sufficient to start the solution.

Equation (5) works well if the orbital eccentricity, e, is appreciable. When e is small, however, the coefficients of $\Delta\omega$ and ΔT become more nearly proportional to each other, and the system of normal equations is indeterminate when $e = 0$. Since a very considerable portion of spectroscopic-binary orbits is circular or nearly circular, that is a serious defect of the Lehmann-Filhés method. Until the 1940s it was common practice to fix the value of T or ω arbitrarily and to solve for the other elements. This led to largely meaningless values of T and ω and, more seriously, to gross underestimates of the uncertainties of those two quantities. Solutions made in this way may still mislead the unwary investigator who happens to find one of the original papers and is unfamiliar with the early practice. Extensive modern recomputations have been made both by Luyten and by Lucy and Sweeney.

In 1941, Sterne published an alternative method of orbital solution, specifically designed to overcome the problem posed by small eccentricities. He gave up the attempt to determine T and ω directly, when the eccentricity was small. Instead he defined a quantity, L, called the mean longitude, where

$$L = \omega + M$$

and M is again the mean anomaly. Sterne also defined a time T_0 at which the mean longitude is zero, so

$$L = \mu(t - T_0).$$

When the orbit is exactly circular, then T_0 is the time of nodal passage, or of maximum radial velocity. For small eccentricities, the equations of condition then take the form

$$\Delta V = \Delta V_0 + \cos L\,\Delta K + \cos 2L\,Ke\cos\omega + \sin 2L\,Ke\sin\omega + \sin L\,\mu K\,\Delta T_0 - \sin L\,(t - T_0)K\,\Delta\mu. \quad (6)$$

Once again, in practice, only rarely is the term $\Delta\mu$ included, and scaling factors may be needed to bring all the unknowns to the same order of magnitude, but $e\cos\omega$, $e\sin\omega$ and T_0 may be determined without difficulty, even when e is small, and from them e, ω and T may be found. Equations (5) and (6) together should suffice for the determination of all orbital elements.

It may turn out, however, that even if an apparently significant value is found for e, the orbit should be treated as circular. The representation of a given set of observations is *always* improved by the use of an extra parameter; the question we have to ask is whether that improvement carries with it any physical significance for the orbit. This question was answered in 1971 by Lucy and Sweeney, who devised a test based on computing the amount by which the residuals are decreased, when an eccentricity is used to represent the observations, compared with those obtained from a circular orbit. They found, and subsequent experience has confirmed, that often a computed eccentricity should be ignored, even if it meets the usual criterion for statistical significance.

Determination of the masses

Our chief interest in obtaining the orbital elements is to determine the masses of the components of the binary system. We have already seen from equation (1) that the total mass is proportional to a^3, and from equations (2) and (4)

$$K_{1,2} \propto a_{1,2} (\propto m_{2,1}).$$

Thus we have two equations for the masses of the two stars in the system (provided that we know the orbital inclination i). Usually K is expressed in km s^{-1}, P in days, a in km and m in units of the solar mass (2×10^{30} kg). These units may seem a little strange to those brought up in a strict SI system, especially since two different units are used for time. They have been found convenient, however, and, in these units,

$$a_{1,2}\sin i = 13\,751(1 - e^2)^{1/2} K_{1,2} P$$
$$m_{1,2}\sin^3 i = 1.0385 \times 10^{-7}(1 - e^2)^{3/2}(K_1 + K_2)^2 K_{2,1} P.$$

Note that m is proportional to K^3. That is the principal reason why great care is needed to determine $K_1 + K_2$ as precisely as possible, since the percentage error in $m_1 + m_2$ is at least three times that in $K_1 + K_2$. To make useful comparisons with computed stellar models, a precision of about 1% in the individual masses is needed. Challenging though this is, it has now been achieved for an appreciable number of systems.

If the two stars are very different in luminosity, then the spectrum of only the brighter can be seen and measured. Obviously, the total mass of the system cannot then be determined, but the so-called mass function, $f(m)$, can be computed from

$$f(m) = \frac{m_2^3 \sin^3 i}{(m_1 + m_2)^2} = 1.0385 \times 10^{-7}(1 - e^2)^{3/2} {K_1}^3 P.$$

Even this permits some inference to be made about the masses, since we can write

$$f(m) = \frac{m_2 \sin^3 i}{(1 + m_1/m_2)^2}.$$

The vast majority of stars obeys the mass–luminosity relation, the more massive star being the brighter. Therefore m_1/m_2 is usually greater than unity and the denominator in equation (7) is thus greater than 4. In general, each star in a single-spectrum binary system must have a minimum mass of $4f(m)$. There are occasional exceptions. In β Lyrae, the spectrum of the more massive component is largely concealed by matter surrounding that star—for a long time, no certain detection of that spectrum was made. The system is massive, but some astronomers who studied the system were misled into supposing that it was several times more massive than it really is.

Modern problems

It has been tacitly assumed in most of the foregoing that the measured radial velocity of a binary component is at all times that of the center of mass of the star. When that is so, good spectroscopic observations combined with good photometric observations (if the binary is eclipsing) can lead to the determination of not only precise stellar masses but also precise stellar radii and luminosities. Such binaries are our principal source of fundamental stellar data and are of fundamental importance in providing observational tests of theories of stellar structure and evolution. In many of the most interesting binaries, however, the measured radial velocity may differ from that of the center of mass of the star. This can come about for any of three reasons, all of which may have effect simultaneously in some binary systems: (i) the surface of the binary component is irradiated by that of the other and the isophotes of the surface of the irradiated component are no longer concentric circles about the center of the stellar disk ('reflection effect'); (ii) one or both components are non- spherical in shape, because of tidal or rotational distortion and, since the luminous flux emerging from any point on the stellar surface is proportional to the local value of the acceleration due to gravity, the stellar isophotes again depart from circular symmetry ('ellipticity effect'); (iii) streams of matter between or around the components contribute to the line profiles in the observed spectrum—especially to those of the hydrogen lines—so that the measured velocity is affected by the presence of the stream and is not simply the orbital velocity of the star.

The reflection and ellipticity effects were well known early in the history of spectroscopic binaries, because the same two underlying causes also affect the light variations of eclipsing binaries. They affect the measured radial velocity because, in each case, they deflect the effective light center of the stellar disk from the geometrical center so that any rotational velocity the star may possess contributes to the observed velocity. Both effects are present in any binary system in which the separation of the two components is no more than a few times their own radii. They become very pronounced, however, in W Ursae Majoris systems. These are binaries with periods of less than a day whose components are so highly distorted as actually to be in contact over a small region of their surfaces. The velocity curves often show appreciable departures from the kind of variation expected from a star moving in a Keplerian ellipse and only recently has it become possible to use the observed velocities to obtain reliable orbital elements for these systems. This is done by computing the flux distribution over each stellar surface and then computing the expected departures of the measured velocities from simple Keplerian motion and comparing the computations with the actual observations (figure 3).

The distortion of velocity curves by the effects of circumstellar matter was first pointed out by Struve in the 1940s. It was especially noticeable in systems resembling Algol. The velocity curve might still look Keplerian in form but suggest an orbital eccentricity that could not be reconciled with the timing of eclipses. (In a circular orbit, the eclipse of one star necessarily occurs halfway between two successive eclipses of the other; in an elliptical orbit that is true only if ω is equal to 90° or 270°.) In fact, the first clue to this kind of distortion emerged in 1930 when E F Carpenter found a large orbital eccentricity for the velocity curve of U Cephei that completely contradicted the photometric evidence, but the interpretation of this result had to await the work of Struve some 10–15 yr later. Struve also predicted that novae and recurrent novae would be found to be members of binary systems—a prediction first confirmed by Kraft from ground-based observations, and then more spectacularly by the discovery of x-ray binaries from space. Such systems, now usually referred to as CATACLYSMIC BINARIES, contain compact components (WHITE DWARFS, NEUTRON STARS or possibly even BLACK HOLES). Streams of gas within these systems reach very high velocities and create 'hot spots' when they collide with the stellar surfaces or with each other. These hot spots can dominate the light of the system, at least at some phases, so both the observed light and velocity variations depart considerably from the expectations based on simple binary motion. Although Struve's hypothesis of gas streaming long remained controversial, modern observations in the ultraviolet, x-ray and radio wavelengths, as well as in the optical region of the spectrum, have left little room for doubt of its basic correctness. Indeed, modern techniques of tomographic analysis (a principle also used in medicine in which 'pictures' taken from several angles—as the binary revolves—are built up into a three-dimensional representation) have made it possible to begin to understand the characteristics of the gas streams themselves.

The gas streams transfer mass between the components of a system, or remove it from the system altogether. These streams arise because evolving stars expand and the presence of a companion limits the amount by which a star can expand and remain stable. Even in systems in which the components are far enough from each other to permit considerable expansion without destroying each other's stability, tidal action between the enlarged components may modify their individual evolution. A possible example of this is provided by the well-known, bright binary CAPELLA, which can be observed both as a spectroscopic and interferometric binary.

In binaries with eccentric orbits, tidal action often betrays its presence by the rotation of the major axis of the orbit, or the line of apsides, which has already been mentioned. The presence of a third body, or general relativistic effects, can also give rise to apsidal rotation, but in most systems tidal distortion is the most important cause. It produces apsidal rotation because stars are not infinitely concentrated to their centers, and do not, therefore, act gravitationally exactly as mass points. This has been known for a long time, and the basic formulae were published by H N Russell in 1928. Because apsidal periods are long, however, and the rate of apsidal rotation is proportional to the fifth power of the stellar radius expressed in units of the separation of the two stars, only in recent decades has sufficient precision been reached for useful deductions from the observations to be possible. Apart from the observation of non-radial oscillations and solar neutrinos, which still give problematical results, measurements of apsidal motion provide the only direct means we have of probing the internal structure of a star. Results tend to confirm the predictions of stellar models.

In most binary systems displaying apsidal motion, the relativistic contribution is small compared with the Newtonian contribution arising from the facts that the stars are not mass points and are tidally distorted. In some close massive systems, however, the relativistic effect can be significant, or even dominant. In DI Herculis, for example, it is the Newtonian effect that is expected to be insignificant compared with the relativistic. Surprisingly, the observed rate of motion is much less than relativity predicts, which led some people to question that theory. On the other hand, binaries containing pulsars provide a very sensitive test of relativity, because the orbital elements can be determined with much greater precision from the variations in the arrival times of the pulses than from radial velocities, and apsidal motion is much more rapid in these systems (about 90° in 20 yr in PSR 1913+16) than in ordinary binaries. There is, however, an even more important test of relativity that can be made with this system—the change in orbital period caused by gravitational radiation from the binary. The measured rate agrees to within half a per cent with the predicted rate. Such close agreement leaves little room, if there had been any earlier, to doubt the correctness of general relativity. The result earned a Nobel prize for Taylor and Hulse who obtained it.

Bibliography

The best review of current state of our knowledge of stellar masses and dimensions and its implications for theories of stellar evolution is given by Andersen in

Spectrum (pl: spectra)

In general terms, the distribution of intensity of electromagnetic radiation with wavelength. Thus when we examine the spectrum of star we are looking at a map of this brightness distribution. In the context of visible light, the visible spectrum is the band of colors produced when white light is passed through a glass prism, which has the effect of spreading out light according to wavelength. From long to short wavelength the colors so obtained are red, orange, yellow, green, blue, indigo, violet. These are the colors that make up the rainbow (although in practice not all of these colors may be discerned).

Such a spectrum is a continuous spectrum, or continuum (i.e. a continuous distribution of radiation over all wavelengths) and is emitted by a hot solid body or hot gas under high pressure. A continuum is also emitted by the free–free radiation and synchrotron radiation processes, but the form of the spectrum is different in each case.

A line spectrum is emitted by a gas under low pressure. If an electron in a high-energy orbit (i.e. of large radius around the atomic nucleus) makes a downward transition to an orbit of lower energy, then the difference in energy between the two orbits, ΔE, is released as a quantum (or 'packet') of radiation having a particular wavelength, λ, and frequency, f. The relationship between ΔE, λ, and f is as follows:

$$\Delta E = hf = hc/\lambda,$$

where c is the velocity of light and h is Planck's constant.

Each possible transition results in its own characteristic spectral line. In the hydrogen atom, the simplest atom, there are a number of series of spectral lines due to the possible transitions. For example, all the possible transitions down to the lowest energy level give rise to the Lyman series of emission lines at ultraviolet wavelengths, and all the possible transitions down to the second energy level (the first excited level gives rise to the Balmer series of lines in the visible spectrum). These lines are characteristic of hydrogen and hydrogen alone. Heavier elements have more complex spectra, and the spectra of molecules are complicated by vibrational and rotational energy states.

Dark absorption-line spectra are produced when atoms and molecules absorb radiation (from a background source) at the same wavelengths at which emission takes place by the mechanism described above. For example, a dark line of wavelength λ is produced when electrons of a given element absorb energy ΔE and make *upward* transitions from lower to higher energy orbits.

Spectrum-X Gamma

Much delayed international x-ray mission. Originally scheduled for launch in 1993, unlikely to fly before 2000. Carries the Soviet–Danish Roentgen Telescope (SODART) for imaging, as well as spectroscopes for extreme ultraviolet and gamma ray studies. Also carries two US instruments and the Joint European Telescope for X-ray astronomy (JET-X) to study faint x-ray sources.

Spencer Jones, Sir Harold (1890–1960)

Astronomer, born in London, England. He was chief assistant to Frank Dyson at Greenwich and worked at the Royal Observatory at the Cape of Good Hope. Following in the tracks of DAVID GILL, he repeated Gill's photographic survey of the southern sky (*Cape Photographic Catalogue*, CPC). He then organized the international project to determine Earth–Sun distance by repeated measurements of the asteroid Eros during its close approach to the Earth in 1930–1 (if the distance to any one object in the solar system can be determined, then the distances between the rest can be found by Kepler's laws). Under his direction, the Royal Observatory at the Cape photographed Eros more than 1200 times; he reduced this and the equal amount of data from other observatories—but it transpired that Gill was nearer the mark. Spencer Jones returned to Greenwich and became Astronomer Royal in 1933. Probably his most significant discovery was of the irregularities in the Earth's rotation, which he proved by showing that the planets all seemed to be together in pulling ahead and falling behind their calculated positions at given times as measured by the Earth's rotation. He replaced the concept of 'universal time,' based on Earth's rotation, by 'ephemeris time', a system of time measurement at first based on the motion of the planets in their orbits and then superseded by the frequency of oscillations in quartz and then cesium atoms. Having experienced the clarity of South African skies, he was depressed by observing conditions in London, and set in train the removal of the Royal Observatory to the Sussex countryside.

Spherical Aberration

The inability of a spherical lens or mirror to bring all parallel rays of light to the same focus. When light reflects from a mirror, the surface of which has a shape that is part of a sphere, the position at which an incident ray is focused depends on its distance from the optical axis (the line that passes through the center of the mirror, perpendicular to its surface). Rays that reflect from points closer to the rim of the mirror are brought to a focus closer to the mirror's surface than rays that reflect from points closer to the optical axis. A similar effect applies to rays of light passing through a simple lens, the surfaces of which have shapes that are parts of spheres.

Spherical aberration causes the image of a point source of light (such as a star) to be spread out into a disk. Between the focal positions for the central and peripheral rays there is a plane at which the smallest image, known as the circle of least confusion, occurs. In the case of a mirror, spherical aberration can be eliminated for rays parallel to the optical axis by making its surface a paraboloid (the profile of a cross section of such a surface is a parabola). For a lens, the effects can be reduced by giving its two surfaces different radii of curvature (the radius of curvature is the radius of the circle that matches the curve of the surface).

As with chromatic aberration (a defect peculiar to lenses), the effects of spherical aberration can be reduced by using lenses with very high focal ratios. During the seventeenth century, this approach led to the construction of very long and unwieldy refractors.

Spica

The star α Virginis, a blue-white giant star, spectral type B1V, of apparent magnitude 0.98. At a distance of 260 light-years, parallax 0.012″, its absolute magnitude is −3.5. The name means 'the Spike' or 'Ear of Wheat', which the Virgin Mary is portrayed holding in the ancient constellation figures.

Spica is a rotating ellipsoidal binary, comprising two large, close components which are elongated towards each other by the strong gravitational attraction between them. Its magnitude varies very regularly between 0.95 and 1.05 over a period of 4.0146 days, as a result of the changing combined surface area of the component stars presented towards us. The primary component is also a regular pulsating variable with a period of 0.17 days.

Spiral Arms

Lanes of gas, dust and hot young stars that spiral outwards from the central bulges of spiral and barred spiral galaxies. The most prominent features of spiral arms are clusters and associations of O and B type stars (highly luminous, high-temperature stars) and HII regions (luminous nebulae), both of which are indicative of recent and ongoing star formation. At radio wavelengths, spiral arms may be identified by measuring the distribution of neutral hydrogen clouds, which radiate at a wavelength of 21 cm, and molecular clouds. Infrared observations reveal clouds of warm dust heated by newly formed stars along the spiral arms.

In some galaxies ('grand design' spirals), the spiral arms are long, narrow and well defined, in others ('flocculent' spirals), they are more clumpy and fragmented, consisting of large numbers of shorter arm segments.

Within our own galaxy, the Milky Way Galaxy, lanes of dust absorb starlight and prevent optical astronomers from seeing stars in the plane of the galaxy at distances much beyond about 10 000 light-years. Nevertheless, enough O, B associations and HII regions can be seen to identify the spiral arms in the neighborhood of the Sun. Radio and millimeter-wave observations of emissions from hydrogen clouds and, more particularly, from molecular clouds, reveal the overall spiral structure. Our galaxy's spiral pattern consists of two or more major arms and a number of shorter segments, one of which—the Orion arm, or 'spur'—contains the Sun. The Sagittarius arm, which includes the stars and interstellar clouds that lie in the general direction of the constellation of Sagittarius, lies closer to the galactic center than the Orion arm and the Perseus arm lies further out.

The galaxy NGC 4622, imaged by the Hubble Space Telescope in 2002 appears to be rotating in the opposite direction to that which is expected. The clockwise rotation is puzzling because of the direction in which the outer spiral arms are pointing. Most spiral galaxies have arms of gas and stars that trail behind as they turn, but this galaxy has two leading outer arms that point toward the direction of the galaxy's clockwise rotation. To add to the conundrum, NGC 4622 also has a trailing inner arm that is wrapped around the galaxy in the opposite direction it is rotating. Astronomers suspect that NGC 4622 interacted with another galaxy as its two outer arms are lopsided, meaning that something disturbed it. NGC 4622 may have consumed a small companion galaxy. The galaxy's core provides additional evidence for a merger between NGC 4622 and a smaller galaxy. This information could be the key to understanding the unusual leading arms.

Spiral Galaxy

A galaxy in which a central bulge of stars is surrounded by a flattened disk that contains a spiral pattern of hot young stars and luminous nebulae. Within the Hubble classification scheme, spiral galaxies, denoted by the letter 'S', are categorized according to the size of the central bulge, the tightness of the spiral pattern and the degree of patchiness in the spiral arms. Sa galaxies have relatively large central bulges, tightly wound and relatively smooth arms. Sb galaxies have somewhat smaller bulges and more open arms that often contain conspicuous HII regions (luminous nebulae) and clumps of hot blue stars; Sc galaxies have small central bulges and loosely wound, 'knotty' arms that typically contain numerous HII regions and clumps of stars. Galaxies with clumsy, chaotic and poorly defined arms are called 'flocculent' spirals, while those with thinner, longer, well-defined arms are termed 'grand design' spirals.

Spiral galaxies contain significant quantities of gas and dust, the relative proportions (by mass) of gas to stars ranging from as little as 2%, for some Sa galaxies to 10–15% in Sc galaxies. The masses of spiral galaxies (i.e. the combined mass of the stars, gas and dust that they contain) range from about one billion (10^9) solar masses to several hundred billion (~4–10^{11}) solar masses, and their diameters from about 15 000 to about 150 000 light-years. Analyses of the rotation curves of spiral galaxies (plots of the rotational velocities at different distances from the centers of galaxies) imply that spiral galaxies contain up to ten times as much dark matter as luminous matter and that their overall masses, therefore, are up to ten times greater than the figures quoted above.

There are two principal candidate mechanisms to account for the existence of spiral structure—self-propagating star formation, and density waves. The self-propagating star formation theory suggests that within major regions of star formation, high-mass stars evolve rapidly and explode as supernovae, the blast waves from these events compressing neighboring gas clouds and triggering further star formation in that part of the galaxy. Within an extensive star-forming region, bright stars and HII regions (luminous nebulae) closer to the galactic center will move ahead of those that are further out, so drawing out the star-forming region into a curving arc. In this way, random bouts of star formation produce a succession of arc segments that make up the clumpy arms of flocculent spirals. According to the density-wave theory, the spiral arms are a wavelike pattern that moves through a galaxy, rather like ripples on a pond, causing stars and gas clouds to bunch together temporarily to form the spiral arms. Individual stars and gas clouds revolve round the center of the galaxy in their own orbits, slowing down and bunching together temporarily each time they encounter a density wave, just as vehicles slow down and bunch together at roadworks or lane closures, travel slowly through the resulting traffic jam, then speed up and spread out at the other end. When a gas cloud enters a spiral arm, it is slowed down and compressed. This initiates a bout of star formation, so giving birth to the hot young stars and HII regions that delineate the arm. The density waves themselves are probably initiated by the asymmetric gravitational field of a central bar structure or by gravitational disturbances caused by neighboring galaxies, or by a combination of both.

Although both processes may have a role to play in any galaxy, self-sustaining star formation seems more appropriate to flocculent spirals and density waves to grand design spirals.

The galaxy NGC 4622, imaged by the Hubble Space Telescope in 2002 appears to be rotating in the opposite direction to that which is expected. The clockwise rotation is puzzling because of the direction in which the outer spiral arms are pointing. Most spiral galaxies have arms of gas and stars that trail behind as they turn, but this galaxy has two leading outer arms that point toward the direction of the galaxy's clockwise rotation. To add to the conundrum, NGC 4622 also has a trailing inner arm that is wrapped around the galaxy in the opposite direction it is rotating. Astronomers suspect that NGC 4622 interacted with another galaxy as its two outer arms are lopsided, meaning that something disturbed it. NGC 4622 may have consumed a small companion galaxy. The galaxy's core provides additional evidence for a merger between NGC 4622 and a smaller galaxy. This information could be the key to understanding the unusual leading arms.

Sporadic Meteor

A meteor that does not belong to an identifiable meteor shower. The meteoroids that produce sporadic meteors are part of the zodiacal dust cloud, which pervades the inner solar system, and are swept up by the Earth as it proceeds in its orbit. On average about five sporadic meteors are visible from any given location on any clear night. The actual number varies with time of night and time of year. Sporadic meteors seen by an observer in the evening can be produced only by incoming meteoroids traveling fast enough to 'catch up' with the Earth, whose rotation is carrying the observer away from the direction from which the meteoroids are coming. But after midnight, when the Earth's rotation carries the observer into the dust cloud, the sporadic rate increases. The seasonal variation has to do with the altitude of the Earth's apex—the point on the celestial sphere toward which its motion at a given time appears to be taking it. The higher the apex is in the sky, the greater is the sporadic hourly rate. For northern-hemisphere observers the apex reaches its greatest altitude at the autumnal equinox and the *contemporaneous sporadic background* (the sporadic hourly rate at a specified time of year) is then 8–10 per hour. The apex is nearest the horizon at the spring equinox, when the rate is just 2–3 per hour.

Square Of Pegasus

A conspicuous asterism of four bright stars forming a square of approximately 15° a side, notable for the absence of any but very faint stars within it. It is formed by the stars β, α and γ Pegasi (apparent magnitudes 2.44, 2.49 and 2.83 respectively) and α Andromedae (magnitude 2.07), and is prominent in the evening sky in autumn.

SS Cygni

SS Cygni (SS Cyg) is a long orbital period ($P_{\rm orb} = 6.6$ h) cataclysmic variable of the dwarf nova (DN) subclass, characterized by semiperiodic brightness changes due to outbursts. This CLOSE BINARY STAR consists of a WHITE DWARF primary which accretes matter from a low-mass, ROCHE-LOBE-filling secondary star.

SS Cyg was discovered in 1896 by Miss Louisa Wells while examining Harvard College Observatory photographic plates. Wells noted that the star varied in photographic magnitude from 7.7 to 12.4. During the 1897 objective prism survey for the Henry Draper catalog, a spectrum of SS Cyg was obtained. However, it was not until detailed observational work in 1943 revealed radial velocity motions that SS Cyg was shown to be a spectroscopic binary, i.e. a close double star. SS Cyg was the second DN discovered; U Geminorum being the first, found by J R Hinds in 1855.

The DN subclass of cataclysmic variables consists of close binary stars in which the mass accreted from the secondary star forms a disk around the primary star. Semiperiodic outbursts, during which time the emitted light from the DN increases greatly, are the signature of a DN type of cataclysmic variable. The DN SS Cyg has outbursts about every 50 days which brighten the system from its normal quiescent level at visual (V) magnitude 11.7 to a maximum level near $V = 8.2$, a factor of 25 in brightness. From the Earth, we view SS Cyg at an inclination angle on the sky of 30°–60° and it is at an estimated distance of 150–180 pc.

At visual wavelengths, the emitted flux from SS Cyg is dominated by light from the ACCRETION DISK but contains a small contribution from the secondary star. The hot inner disk and the white dwarf dominate at ultraviolet wavelengths with the secondary star and the outer disk being the major contributors in the infrared. X-ray observations of SS Cyg imply that, during quiescence, the hot inner disk regions are likely to be a single-temperature plasma. During outburst, a spherical x-ray-emitting corona forms around the white dwarf and mass is lost from the system in the form of a wind. Extreme ultraviolet observations (70–130 Å) made at outburst show strong emission due to highly ionized Ne, Mg and Si produced within a region of temperature equal to 290 000 K.

The accretion stream, disk and hot spot

Figure 1 shows an optical spectrum of SS Cyg at quiescence. In the figure, it can be seen that the dominant spectral features are emission lines, due to hydrogen and helium, which are produced in the accretion disk and hot spot. These strong, broad emission lines allow determinations of many physical parameters within the binary, foremost of which are estimates of the stellar masses. As the binary rotates, the accretion disk follows the orbital motion of the white dwarf. Thus, measurements of the radial velocity changes of the disk emission lines provide an approximate tracer of the true

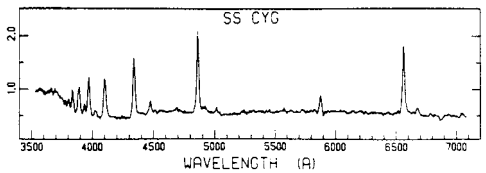

Figure 1. The optical spectrum (3500–7000 Å) of SS Cyg, shown during quiescence, is dominated by emission from the accretion disk. Prominent emission lines due to hydrogen (particularly Hα (6563 Å) and Hβ (4861 Å)) and weaker helium (He I (4471, 5876 Å)) are easily seen. The underlying continuum begins to rise at the blue end of the spectrum where the Balmer jump is seen in emission.

orbital motion of the primary star. Using Kepler's law, slightly reconfigured for our purposes, we have

$$\sin^3 i = \frac{K_1^3 P}{2\pi G M_2}\left(\frac{q+1}{q}\right)^2$$

where i is the binary inclination, M_2 is the mass of the secondary star, P is the orbital period, G is Newton's gravitational constant, K_1 is the observed maximum shift of the radial velocity curve, and q is the mass ratio of the binary defined as M_2/M_1. Typically, the orbital period and the K_1 amplitude are measured from observation, while M_2 is assumed[1] and i is approximated in various ways. The result is that q can be determined, and from it, the mass of the white dwarf ($M_{\rm WD}$).

The gas stream leaving the secondary star falls towards the primary but is curved in the direction of orbital motion owing to its stored angular momentum. This stream strikes the edge of the accretion disk and forms what is termed the hot spot. At the hot spot, the gas stream and the Keplerian orbiting accretion disk material mix, producing a region of enhanced density, temperature and light emission.

The material orbiting within the accretion disk slowly loses angular momentum through viscous heating and spirals inward, eventually accreting onto the white dwarf equatorial regions. The rate of quiescent mass transfer ($\dot{M}$) from the secondary star in SS Cyg is $8 \times 10^{-11} M_\odot$ yr^{-1} (5×10^{15} g s^{-1}), typical of DN with similar orbital periods. This value is not necessarily the rate of mass accretion onto the white dwarf surface, as the accretion disk provides a buffer and storehouse for the material. The accretion disk mass, $\sim 0.1 M_\odot$, remains nearly constant during interoutburst periods but some small fraction of it (~10%) is accreted onto the white dwarf during an outburst. Gravitational energy release by the accreted material is the cause of the disk heating and brightening observed during outburst. Accretion disks in DN have radii approximately given by $R_{\rm d}/a \sim 0.3$, where a is the distance between the two stars.

[1] A further relation can be derived which yields the radius of the Roche lobe of a secondary star given the binary orbital period. One then assumes the secondary star to be a main sequence star of this radius, hence a mass estimate can be made.

For SS Cyg, $R_d \sim 4.5 \times 10^8$ m, in good agreement with observation.

Models of accretion disks in long-period DN, such as SS Cyg, are based on the belief that the material within the disk is optically thick and mass and energy, within the disk, are conserved. This model, usually referred to as a α-disk model, predicts a temperature structure which varies with radius as

$$T_{\rm eff}(r) \propto (M_{\rm WD}\dot{M})^{1/4} r^{-3/4}.$$

In SS Cyg, we find that its accretion disk has a high temperature ($T \sim 20\,000$ K) inner (optically thin) edge, cooling to ~4000 K or less at the outer edge. Since optically thick material radiates as a blackbody, the output spectrum predicted from an accretion disk is simply a summation of various annuli, each of some characteristic emission temperature (see BLACK-BODY RADIATION). Thus, the output continuum flux distribution will be of the form

$$F_\lambda \propto \lambda^{-2.3}$$

in the optical and IR bandpasses.

As the material in the accretion disk and hot spot region interacts with itself, small brightness changes occur of order a few tenths of a magnitude. These changes occur randomly or, at times, with quasi-periodic time-scales, and are termed flickering. Flickering is a tell-tale sign of a stellar system in which accretion is occurring. Power spectral analysis of the flickering in SS Cyg has shown that the amplitude increases towards the blue, indicative of a higher level of activity occurring in the hotter, inner disk regions (see also CORRELATION FUNCTION AND POWER SPECTRA IN COSMOLOGY).

During minimum light, photometric observations of DN can be used to estimate the inclination of the binary system. This type of observation assumes that the photometric signature from the disk and hot spot can, in principle, be interpreted to indicate whether the accretion disk is seen edge-on ($i = 90^\circ$) or tilted at some angle. In SS Cyg, minimum light optical photometry generally shows no modulations, indicating a low inclination ($i \sim 38^\circ$); however, occasional low-amplitude humps appear in both the optical and the UV, implying a higher binary inclination, $i \sim 50^\circ$. This uncertainty in the inclination at which we view SS Cyg leads directly to an uncertainty in the masses derived for its stellar components.

Outburst behavior

SS Cyg is probably the best-studied DN, having photometric information available from before 1900 up to the present. Figure 2 presents a small segment of photometric data for SS Cyg showing a number of outbursts. Outbursts occur every 49.5 ± 15.4 days in SS Cyg and have durations which are near either 7–8 days or 15 days. Other DN, similar to SS Cyg, show this bimodal structure as well. Sometimes the outbursts in SS Cyg tend to occur in a 'short–long–short–long' sequence with the outburst amplitude being correlated with the time since the last outburst and the time until the next

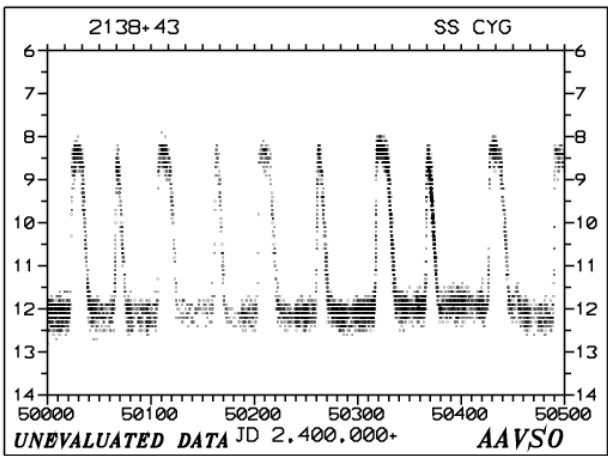

Figure 2. A typical 500 day light curve segment for SS Cyg. Notice that the outbursts are only semi-periodic and do not exactly alternate between long and short duration. The quiescent magnitude of SS Cyg is near 12 and the outbursts rise to near 8.5, a factor of about 25 in brightness. The x-axis is labeled in days starting with Julian day 2 450 000.

one. The brightest outbursts have an optical luminosity of $L_{\rm opt} \sim 5 \times 10^{34}$ erg s^{-1} or an integrated luminosity (over the entire outburst) of 3×10^{40} erg s^{-1}.

The cause of DN outbursts is thought to be a disk instability, not an increase in mass transfer from the secondary star. This disk instability, known as the thermal limit cycle, occurs when the material in the accretion disk has its local temperature and density values increased beyond some critical level (typically when $T > 8000$ K), causing a rapid ionization of the (mostly) hydrogen gas. This leads to a heating front which propagates throughout most of the disk, ionizing some fraction of it. The alternating 'long–short' outburst cycle is thought to be caused by this heating front moving throughout the entire disk at times and not making it to the outer disk edge at other times.

During outburst, optical oscillations have been seen in SS Cyg with periods of 7.3–10.9 s. These short-period modulations have also been seen at x-ray and EUV wavelengths. Because of their high frequencies, these brightness variations are thought to be associated with the very inner regions of the accretion disk close to or at the surface of the primary star.

The stellar components

SS Cyg contains a $(1.1 \pm 0.30) M_\odot$ white dwarf with a radius about equal to that of the Earth and with an effective temperature of 34 000–40 000 K. The mass-losing secondary star is a main sequence star of approximate spectral type K5 V with a mass of $(0.70 \pm 0.20) M_\odot$. The two stars orbit their common center of mass with a period of 6.6031 h, having a separation of only about the diameter of the Sun. Because of their close proximity and the gravitational influence of the primary, the secondary

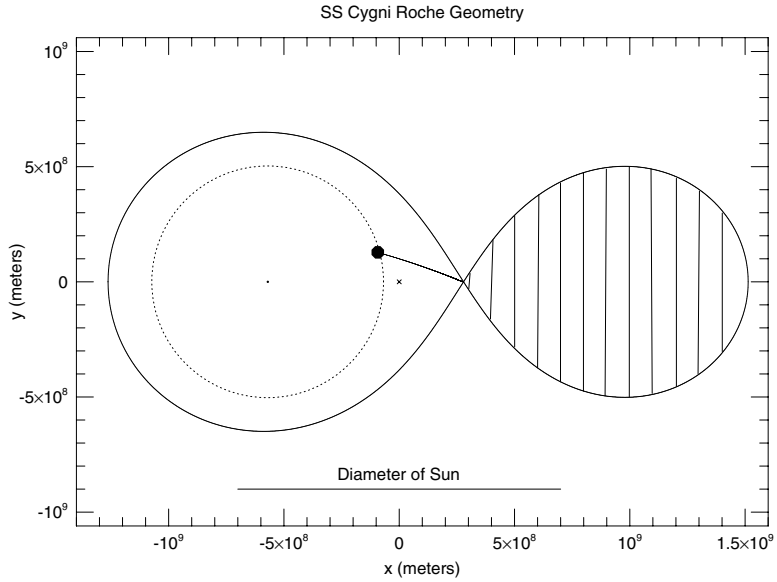

Figure 3. The Roche geometry for the DN SS Cyg. The ∞ shape is the critical Roche surface of the binary. The secondary star (right) fills its Roche lobe, transferring mass through the L1 point via a ballistic gas stream to form an accretion disk (dotted circle) surrounding the primary (left). The gas stream impacts the accretion disk at the hot spot (large filled dot). The small 'x' is the center of mass of the binary and the white dwarf (small dot) is shown to scale. The binary orbital motion is counterclockwise in this cartoon and the diameter of the Sun has been added for a size comparison.

star completely fills its Roche lobe, causing matter to be transferred through the L1 point towards the primary star. This material forms an accretion disk surrounding the primary star. Figure 3 illustrates the Roche geometry and other aspects of SS Cyg.

The original binary components of SS Cyg were a massive main sequence star ($>6.5M_{\odot}$) in a wide orbit with a low-mass main sequence star, fairly similar to the present-day secondary. The massive primary evolved off the main sequence and expanded greatly, engulfing the orbiting secondary in a common envelope, while its core became essentially the present-day white dwarf. Orbital angular momentum lost by the secondary caused expansion and loss of the common envelope, while greatly reducing the orbital separation. When the binary emerged from this so-called common envelope stage, it probably had an orbital period of a few days or less and was detached, the secondary star not filling its Roche lobe. GRAVITATIONAL RADIATION losses eventually shrunk the orbital separation of the two stars enough to cause the binary to become semidetached, synchronizing the rotation of the secondary. At this point, mass transfer commenced and the binary became a cataclysmic variable. SS Cyg has been a mass-transferring binary for only a short time, about 0.2–0.3 Gyr.

The secondary star becomes distorted in shape once it is confined by the Roche equipotential surface. This causes its properties to deviate from those of a single main sequence star. Continued mass exchange and magnetic braking will rapidly decrease the orbital separation of SS Cyg ($P_{\rm orb}$ will be $\sim$3 h in another 0.1–0.2 Gyr), leading to a non-equilibrium configuration of the secondary star. The secondary will expand, in response to continued mass loss, becoming up to 10–20% larger than a main sequence star of the same mass.

Single main sequence K5 stars are known to show stellar activity, such as starspots, and to show activity cycles similar to those which are seen in our own Sun. Thus, it is not surprising to think that such cycles might also exist on the secondary star in SS Cyg. SS Cyg has been observed to show a cyclic variation in its outburst interval and a 20% change in its quiescent brightness. Both of these variations occur within a period of about 7.3 yr and they have been attributed to solar-type starspot cycles occurring on the secondary.

Because of the closeness of the stellar components and the high temperature of the white dwarf, irradiation of the secondary star occurs. Emergent flux from the white dwarf illuminates the face of the secondary, near L1, with $\sim\frac{1}{10}$ of its total flux. (The accretion disk provides some shielding of the secondary star from direct illumination by the white dwarf.) Radiation from the accretion disk and hot spot region is also present, but much weaker owing to their lower temperatures. The effects of irradiation in SS Cyg cause very weak secondary star Balmer line emission (not visible in figure 1) and slight expansion of the secondary atmosphere near L1. During outburst, the inner disk becomes much hotter, emitting larger amounts of high-energy radiation. This radiation causes increased secondary star heating leading to phase-dependent secondary star spectral properties.

SS433

A complex binary system within a SUPERNOVA REMNANT ('W50') in the constellation Aquila, which has proved to be of great astrophysical significance since it was discovered by the x-ray satellite ARIEL 5 in 1976. The unusual name derives from its inclusion in a catalogue of emission-line stars published by B Stephenson and N Sanduleak in 1977. As it is a variable star system it is also designated 'V1343 Aquilae'.

In addition to the x-ray observations, SS433 has also been studied at optical, radio and gamma-ray wavelengths. The combined results indicate that it is a system of great complexity and have stimulated considerable interest among both observational and theoretical astrophysicists over many years.

Particular attention was first drawn to the object by observed peculiarities in its optical spectrum. In addition to a background continuum, there are also strong emission lines due to hydrogen and helium—not in itself unusual. What is much more puzzling is that these emission lines seem to have a dual nature: normal, broad, 'stationary' lines are present, but so too are narrower lines which vary considerably in wavelength over a period of 164 days. These variations in wavelength indicate Doppler red- and blue-shifts alternately. The stationary emission lines also exhibit a more modest variation, with a period of 13.1 days.

Several conflicting interpretations have been proposed, which for many years could not be reconciled. A measure of agreement has been reached, however, and it is now generally accepted that the most likely structure for this remarkable object is substantially as follows.

A binary system, of orbital period 13.1 days, comprises a hot, massive star (estimated at between 10 and 20 solar masses) and a NEUTRON STAR (presumably the W50 supernova remnant) of perhaps 1.5 to 3 solar masses. A stellar wind from the massive star transfers matter through the LAGRANGIAN POINT, feeding an ACCRETION DISK surrounding the neutron star. Not all of this matter reaches the surface of the neutron star, however, part being ejected at enormously high velocity (of the order of 80 000 kilometres per second) via two opposed, narrow jets which precess in a period of 164 days, sweeping out two conical volumes of space of about 40° angle.

The massive star, and possibly the accretion disk, contribute the background continuum. The stellar wind produces the broad component of the stationary emission lines, and the mass-transfer from the massive star to the accretion disk produces the narrow emission lines. The changing aspect of the accretion disk through the 164-day period explains the variation in total light from the system, and its periodic partial eclipses account for the lesser 13.1-day variation. The precessional motion of the jets explains the moving emission lines with their observed Doppler effects. Some minor variations in the emission spectrum have also given rise to the suggestion that there may be a 'hot spot' in the accretion disk.

No doubt observation and discussion of SS433 will long continue, with a view to gaining further insight into the structure of this enigmatic object, which has rightly been described as 'unique in astronomy'.

Standard Model of Particle Physics

The Standard Model describes all the confirmed data obtained using particle accelerators and has enabled many successful theoretical predictions to be made. It has been tested with per mille accuracy, at which level its calculable quantum corrections play an essential role. Its only missing feature is a particle, called the Higgs boson, whose coupling to the other particles is believed to generate their masses. However, the Standard Model is theoretically unsatisfactory despite its many successes, and possible extensions to provide a more unified picture of the different particle interactions, the apparent proliferation of different particle species and the origin of their masses are being proposed. Evidence has recently been presented that NEUTRINOS may alter their nature when they propagate over long distances. This is expected if neutrinos have masses, which are not predicted by the Standard Model. If confirmed, this may be the first evidence for particle physics beyond the Standard Model.

The FUNDAMENTAL PARTICLE interactions described by the Standard Model are the electromagnetic, weak and strong nuclear forces. Electromagnetic forces have long been known, since the discovery of electromagnetic wave radiation by Hertz in 1885 and the early days of quantum physics, to be mediated by the exchange of the photon (see figure 1), a massless boson of unit angular momentum (spin 1) with two polarization states. The long-established quantum theory of electrodynamics is called QED. Yukawa conjectured that the weak interactions such as β decay were mediated analogously by the exchange of massive intermediate bosons, as also shown in figure 1. This hypothesis was put on a firm theoretical basis by Glashow, Weinberg and Salam in their unified theory of the weak and electromagnetic interactions, and the intermediate bosons (weighing about 80 and 91 GeV) were discovered at CERN in 1983. The strong nuclear interactions are known also to be mediated by massless bosons called gluons, see also figure 1, which were discovered at DESY in 1979. Thus all the fundamental interactions have very similar structures, but why only the weak bosons are massive is a puzzle to which we return later.

The first elementary matter particle to be identified was the spin-1/2 electron (weighing about 1/2 MeV), followed by the unstable muon (weighing about 100 MeV) that was first detected in COSMIC RAYS. These were shown each to have an associated neutrino, the electron neutrino being produced in weak β decay and the muon neutrino being produced either in association with a muon or in muon decays. These particles do not have strong nuclear interactions, only weak and (in the case of the electron and muon, which are charged particles) electromagnetism, and are called LEPTONS. A third type of charged lepton (the τ weighing about 1.78 GeV) was discovered in accelerator experiments at SLAC in 1975 and is also believed to have its own associated neutrino. Accelerator data have established upper limits on the possible masses of the neutrinos, which are much less than those of the corresponding charged leptons.

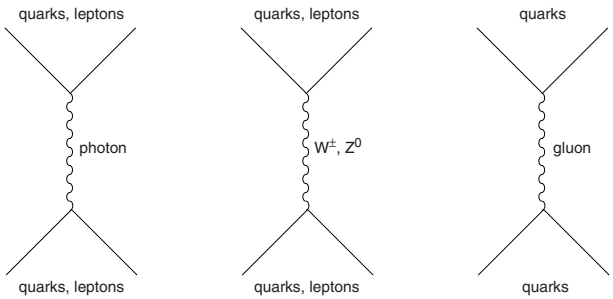

Figure 1. The fundamental forces between elementary particles are mediated by intermediate bosons: the photon of electromagnetism, the massive $W^{\pm}$ and Z^0 bosons of the weak interactions and the gluons of the strong interactions.

From the 1940s onwards, many strongly interacting particles (HADRONS) were discovered. It was proposed in 1964 that these could all be understood as composite bound states of more elementary entities called QUARKS. At that time, all the known hadrons could be constructed out of just three quark species of spin 1/2 and fractional charge Q: up ($Q = 2/3$), down and strange ($Q = -1/3$). Such pointlike constituents inside protons were discovered by experiments at SLAC in 1968. Initially it was a puzzle how quarks could appear almost free at high energies, corresponding to short distances, but were never seen singly, only confined inside hadrons. This puzzle was resolved when it was demonstrated that the couplings of gluons became weaker at high energies (short distances), a property known as asymptotic freedom.

Shortly afterwards, a key step in the establishment of the Standard Model was the discovery in a neutrino experiment at CERN in 1973 of a novel type of weak interaction, called neutral currents, in which the charges of the participating particles do not change, in contrast to the familiar weak interactions, called charged currents, in which the charges of participating quarks and leptons do change. Such neutral-current interactions were predicted by many unified theories of the weak and electromagnetic interactions, and their discovery provided the first circumstantial evidence that some such unified theory might be correct. The second piece of evidence for such a theory was provided by the discovery in accelerator experiments at BNL and SLAC in 1974 of hadrons containing a fourth quark constituent weighing about $1\frac{1}{2}$ GeV. This was baptized charm and had been predicted by unified electroweak theories, in order to explain the fact that neutral-current interactions that would change quark type, e.g. strange $\rightarrow$ down, are very suppressed, whereas there do exist charged-current interactions: strange $\rightarrow$ up. The charm discovery briefly pre-dated the τ lepton discovery mentioned earlier. Consistency of the simplest unified electroweak theory then required the existence of two more quark types, and the first of these (bottom), weighing about 5 GeV, was discovered in an accelerator

experiment at FNAL in 1977. The spectrum of quarks was apparently completed by the discovery at FNAL in 1995 of the top quark, which weighs about 175 GeV.

The mathematical framework for theories of particle interactions is provided by gauge theories, which offer the only consistent description of the interactions of spin-1 particles. A gauge theory is based on a continuous internal symmetry, e.g. changing the phase of the quantum-mechanical wave function in the case of the prototype gauge theory, QED. When one makes this symmetry local, i.e. allows space-dependent phase transformations, one must introduce a spin-1 gauge field. This is analogous to the way Einstein realized general coordinate invariance with a spin-2 metric field. Gauge theories differ in their choice of gauge group and in the group transformation properties of the matter particles. In the case of the Standard Model, the strong interactions are described by a theory transforming the wave functions of quarks, called QCD. The unified electroweak interactions are described by a combination of transformations acting on both quarks and leptons, first written down by Glashow in 1961, Weinberg in 1967 and Salam in 1968.

The establishment of the Glashow–Weinberg–Salam model as the correct unified electroweak theory proceeded in several steps over the following decade. A series of detailed experiments refined measurements of the neutral currents, verifying that their properties were consistent with the Glashow–Weinberg–Salam model. A crucial step was the observation at SLAC in 1978 of parity violation in deep-inelastic electron–proton scattering, which was followed by similar observations in atomic physics. The culminating step was the discovery of the weak intermediate bosons, $W^{\pm}$ for the charged-current weak interactions and Z^0 for the neutral currents, in proton–antiproton collisions at CERN in 1983.

Subsequent developments have been dominated by a series of precision tests of the Standard Model, including both its strong and its electroweak sectors. In a number of experiments at energy scales varying from about 1 GeV to about 200 GeV, it has been shown that the strong nuclear interactions indeed weaken at higher energies, as seen in figure 2. The 'strong' interactions are truly strong only at energy scales $\lesssim$1 GeV, corresponding to distances $\gtrsim$0.2 fm, where quarks are confined within hadrons. Detailed calculations of hadron spectroscopy require extensive numerical simulations of discretized (lattice) versions of QCD on powerful computers. These are currently able to reproduce experimental measurements to within a few per cent. Calculations at higher energies (shorter distances) may be made using techniques from quantum field theory. They predict an energy dependence of the strong coupling that is in very good agreement with the experimental measurements shown in figure 2. This concordance confirms that there are no other light strongly interacting elementary particles beyond the gluons and quarks introduced earlier. The present data shown in figure 2 indicate that the strong coupling strength, analogous to the fine-structure constant of QED, has

the value 0.119 ± 0.004 when measured at an energy corresponding to the mass of the Z^0 weak intermediate boson.

Tests of the electroweak sector of the Standard Model have been dominated by high-energy experiments on e^+e^- collisions at CERN, using the LEP accelerator, and at SLAC, using the SLC accelerator. A compilation of LEP measurements of the cross sections for e^+e^- annihilation into charged-lepton and quark–antiquark pairs is shown in figure 3. This is dominated by the Z^0 resonance peak, which must be one of the most carefully studied Breit–Wigner resonances in physics, with about 2×10^7 decays observed and measured. The height and width of the peak depend not only on the observed Z^0 decay modes but also on possible unseen decay modes such as those into neutrino–antineutrino pairs. Extra invisible decays would shorten the Z^0 lifetime and hence, by the UNCERTAINTY PRINCIPLE, increase the natural width of the Z^0 resonance peak. The measurements shown in figure 3 tell us that there are precisely three neutrino species, no more and no less. These correspond to the three known charged leptons, the electron, muon and tau. According to the Standard Model, there can only be three corresponding pairs of quarks. We therefore think there can be no further quarks beyond the six already known.

The data shown in figure 3 provide a very accurate determination of the mass of the Z^0: 91.1867 ± 0.0021 GeV. To arrive at this precision, it was necessary to take into account many effects that were considerably larger than the quoted error. These included terrestrial tides, which caused the LEP machine to expand and contract, and hence its energy to vary by $O(10)$ MeV, and even the passing
